Light active finger motion is allowed immediately and a splint is worn for comfort only. Heavy activity is allowed after union is achieved.

Fig. 19.61 Lateral radiograph of a thumb MCP arthrodesis with tension band.

Fig. 19.62 PA views of DIP joint arthrodesis with headless compression screws.

Outcomes, prognosis, and complications

MCP or PIP arthrodesis effectively relieves pain at the expense of motion. Often, the severely arthritic and painful joint has little motion prior to surgery, and in many cases hand function is improved rather than worsened after arthrodesis. Although the complication rate is lower than that of arthroplasty, complications are not unusual, and may include delayed union or nonunion, infection, skin flap compromise, and hardware-related problems such as loss of fixation, palpability, and tendon irritation.

Correction of swan-neck deformity

Swan-neck deformity is more debilitating than boutonniere deformity because the fingers cannot be flexed into the palm for grasping objects. Swan-neck deformity can be divided into four types, based upon the degree joint mobility and arthritic changes. In a finger with type I deformity, full active PIP flexion is preserved, there is no intrinsic tightness, and patients have little if any functional problems. In a finger with type II deformity, intrinsic tightness is present. With the MCP in ulnar deviation and flexion, PIP flexion is possible. However, if the MCP deformity is corrected by placing it in extension and correcting ulnar deviation, the ulnar intrinsics are tightened, and PIP flexion becomes more difficult. Fingers with type III deformity have more severe intrinsic tightness, and PIP flexion is difficult or impossible regardless of MCP position. In the type IV deformity substantial arthritic changes are present.

In type I deformities, a silver ring splint that prevents PIP hyperextension, while at the same time allowing PIP flexion, is adequate treatment. For type II deformities an intrinsic release and a PIP extension block are required. A Bruner incision is made over the PIP joint and the flexor tendon sheath is exposed. The ulnar intrinsics are exposed through the volar incision and are released as described above. A transverse incision is then made in the midportion of the A2 pulley. One slip of flexor digitorum superficialis (FDS) is transected with tenotomy scissors as proximally as possible. The transected end which remains attached distally at the FDS insertion is passed through the slit in the A2 pulley, and turned distally. It is then sutured to itself near the FDS insertion through a small window in the flexor tendon sheath (Fig. 19.63). This is tensioned so that the joint cannot be passively extended beyond 20–30° of flexion. If the MCP joint is subluxated and ulnarly deviated, MCP arthroplasty and soft-tissue reconstruction should be performed as well. Persistent DIP flexion is treated with arthrodesis if necessary.

In type III deformity, the PIP joint is stiff regardless of MCP position. PIP flexion is limited not only by intrinsic tightness, but also because the lateral bands are fixed in a dorsal position. A dorsal skin contracture further complicates the deformity. The first goal is to regain passive mobility in the PIP joint. Serial casting or dynamic splinting should be used in an attempt to restore passive mobility. If passive mobility is restored, the type III swan-neck is converted to a type II swan-neck, and is treated accordingly. However, if nonoperative methods fail, passive motion must be restored surgically. A longitudinal incision is made over the PIP joint, with an oblique extension over the dorsal aspect of the middle phalanx. Skin flaps are elevated. A longitudinal incision is made on each side of the central slip, releasing the dorsally displaced lateral bands (Fig. 19.64). The joint is passively flexed, and the lateral bands should slide volarly. If the joint cannot be flexed, a dorsal capsulotomy and collateral ligament recession may be required. An intrinsic release is performed as described above. The PIP joint is then pinned in flexion. The skin is closed proximally, but the oblique distal portion of the incision is allowed to gap open and heal secondarily (Fig. 19.65). This takes tension off the dorsal skin closure, and prevents skin necrosis.

In type IV swan-neck deformity with articular destruction, PIP arthrodesis is a reasonable option. In the ring and small fingers, PIP arthroplasty combined with an FDS sling is an alternative.

Postoperative care

The K-wire is removed and active and passive PIP motion within a dorsal blocking splint is initiated, as soon as finger edema is improved. After the finger has healed and passive mobility is restored, the swan-neck deformity can be treated with an FDS tenodesis. If present, MCP deformity should be corrected as well. Persistent DIP flexion is treated with arthrodesis.

Correction of boutonniere deformity

Boutonniere deformity is less functionally limiting than swan-neck deformity because the patient retains the ability to flex the finger for pinch and grasp. Furthermore, surgical treatment of boutonniere deformity creates the risk of converting a boutonniere deformity into a swan-neck deformity. Because of this, surgery should only be considered for moderate or severe boutonniere deformity that substantially affects hand function.

Stage I boutonniere deformity is mild, with only a slight extension lag at the PIP joint. The PIP joint is passively correctable and the MCP joint is normal. There is little functional limitation. However, if DIP joint hyperextension is severe, it can be treated with an extensor tenotomy.[60] A longitudinal incision is made over the dorsal aspect of the middle phalanx. Skin flaps are elevated and the extensor mechanism is exposed. An oblique incision is made through the entire extensor mechanism at the level of the middle of the middle phalanx, allowing the DIP joint to flex. Care should be taken not to injure the oblique retinacular ligament. If a mallet deformity occurs, it is treated with a splint or with DIP arthrodesis. Finger motion is allowed immediately postoperatively. A dynamic PIP extension splint is worn for 6 weeks postoperatively.

Stage II boutonniere deformity involves a more severe PIP flexion contracture of 30–40°. MCP hyperextension is present, and DIP hyperextension is more severe. If the PIP joint is not passively correctable serial casting should be attempted preoperatively. If serial casting fails to restore passive mobility, surgery is required to restore passive motion. Once the joint is supple, the boutonniere deformity can be corrected. A longitudinal incision is made over the PIP joint, and extended distally over the middle phalanx. An extensor tenotomy is performed as described above to allow DIP flexion. At the PIP joint, the goal is to shorten the central slip and correct the volar subluxation of the lateral bands. The central slip is transected 3 mm proximal to its insertion on the base of the middle phalanx, leaving enough for a later repair. A 15-blade

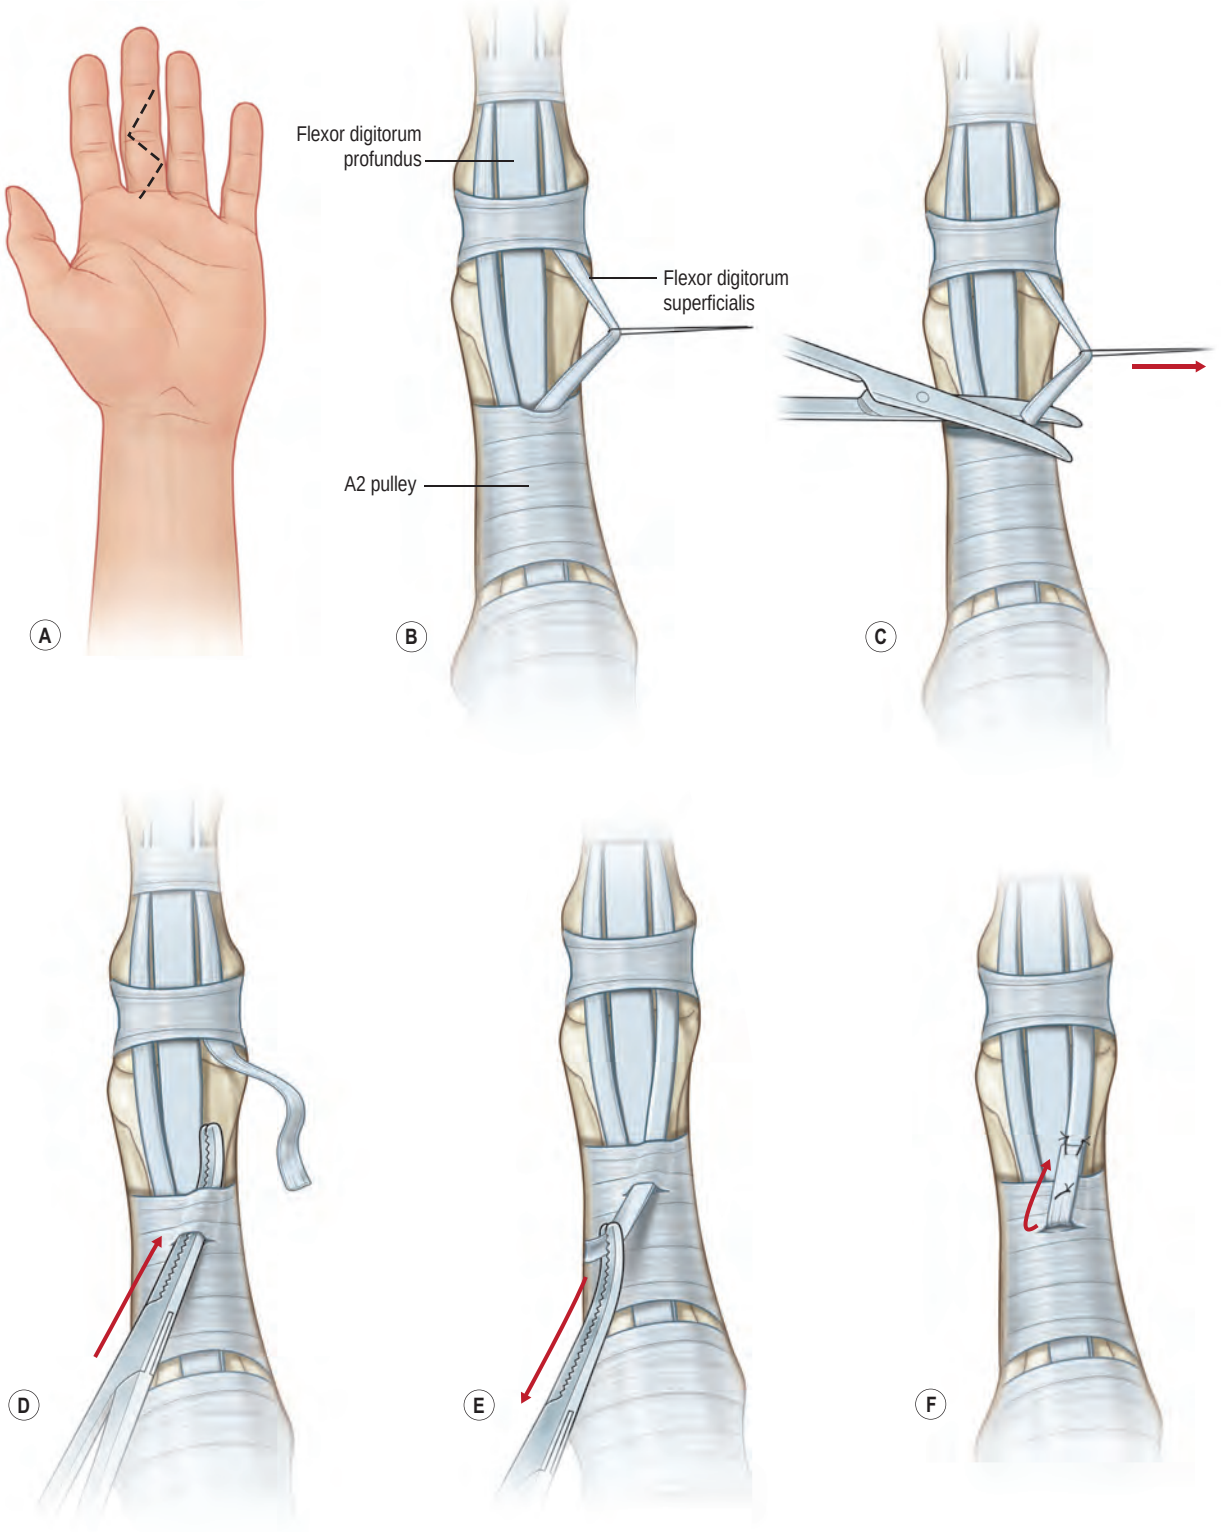

Fig. 19.63 Sublimis sling for correction of swan-neck deformity. A Bruner incision is made **(A)** exposing the FDS and FDP. One slip of FDS is isolated **(B)** and divided proximally **(C).** The FDS slip is then passed through an incision in the A2 pulley **(D, E)** and then sutured back on itself **(F)**, creating a block to hyperextension of the PIP joint.

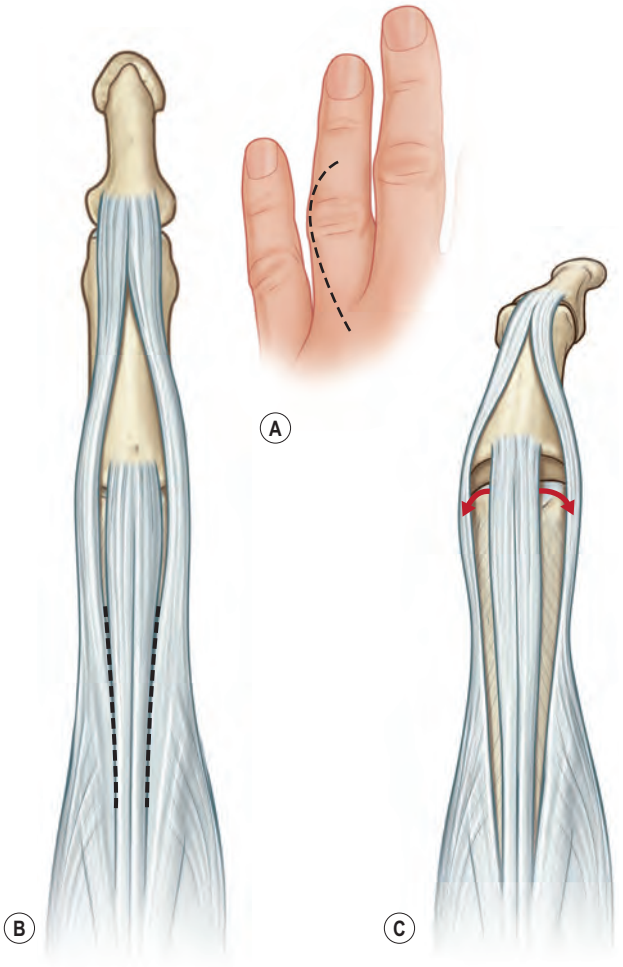

Fig. 19.64 An incision is made between the central slip and the lateral bands, allowing the lateral bands to relocate volarly with PIP joint flexion.

Fig. 19.65 When there is an insufficiency of dorsal skin in cases of long-standing swan-neck deformity, the distal portion of the incision is allowed to gap and heal secondarily.

is used to separate the central slip from the volarly subluxated lateral bands. A longitudinal incision is then made in the transverse retinacular ligament on each side of the finger, just volar to the lateral band. The lateral bands are then mobilized dorsally, and the PIP joint is brought into extension. The central slip is advanced distally towards the distal remnant at the central slip insertion. Excess central slip is excised, usually measuring about 5 mm in length, and the central slip is sutured to the remnant on the base of the middle phalanx using nonabsorbable sutures. Next, the lateral bands are sutured to the central slip using horizontal mattress sutures (Fig. 19.66). It should be possible to passively flex the PIP joint after tendon reconstruction.

In severe boutonniere deformity, the PIP joint is severely flexed and cannot be passively extended. In many cases, the PIP joint is arthritic or the joint surfaces have remodeled. PIP arthroplasty combined with soft-tissue reconstruction can be considered. However, in this situation PIP arthrodesis is probably the most reasonable option.

Postoperative care

The PIP joint is splinted in full extension for 4 weeks, and then finger motion is begun with a wire-foam dynamic extension splint during the day, and a volar PIP extension splint at night for 6 weeks.

Outcomes, prognosis, and complications

Outcomes after correction of swan-neck and boutonniere deformities are variable, and depend largely upon the severity of the original deformity. The most common complications are stiffness, recurrence, and pain. It should be emphasized that boutonniere deformity is in general a less debilitating deformity than swan-neck deformity, and the surgeon should be careful not to convert a boutonniere to a swan-neck by overcorrection.

Hints and tips

- Swan-neck deformities can be more debilitating than boutonniere deformities.
- The surgeon should be careful not to overcorrect a boutonniere deformity, thereby creating a swan-neck deformity.

Correction of thumb deformities

The most common thumb deformity is a boutonniere deformity (type I thumb deformity), with MCP flexion, IP hyperextension, and CMC abduction (Fig. 19.67). Early in the disease process the joints are passively correctable, and splinting may be adequate treatment. If splinting fails to improve function, reconstruction of the extensor mechanism can be performed. A dorsal incision is made over the MCP joint, and the extensor mechanism is exposed. An incision is made between the EPB and EPL tendons, and tenosynovectomies of the attenuated or ruptured EPB tendon and of the volarly subluxated EPL are performed. A transverse capsulotomy is made, leaving most of the capsule attached distally to the base of the proximal phalanx. MCP joint synovectomy is performed.

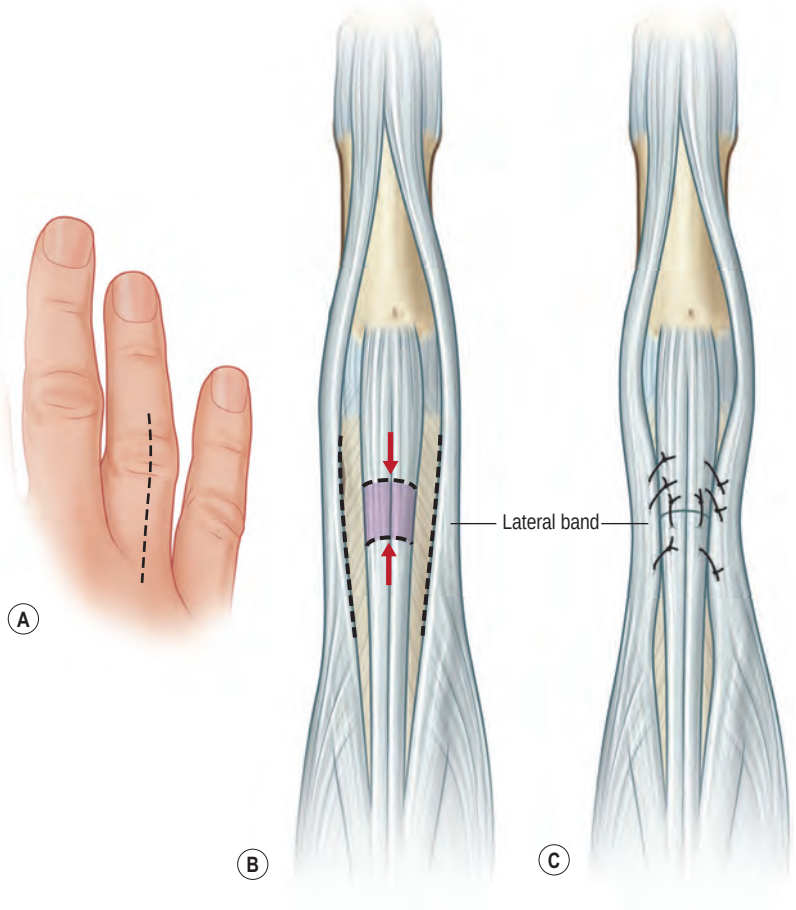

Fig. 19.66 Correction of boutonniere deformity. Excess central slip is excised and closed, and the volarly subluxated lateral bands are mobilized dorsally and sutured to the central slip. Care must be taken not to create a swan-neck deformity.

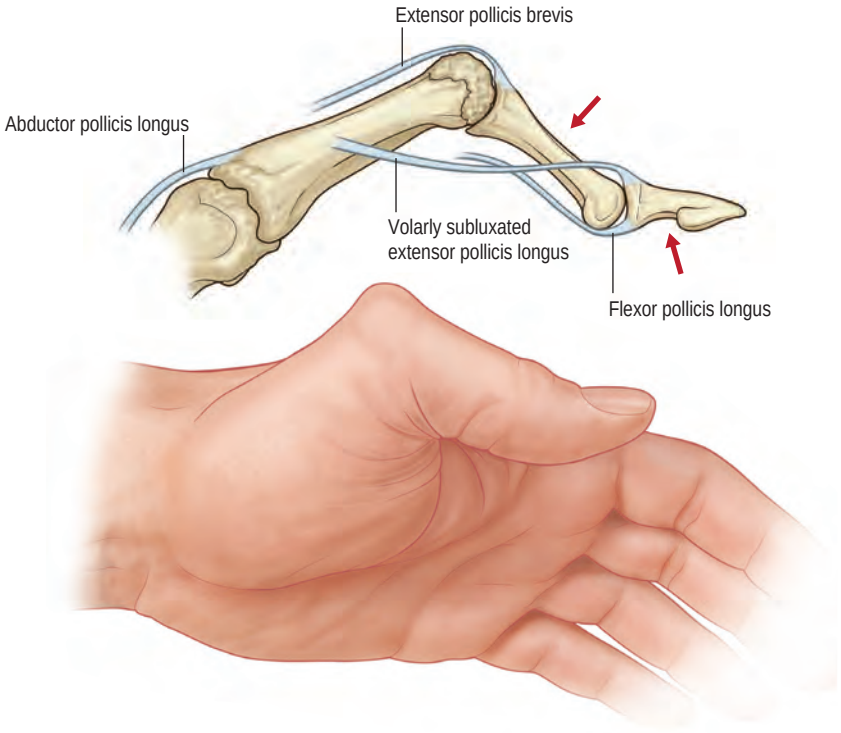

Fig. 19.67 Boutonniere deformity of the thumb. Synovitis at the MCP joint results in attenuation or rupture of the EPB near its insertion. The EPL is volarly subluxated.

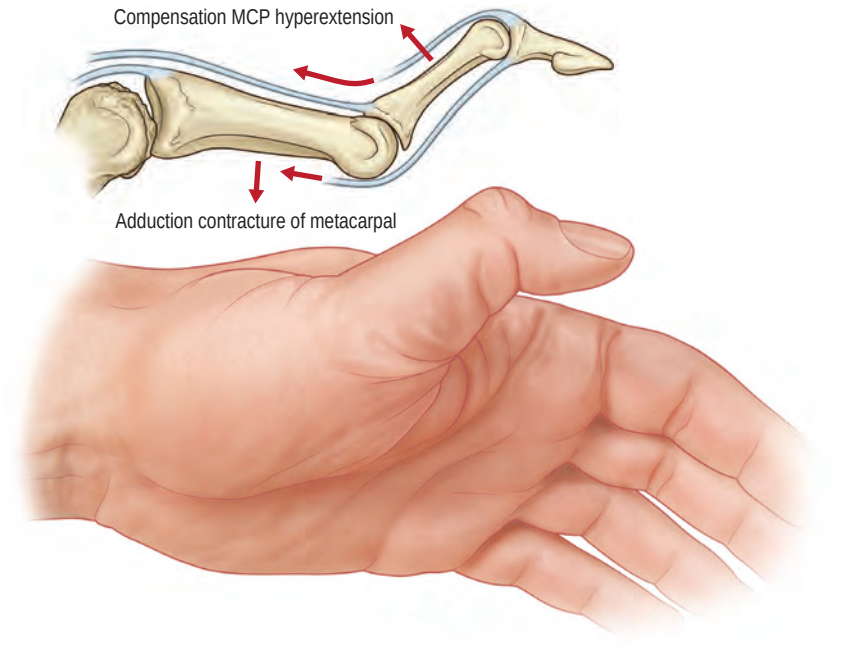

Fig. 19.68 Swan-neck deformity of the thumb. Synovitis and subluxation at the CMC joint results in metacarpal adduction contracture and compensatory hyperextension at the MCP joint.

The EPL tendon is divided between the MCP and IP joints, and is mobilized proximally. This allows the IP joint to move into flexion. A small transverse incision is made in the distal aspect of the MCP joint capsule, just distal to the MCP joint. The MCP joint is then positioned in full extension, and the proximal EPL tendon is passed through the incision in the capsule. It is then turned proximally and sutured to itself under tension. The EPB is advanced and sutured to the base of the proximal phalanx and to the adjacent EPL tendon. The MCP joint is pinned in extension for 6 weeks. Motion at the IP joint is initiated immediately after surgery, but the IP joint is splinted in extension between exercises to prevent development of an extension lag. The MCP K-wire is removed in 6 weeks, splinting is discontinued, and motion is initiated.

In more severe boutonniere deformities, the MCP and IP joints can become fixed or arthritic. Treatment depends upon the status of these two joints. If the IP joint is fixed in extension but the articular surfaces remain intact, joint release with EPL release is performed. If the IP joint is arthritic, arthrodesis is performed. The fixed or arthritic MCP joint is treated with arthrodesis if motion can be preserved at the IP joint. If IP joint arthrodesis is required, the MCP joint should be treated with silicone arthroplasty and extensor tendon reconstruction.

Swan-neck deformity (type III thumb deformity) is the second most common thumb deformity. Dorsoradial CMC subluxation occurs, and metacarpal adduction contracture develops, followed by MCP hyperextension and IP flexion (Fig. 19.68). Early disease is treated with ligament reconstruction and tendon interposition (LRTI). More advanced disease is also treated with LRTI, but may also require a webspace release and adductor pollicis release. After trapezial resection, a four-flap Z-plasty is designed in the first webspace. The skin is incised and skin flaps are elevated. If the skin release alone is not sufficient to allow contracture release, dissection is carried down to the adductor pollicis and first dorsal interosseous. The contracted fascial bands of the adductor pollicis and first dorsal interosseous are released. If necessary, the adductor pollicis is released from its origin on the third metacarpal. The LRTI is then completed. Significant MCP hyperextension is treated with MCP arthrodesis.

Treatment for type II and type V thumb deformities is individualized, and depends upon the specific deformity at each joint. Type IV deformity, or gamekeeper's thumb, is treated with MCP arthrodesis.

Postoperative care

A thumb spica splint is used to immobilize the thumb for 4–6 weeks postoperatively. After 4–6 weeks, splinting is weaned and active motion is initiated. Motion is advanced, light activity is allowed, and gentle strengthening is initiated gradually, as tolerated.

Outcomes, prognosis, and complications

As with finger deformities, outcomes are related largely to the severity of the deformity and the degree of arthritis present before surgery.

Tendon surgery and carpal tunnel syndrome

Carpal tunnel syndrome

Carpal tunnel syndrome is common in RA patients and is secondary to the mass-effect of proliferative flexor tenosynovitis within the carpal tunnel. Very mild and intermittent carpal tunnel syndrome can be treated with medical management of the RA, splinting, and steroid injections. However, significant, constant, or progressive symptoms should be treated surgically. Standard carpal tunnel release is generally inadequate. An extended carpal tunnel release with flexor tenosynovectomy is usually required.

A standard carpal tunnel release is performed, and the carpal canal is examined for the presence of synovitis. If synovitis is present, the incision is extended distally to the distal palmar crease in a zig-zag fashion, and proximally across the wrist crease in a zig-zag fashion, continuing at least

Fig. 19.69 Carpal tunnel release in patients with rheumatoid arthritis usually requires an extensive flexor tenosynovectomy using an extensile exposure.

Fig. 19.71 The carpal tunnel is decompressed after tenosynovectomy.

5 cm proximally in the forearm. Care is taken to keep the incision ulnar to the palmar cutaneous branch of the median nerve. Distal to the transverse carpal ligament, dissection is performed with tenotomy scissors, elevating skin flaps, while preserving the superficial palmar arch and the branches of the median nerve. Proximally, scissors are used to dissect down to the antebrachial fascia which is divided longitudinally, ulnar to the palmaris longus, exposing the full extent of the tenosynovitis (Fig. 19.69). Next the median nerve is identified proximally, where there is less synovitis, and a vessel loop is passed around it. Next, flexor tenosynovectomies are performed, beginning with the FDS tendons and progressing to the FPL and FDP tendons (Fig. 19.70). Each tendon should be addressed individually, working sequentially, and removing all hypertrophic synovium (Fig. 19.71). The fingers should be flexed by retracting on the flexor tendons, one by one, to ensure that excursion is not limited. The median nerve is examined. Hypertrophic synovium is carefully removed from the nerve with tenotomy scissors, preserving the deep motor branch distally, and the palmar cutaneous branch proximally. Finally, the floor of the carpal tunnel is examined. Sharp bony erosions or osteophytes should be removed using a rongeur, and soft tissue or capsule sutured over the smoothed area. The skin is closed with horizontal mattress sutures.

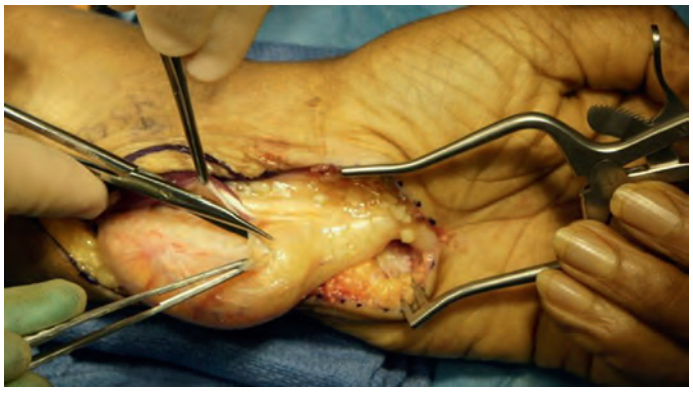

Fig. 19.70 Tenosynovectomy is performed one tendon at a time, while protecting the median nerve.

Postoperative care

A volar forearm based wrist splint is applied for 2 weeks. Finger motion is initiated immediately. Full activity without restrictions may resume 5 weeks after surgery.

Outcomes, prognosis, and complications

Carpal tunnel release with flexor tenosynovectomy is effective at relieving carpal tunnel symptoms, particularly in patients who experience symptoms only intermittently, or who have had symptoms for a short period of time. Patients who have constant numbness, particularly if associated with two-point discrimination changes or thenar atrophy, will have slow or even incomplete relief of symptoms. Complications will be more common with carpal tunnel release in this population, due to the presence of adhesions and synovitis within the carpal canal.

Secondary procedures

Recurrence of carpal tunnel symptoms is minimized by effective medical control of the RA. However, if tenosynovitis recurs and leads to recurrent carpal tunnel symptoms, repeat carpal tunnel release and tenosynovectomy is indicated in order to relieve pressure on the median nerve. Secondary surgery is tedious, and great care must be taken to avoid injury to the median nerve. The incision and initial dissection should begin a few centimeters proximal to the original incision, so that the median nerve can be identified in a tissue plane that has not been previously operated on. Dissection is then carried distally, protecting the median nerve while completing the flexor tenosynovectomy through the distal forearm and carpal tunnel.

Hints and tips

- Carpal tunnel syndrome may be the initial presenting complaint in RA.
- RA patients typically require an extensile incision, with flexor tenosynovectomy.
- A standard or limited-incision carpal tunnel release is generally not indicated, and will not treat the underlying pathology.

Flexor tendon ruptures

Flexor tendon ruptures present with an acute loss of finger flexion. However, in a rheumatoid patient with limited motion due to flexor tenosynovitis or joint destruction, a flexor tendon rupture may go unnoticed. A difference between the active and passive finger ROM is suggestive of rupture, but can also be due to flexor tenosynovitis or a rheumatoid trigger finger.

FPL rupture is common, and is due to a sharp bony edge on the volar aspect of the scaphoid (Mannerfelt lesion). The incision for flexor tenolysis is made as described above. Flexor tenolysis is performed. The osteophyte is removed with a rongeur, and the capsule closed over the area to provide a smooth gliding surface (Fig. 19.72). If both ends of the ruptured tendon can be identified within the wrist and palm incision, a small bridge graft of palmaris longus

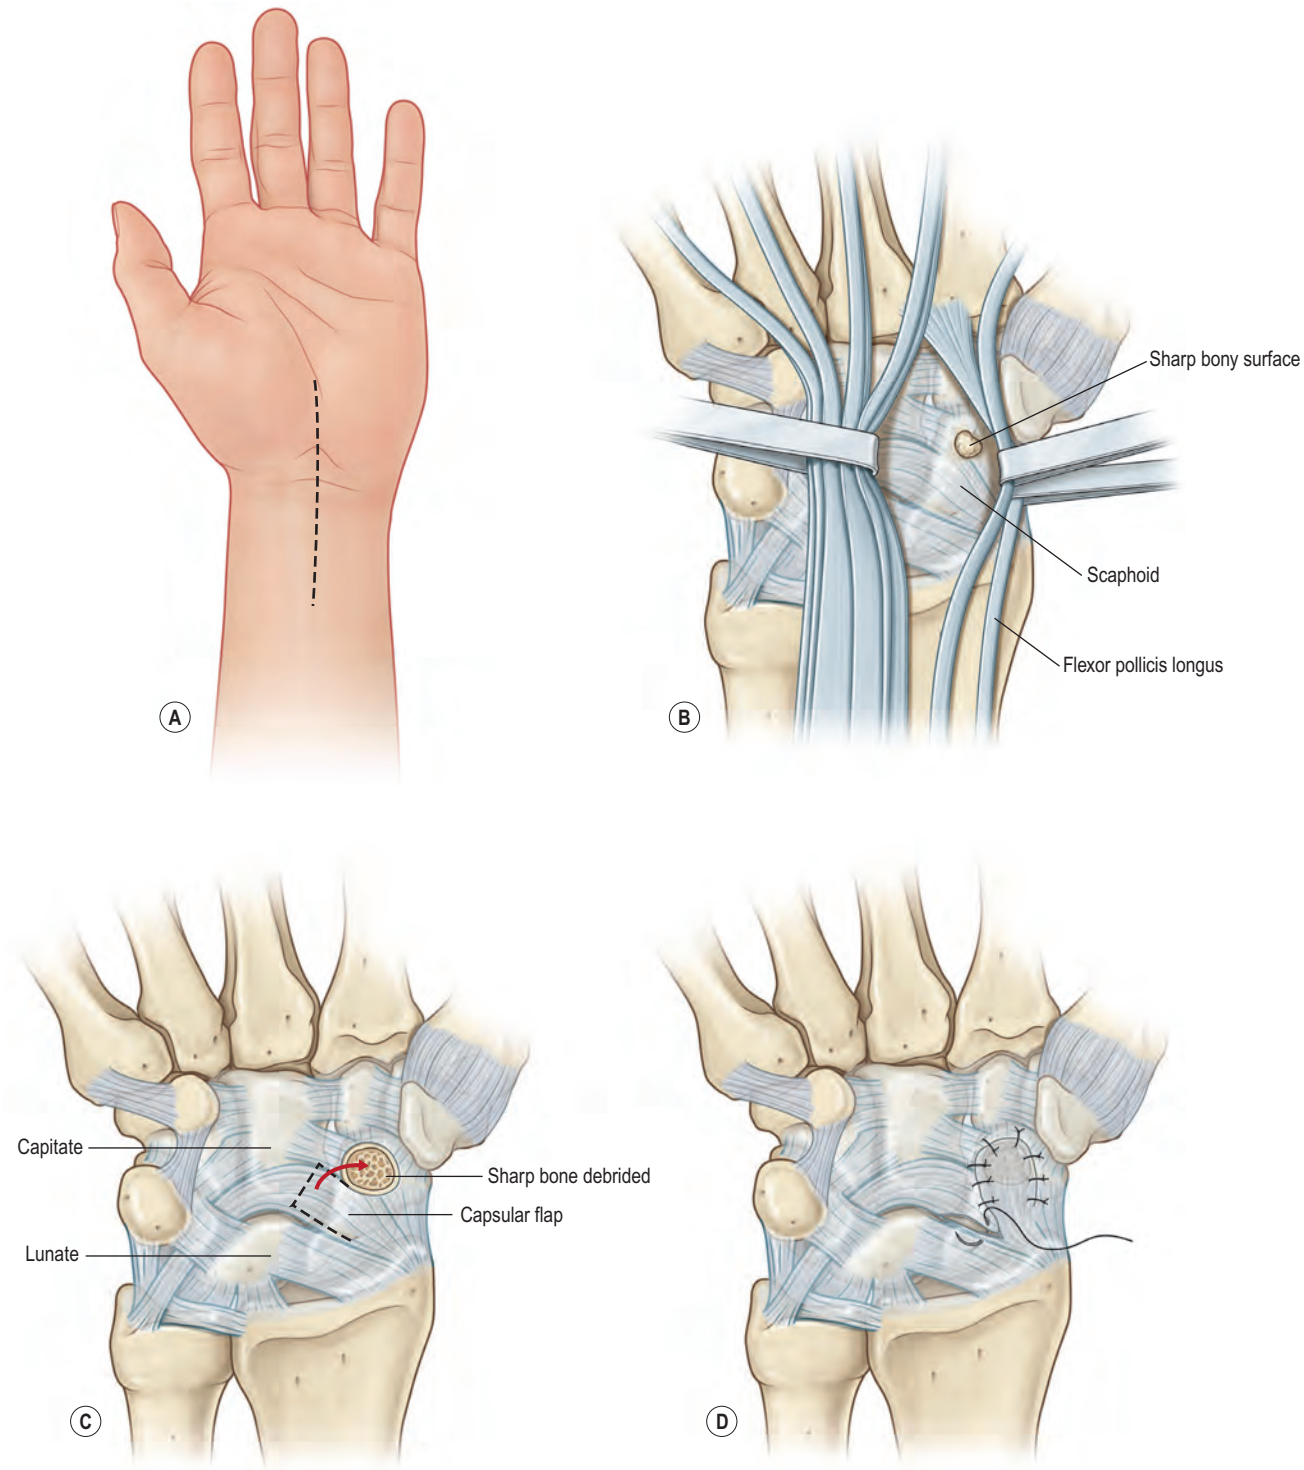

Fig. 19.72 Mannerfelt lesion. The osteophyte on the volar aspect of the scaphoid is identified and removed. Next, a flap of volar capsule is elevated and rotated to cover the rough bony surface.

or a strip of the FCR is used. It is weaved proximally and distally into the FPL using a Pulvertaft weave and 3-0 horizontal mattress sutures to secure the weave. It is important to resect frayed and damaged tendon edges, and graft into healthy tendon. If grafting within the palm is not possible, tendon transfer is required. A Bruner incision is made on the long finger over the proximal phalanx. The FDS is divided 1.5 cm proximal to its insertion and retracted into the palmar wound. Another Bruner incision is made over the thumb IP joint. Dissection is carried down to the flexor tendon sheath, and the FPL insertion. The sheath is opened near the FPL insertion, and the FPL is retracted and delivered into the distal thumb incision. The FPL is divided transversely with scissors, leaving a 1-cm stump attached to the insertion. The FPL stump is then divided longitudinally in its midline along its entire remaining 1 cm length, along its insertion. A small amount of elevation of the central portion of the insertion is performed, but care is taken to keep most of the insertion intact. The volar aspect of the base of the distal phalanx is roughened with a small rongeur to provide a surface for tendon healing. The FDS is delivered through the fibro-osseous canal of the thumb using a pediatric feeding tube. Two suture anchors with 3-0 Ethibond are placed in the base of the distal phalanx, between the split halves of the FPL stump. The FDS is then laid down between the split halves of the FPL and secured to the bone by tying it down to the suture anchors. Next, the two halves of the FPL stump are brought around and volar to the FDS tendon, and sutured to the FDS tendon with horizontal mattress sutures, reinforcing the insertion. Tension should be set so that IP extension occurs with wrist flexion, and full flexion into the palm occurs with wrist extension.

An isolated FDS rupture does not necessarily result in significant functional loss. An end-to-side suture to an adjacent FDS is performed if the rupture occurs within the palm or carpal tunnel, using a Pulvertaft weave. Flexor tenosynovectomy and treatment of any sharp bone edges should be performed. If the FDS rupture occurs within the finger, a tenosynovectomy with resection of the FDS should be performed.

FDP rupture may also not result in severe functional loss, if isolated. Flexor tenolysis, and treatment of any sharp bony edges should be performed. If the rupture occurs within the palm or wrist, an end-to-side suture to an adjacent FDP is performed. If FDP rupture occurs within the finger and the FDS is functional, the FDP is resected. If the DIP joint hyperextends during pinch or grip, DIP arthrodesis is performed.

Rupture of both the FDS and FDP results in significant functional loss. If the ruptures are within the palm or carpal tunnel, end-to-side suturing of the FDP to an adjacent tendon is performed. Alternatively, a bridge graft can be used as described above for the FPL, with the FDS serving as a donor graft. If both tendons have ruptured within the flexor tendon sheath, a staged reconstruction can be considered. However, the outcome of staged flexor tendon reconstruction in patients with RA is often disappointing, and patients should be counseled that recovery of motion will be limited. In patients with arthritis of the IP joints, the best option is arthrodesis of the PIP and DIP joints in a functional position, with preservation of some finger motion at the MCP via the intrinsics.

Postoperative care

If tendon transfers are performed, the hand and fingers are immobilized in such a way as to take tension off of the transfer. The transfer is immobilized for 3–4 weeks, after which motion and retraining are begun under the guidance of a therapist. It should be noted that there is an increasing interest in early movement protocols following tendon transfer surgery, and this may result in improved outcomes or earlier recovery.

Outcomes, prognosis, and complications

Patients have the potential to maintain good finger function after isolated rupture of the FDS or FDP, if their pre-rupture finger function was good and if they receive appropriate treatment in a timely fashion. However, if pre-rupture finger function was limited, outcomes will be poor even if the rupture is treated appropriately. Outcomes after rupture of both the FDS and FDP are poor, regardless of pre-rupture finger function or the method of treatment.

Trigger fingers

Triggering can occur due to the presence of rheumatoid nodules or because of hypertrophic synovium. A very small nodule or synovitis can significantly affect tendon excursion and finger function. Furthermore, the location of the pathology is variable. Although the source of triggering can often be located preoperatively, the surgeon should plan for the possibility of an extensile incision.

The operation is performed under sedation and with local anesthetic, so that the patient can actively flex the finger after tenosynovectomy. A Bruner incision is made over the finger. Initially, the incision is limited to the suspected area of pathology, and can be extended later if necessary. Skin flaps are elevated and the flexor tendon sheath is exposed, preserving the neurovascular bundles. A window is made within the flexor tendon sheath at the level of the cruciate pulley, or at the A1 or A3 pulley nearest the pathology. The flexor tendons are retracted out of the flexor tendon sheath individually through the window using a Ragnell retractor. Synovium is removed from the flexor tendons using tenotomy scissors or a synovial rongeur, taking care to preserve the vincula (Figs. 19.73 & 19.74). If a rheumatoid nodule is encountered, it is excised. If pathology is more extensive, more windows are created within the sheath at the cruciate, A1 or A3 pulleys, allowing full access to the tendons. Rarely, it is necessary to excise the FDS tendon in order to allow FDP excursion. Complete release of the A1 pulley is avoided to lessen the chance of abnormal pull of the flexor tendon that would contribute to ulnar deviation. The patient is awakened and asked to actively flex the finger. If active motion is less than passive motion, or if triggering has not resolved, the surgeon must search for further pathology.

Postoperative care

A light dressing is placed and active and passive motion is begun immediately postoperatively, including tendon gliding exercises.

Outcomes, prognosis, and complications

A good outcome is dependent upon identification and treatment of the cause of the triggering. In order to prevent

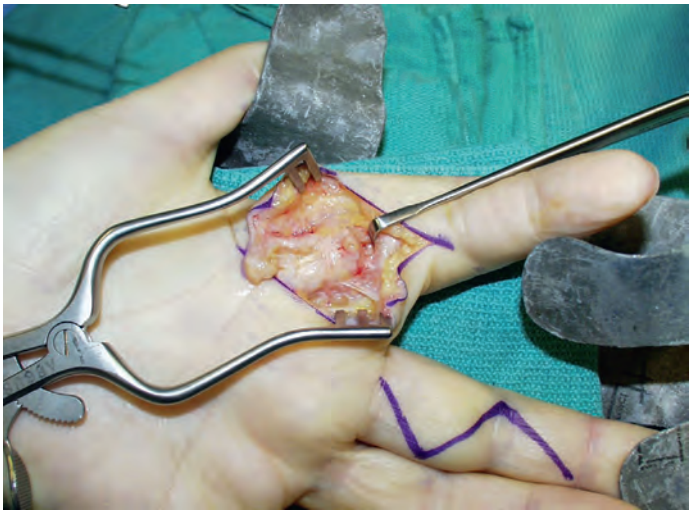

Fig. 19.73 Proliferative synovitis can be seen protruding through rents in the flexor tendon sheath.

the complication of persistent postoperative triggering, the surgeon must make sure that he or she has located and addressed all potential sources of triggering by having the patient actively range the finger prior to incision closure.

Extensor tendon ruptures

Extensor tendon ruptures most commonly occur at the wrist (Video 19.1 ▶). They are due to a combination of erosive tenosynovitis and attritional wear over a sharp spicule of bone at the ulnar side of the wrist, often arising from the ulnar head or DRUJ. Rupture of the EPL is common as well. In addition to treating the rupture, it is critical to address the underlying cause in order to prevent subsequent ruptures.

A dorsal wrist incision is made, skin flaps are elevated, and the retinaculum is incised as described above. A dorsal tenosynovectomy is performed as described above. The ruptured tendon is identified, and soft friable ends are resected with tenotomy scissors until the proximal and distal stumps consist

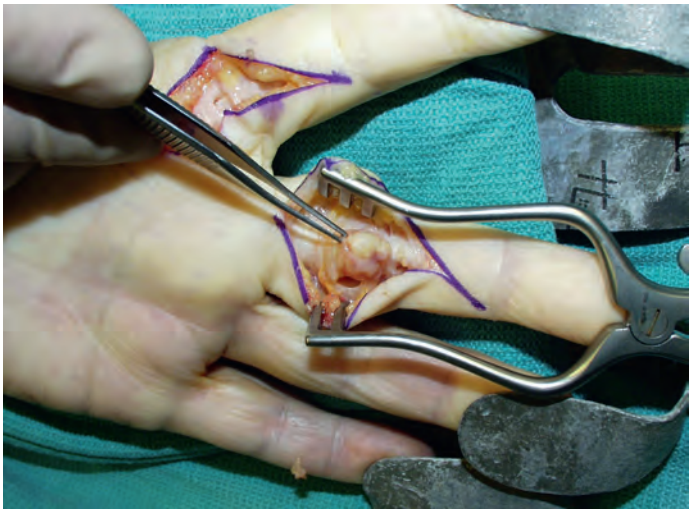

Fig. 19.74 A large piece of synovitis is being removed through a small opening in the flexor tendon sheath just distal to the A2 pulley.

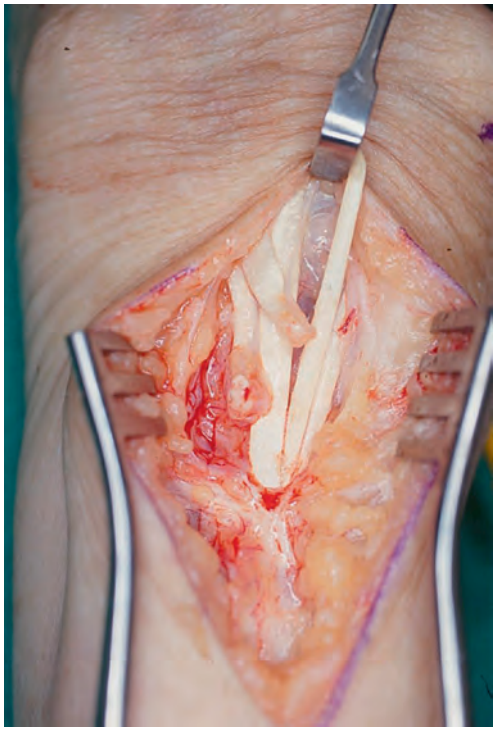

Fig. 19.75 The small finger extensors (EDC and EDQ) have ruptured at the level of the wrist, and their distal ends can be seen just distal to the extensor retinaculum.

of healthy tendon. The cause of the rupture should be sought, and is usually related to a sharp edge of bone. Care should be taken to smooth down all bony surfaces. In many cases a Darrach procedure is indicated, and can be performed at this time as described above. Next, a retinacular strip is transferred volar to the extensor tendons to cover any remaining exposed areas of bone. Next, the tendon reconstruction is performed. Rarely, the tendon ends can be repaired primarily. In most cases, there is a substantial zone of injury that precludes direct repair.

The reconstruction depends upon the number of tendons ruptured. If the tendon(s) to a single finger is (are) ruptured, the distal stump(s) should be sutured to an adjacent tendon using an end-to-side Pulvertaft weave (Figs. 19.75 & 19.76). Alternatively, the extensor indicis proprius (EIP) can be transferred in an end-to-end fashion to the ruptured tendon (Fig. 19.77). For the EIP transfer, a longitudinal incision is made over the index MCP joint, extending distally to the middle of the proximal phalanx. Skin flaps are elevated, exposing the extensor mechanism. The interval between the ulnarly located EIP and the radially located extensor digitorum communis (EDC) is identified and incised longitudinally, separating the two tendons. The sagittal band is carefully elevated off the EIP with a 15-blade, for later repair. The EIP is divided as far distally as possible, and retracted into the dorsal wrist incision. The distal stump of the EIP is sutured to the adjacent EDC, the sagittal band is repaired and the skin is closed. The EIP is then Pulvertaft weaved into the EDC and extensor digiti quinti (EDQ) of the small finger. It is important to tension the transfer correctly, creating a natural cascade of the fingers. The wrist is passively flexed and extended, checking the tenodesis effect. With the wrist flexed, the MCP joint should easily come

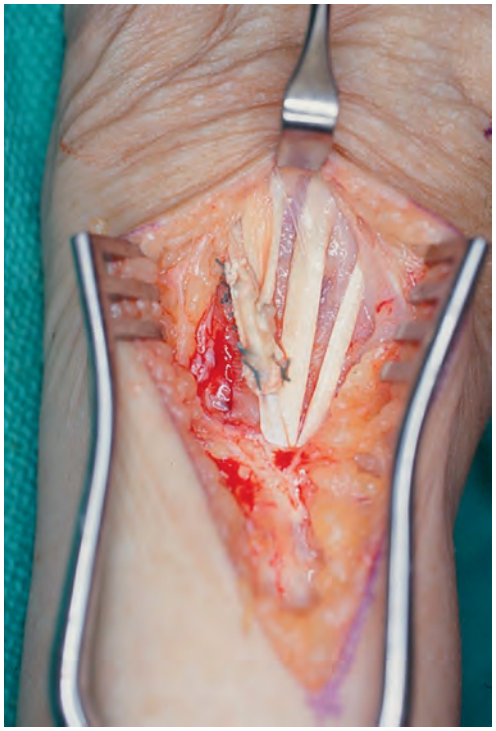

Fig. 19.76 The small finger extensors (EDC and EDQ) have been transferred end-to-side to the ring finger EDC.

into full extension or slight hyperextension. With the wrist extended, it should be possible to passively flex the MCP joint. It is preferable to slightly over-tighten the transfer, as there will be some loosening with time.

If both the small and ring finger extensor tendons are ruptured, the ring finger EDC is transferred to the long finger EDC in an end-to-side fashion. The small finger extensors, however, will not reach the long finger EDC, and end-to-side transfer usually cannot be performed. Therefore, the EIP tendon is transferred end-to-end to the small finger extensors (Fig. 19.78). The EIP is transferred to both the EDC and EDQ of the small finger, using a Pulvertaft weave. Again, setting tension properly is critical. The natural cascade of the fingers and the tenodesis effect are used as a guide to set the tension.

If three or four of the extensor tendons are ruptured, an FDS transfer is often performed. With three ruptures, the long finger EDC is sutured to the adjacent intact index EDC, and the ring FDS or EIP is used to restore extension of the small and ring fingers (Fig. 19.79). With four ruptures, two FDS transfers are required. The long FDS is used to restore index and long finger extension, and the ring FDS is used to restore ring and small finger extension (Fig. 19.80). For FDS harvest, a Bruner incision is made over the proximal phalanx of the appropriate finger. Skin flaps are elevated, and the flexor tendon sheath exposed. A small opening is made in the flexor tendon sheath, and the FDS is divided 1.5 cm proximal to its insertion. A longitudinal volar incision is made in the distal forearm proximal to the wrist flexion crease, and ulnar to the palmaris longus. Dissection is carried down to the FDS tendons, and the divided FDS is retracted into the wrist incision. The FDS is passed around the radial subcutaneous border of the wrist and delivered into the dorsal wrist incision. The transfer is completed and tensioned as described above.

Clinical tip

- The FDS tendons may be routed through an opening in the interosseous membrane for a straighter line of pull.
- It is critical to make a wide interosseous tunnel, both in transverse and in longitudinal dimensions so that the FDS tendons have a straight line of pull, and do not become entrapped.

EPL rupture is not always symptomatic, and may not require treatment. IP extension is usually preserved through the intrinsics, and MCP extension may or may not be lost. If MCP extension is lost and thumb function is affected, the EPL rupture is treated with an EIP to EPL transfer. The EIP is harvested as described above, and is retracted into the wrist incision. It is then passed distally to the dorsal aspect of the thumb, and transferred to the EPL with a Pulvertaft weave at the level of the metacarpal. It should be tensioned so that the MCP joint fully extends with the wrist flexed. With the wrist extended, it should be possible to passively flex the MCP joint.

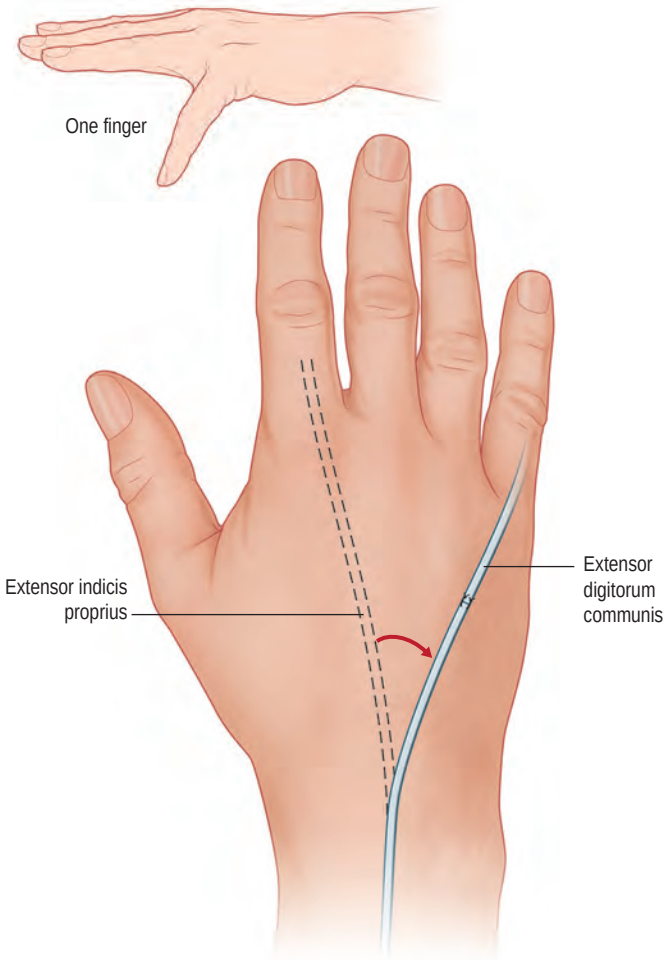

Fig. 19.77 Rupture of the EDC and EDQ to the small finger. The EIP is transferred to the small finger extensors.

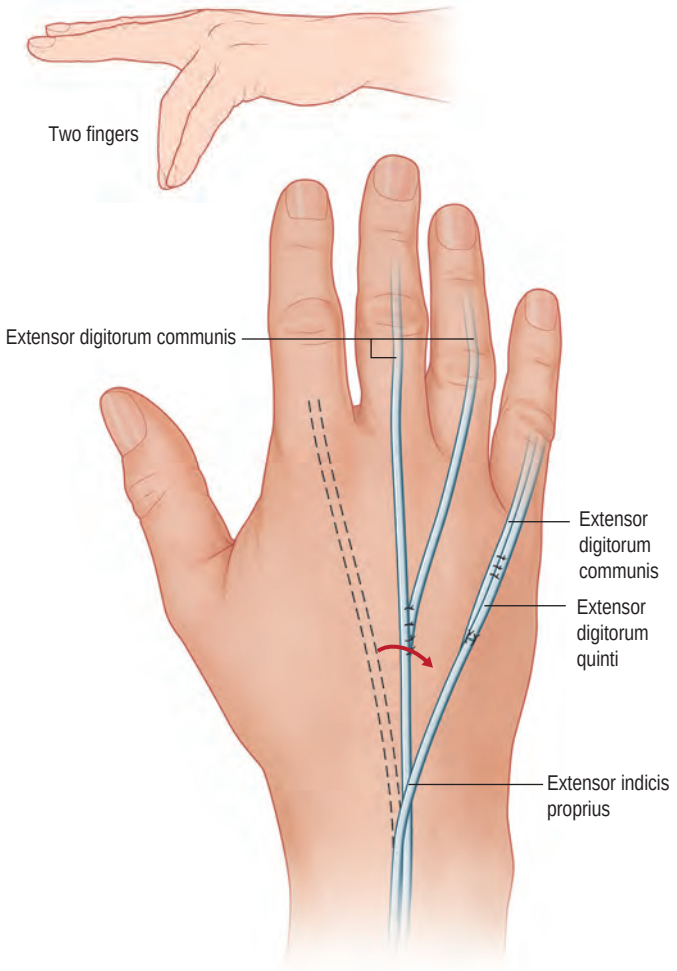

Fig. 19.78 Rupture of the small and ring finger extensors. The ring finger EDC is transferred end-to-side to the long finger EDC. The EIP is transferred end-to-end to the small finger extensors.

Postoperative care

For finger extensor tendon transfers, the wrist and MCP joints are splinted in extension for 4 weeks. Active motion and retraining is begun under the supervision of a hand therapist after 4 weeks. Gentle passive flexion can be started at 6 weeks, and strengthening at 8 weeks. Full activity and discontinuation of extension splinting occurs at 12 weeks. The thumb is protected in a thumb spica splint with the MCP and IP joints extended for 4 weeks, after which motion is initiated.

Outcomes, prognosis, and complications

Restoration of MCP extension can be reliably achieved with tendon transfers in patients who have preserved MCP joints. In patients with volarly subluxed and arthritic MCP joints, it is preferable to restore joint alignment and passive mobility by arthroplasty and soft-tissue reconstruction prior to performing tendon transfers. Any attempt to restore extension without first addressing MCP deformity or arthritis will result in suboptimal outcomes. Recurrent rupture can occur, and is minimized by correcting the underlying causes, including extensor tenosynovitis, rough bony surfaces, and the caput ulna.

Hints and tips

- Once an extensor tendon rupture occurs, subsequent ruptures can occur in rapid sequence.
- Although not an emergency, there is some urgency to treating the underlying cause.
- The surgeon should be careful to treat the underlying cause of the rupture when performing tendon transfers for extensor tendon rupture.
- The surgeon should have a low threshold for performing a distal ulna resection if there is concern that distal ulna or DRUJ pathology caused the ruptures.

Other rheumatologic disorders of the hand and wrist

Seronegative spondyloarthropathies

Seronegative spondyloarthropathies include Reiter's syndrome, psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel disease-associated arthritis. The most common seronegative spondyloarthropathy to affect the hands is psoriatic arthritis. Patients are usually RF negative, have an inflammatory arthritis, and have psoriasis (Table 19.1). Psoriasis affects 2% of the population and onset usually occurs in the 2nd decade of life.[61] Among patients with psoriasis, the prevalence of psoriatic arthritis is unknown, but ranges from approximately 5% to 40%.

Radiographic findings are diverse, and may include erosions and resorption, osteolysis, periostitis, ankylosis (often at the PIP joint), or juxta-articular bone formation. Radiographs may reveal a "pencil-in-cup" deformity at the DIP joint, which is the result of new marginal bone formation at the base of the distal phalanx, combined with osteolysis of the head of the middle phalanx.

Joint involvement can be symmetric or asymmetric, and may be oligoarticular or polyarticular. The small joints of the hands and feet are most commonly affected, and DIP involvement is often a prominent feature of psoriatic arthritis. Although tenosynovitis and tendon ruptures are rare, inflammation at tendon insertions may occur. Another occasional finding is dactylitis, which involves swelling and inflammation of an entire digit. The nails also develop abnormalities. Pitting is the classic finding, although onycholysis, nail dystrophy, leukonychia, and hyperkeratosis can occur as well. The most common finger deformity is a PIP flexion contracture, with compensatory MCP hyperextension. This is not a true boutonniere deformity. Swan-neck deformities can occur secondary to a mallet finger. In the thumb, a boutonniere deformity can occur, and the CMC joint can become arthritic as well. Wrist arthritis and DRUJ arthritis can occur as well. Rarely, severe osteolysis, or arthritis mutilans, results in collapse of the fingers known as the "opera glass hand".

Swan-neck deformity is treated in a similar fashion to swan-neck deformity associated with RA. Severe fixed PIP flexion contractures are treated with arthrodesis. MCP extension contractures with associated joint destruction are treated with silicone arthroplasty. Arthritis mutilans is treated with arthrodesis, often requiring bone graft. Wrist involvement is

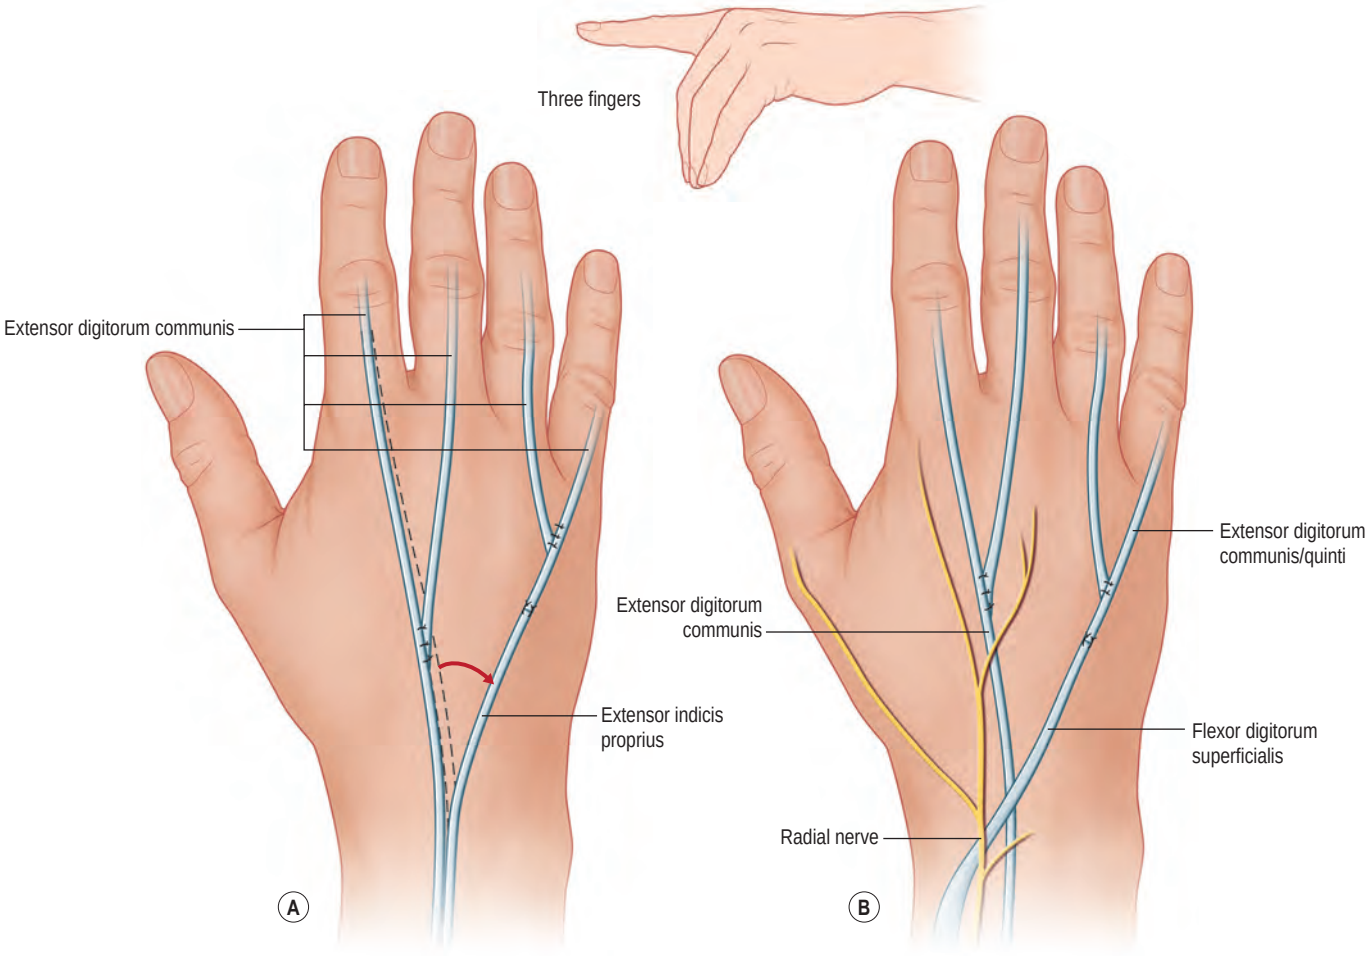

Fig. 19.79 Rupture of the long, ring, and small finger extensors. The EDC of the long finger is transferred end-to-side to the EDC of the index finger. The EIP **(A)** or the FDS **(B)** can be transferred to the small and ring finger extensors.

Table 19.1 **Characteristics of other rheumatologic conditions of the hand**

	Serology	Radiographs	Examination
Psoriatic arthritis	Negative	Erosions Resorption Osteolysis Periostitis Ankylosis (PIP) Juxta-articular bone formation Pencil-in-cup (DIP)	Psoriasis Nail abnormalities Dactylitis PIP flexion contracture Opera glass hand swan-neck deformity
SLE	ANA Anti-DNA Antiphospholipid antibody Leucopenia Hemolytic anemia Thrombocytopenia	Preservation of joints Secondary OA	Deformity similar to that seen in RA Malar rash Discoid rash Serositis Other
Scleroderma	ANA Anti-centromere Anti-topoisomerase I Anti-RNA polymerase	Tuft resorption Secondary OA	Cutaneous telangiectasia Raynaud's Cutaneous sclerosis Ischemic ulceration Joint contracture due to skin contracture
Gout	Hyperuricemia Negatively birefringent crystals (synovial analysis)	Sclerotic joint margins Overhanging edges Erosion from tophi (late) Joint destruction (late)	Red, hot, swollen joint MTP of great toe involvement Tophi
Pseudogout (CPPD)	Negative	Chondrocalcinosis of TFCC Scapholunate widening Scapholunate advanced collapse pattern arthritis	Presentation may be similar to osteoarthritis May be chronic inflammatory arthritis (mono-, oligo-, or polyarticular) May present as acute pseudogout attack (red, hot, swollen joint)

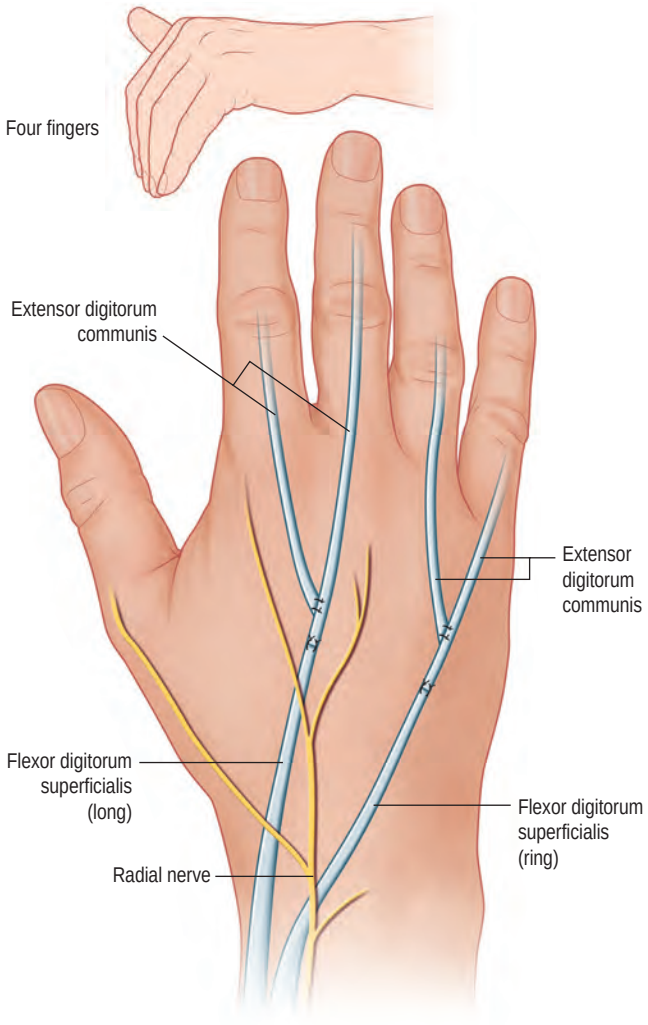

Fig. 19.80 Rupture of the extensor tendons to all four fingers. The long finger FDS is transferred to the index and long finger extensors, and the ring finger FDS is transferred to the ring and small finger extensors.

treated with limited intercarpal fusions or complete wrist arthrodesis, depending upon the pattern of joint involvement. A Darrach procedure may be indicated for DRUJ arthritis.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease (see Table 19.1), in which tissue damage is caused by autoantibodies and immune complexes. It affects five in 10 000 people in the United States, and women are affected much more frequently than men (9:1). African Americans and Latinos are affected more often than Caucasians, and tend to have a more severe disease process. Susceptibility is related to multiple genes. Many potential environmental triggers have been implicated, including Epstein–Barr virus (EBV) infection, multiple medications, dietary factors and bacteria.

The diagnosis of SLE is primarily clinical, and is supported by positive laboratory findings. Extra-articular manifestations are diverse and may include malar rash, discoid rash, photosensitivity, cardiovascular disease, oral ulcers, arthritis, serositis, proteinuria, seizures, psychosis, leukopenia, hemolytic anemia, thrombocytopenia, and many others. Seropositivity for antinuclear antibody (ANA) is very sensitive (95%), although there are cases of ANA-negative lupus. However, specificity is low and ANA may be positive in multiple rheumatologic diseases. Other supportive laboratory findings include anti-DNA, anti-Sm nuclear antigen, and antiphospholipid antibodies.

The IP joints, MCP joints, and wrist are commonly involved, and may be the initial presenting symptoms of the disease. Patients experience swelling, pain, effusion and morning stiffness. The arthritis associated with SLE is not erosive, and may not be deforming. If finger deformities do occur, they are very similar to those seen in rheumatoid arthritis. Volar subluxation and ulnar deviation occurs at the MCP joints, and swan-neck or boutonniere deformities may occur, but with an absence of destructive joint changes. In addition, tenosynovitis may occur, and may result in tendon ruptures. Synovitis within the carpal tunnel may lead to carpal tunnel syndrome. In addition, patients may develop subcutaneous nodules along the flexor tendons, histologically similar to those that develop in rheumatoid arthritis.

In many cases, the finger and wrist deformities that occur with SLE are passively correctable. In these cases splinting can be quite helpful. Intrinsic stretching can also be helpful to decrease MCP flexion and ulnar deviation. Because of poor soft-tissue quality, soft-tissue procedures alone are rarely successful, and the mainstays of surgery in the fingers are arthrodesis and arthroplasty, which can be combined with soft-tissue procedures. Partial wrist arthrodesis or total wrist arthrodesis may be beneficial, depending upon the deformity and instability pattern. The Darrach procedure is often indicated for dorsal subluxation of the ulna, which can often cause attrition ruptures. Because of the many organ systems involved, patients must have a thorough medical workup and preoperative clearance.

Scleroderma

Scleroderma, or systemic sclerosis (see Table 19.1), is a disease of the connective tissue and small blood vessels that affects multiple tissues. It is rarer than either rheumatoid arthritis or SLE, with a prevalence of <300 per 1 million in the United States. Like most rheumatologic disorders it is more common in women than men, and onset typically occurs in the 3rd or 4th decade of life. The disease is idiopathic, but there is a genetic component and an environmental trigger is likely required to initiate the disease. Systemic sclerosis can present as limited cutaneous disease (often involving the fingers or hands), diffuse cutaneous disease, or CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal involvement, sclerodactyly, and telangiectasias). Systemic sclerosis can affect the lungs, resulting in interstitial disease and pulmonary fibrosis. Cardiac, vascular, renal, gastrointestinal and other organ systems are also commonly involved. The diagnosis is clinical, and is supported by antibody testing. Nail fold capillary microscopy is also helpful. ANA, anti-centromere, anti-topoisomerase I, anti-RNA polymerase antibodies are all associated with systemic sclerosis.

Raynaud's phenomenon affects almost all patients, and is present in limited cutaneous, diffuse cutaneous, and CREST forms of the disease. Critical ischemia, however, occurs due to vascular disease related to the systemic sclerosis, and is not

due to Raynaud's phenomenon. Occlusive vascular changes affect the medium-sized vessels, and the ulnar artery in particular. Ischemic ulceration may occur in the fingertips, on the extensor surface over flexed joints, and in areas of calcinosis. Ischemia-related resorption of the tufts can occur, and is termed acro-osteolysis. Cutaneous telangiectasia may be seen on the palm. Treatment of the vascular manifestations of the disease is outside the scope of this chapter.

Finger deformities are related to skin contracture, and to fibrosis and contracture of joint ligaments and capsule. Arthritis and joint destruction do not occur directly. If joint changes or arthritis are seen, they are usually osteoarthritic changes that occur secondary to prolonged deformity and abnormal motion. The most common deformity in the hand is PIP flexion contracture. These contractures can be severe, and dorsal skin ulceration can occur with tendon or joint exposure. MCP hyperextension occurs secondarily, and can become fixed as well. In addition, the first webspace contracture is common. Soft-tissue loss over joints should be treated conservatively, with Silvadene dressing changes and minimal debridement. Ultimately, bony debridement or amputation may be required. At times, skin breakdown occurs over an area of calcinosis. Removal with a curette and irrigation with saline is performed. For severe PIP contractures with intact overlying skin, arthrodesis may be indicated. Care should be taken when managing the skin, and minimal skin flap elevation should be performed. In addition, significant bony resection should be performed, in order to take tension off the overlying skin. A compression screw or removable K-wires should be used in order to avoid subcutaneous hardware. Dressings should be light, and noncompressive. Patients should be cautioned about the possibility of wound healing problems, potentially resulting in the need for amputation. At the MCP joint resection arthroplasty is indicated for severe fixed extension contracture. A volar longitudinal incision is made directly over the metacarpal head. Dissection is carried down to the flexor tendon sheath, retracting the neurovascular bundles radially and ulnarly. The A1 pulley is incised, and the flexor tendons retracted. A 15-blade is used to create a volar arthrotomy through the volar plate and joint capsule. Subperiosteal dissection is then performed, exposing the head and neck of the metacarpal. A sagittal saw is then used to resect the metacarpal head. Bony resection is performed until MCP flexion is possible. The skin is closed and the patient is splinted with the MCPs flexed. Motion is allowed as soon as skin healing has occurred. First webspace contracture is difficult to treat. Because of the stiff nature of the skin, Z-plasties are rarely successful, and the contracture must be treated more like a severe burn contracture. A long transverse incision is made in the first webspace. Dissection is carried down to the adductor pollicis and first dorsal interosseous. Tight fascial bands are released with tenotomy scissors until the thumb can be abducted. If thumb CMC arthritis or CMC subluxation contributes to the adduction deformity, trapeziectomy can be performed through a separate incision. A full-thickness skin graft is used to close the defect, and should be harvested from an area with minimal skin involvement.

Postoperative care

The thumb should be pinned in abduction for 6 weeks, followed by motion and intermittent splinting.

Crystalline arthropathy (gout)

Gout is characterized by recurrent bouts of acute arthritis, eventually progressing to chronic arthritis (see Table 19.1). It affects approximately 1% of the population, and is more common in men. Risk factors include obesity, alcohol use, hypertension, renal disease, and certain medications. Triggers for an acute gout attack include physiologic stress, fever, surgery, dehydration, and alcohol use. In addition, foods that are high in purine increase the risk of a gout attack, including oatmeal, mushrooms, lentils and spinach.

Initially gout attacks are monoarticular, and involvement of the MTP joint of the great toe is classic. The joint becomes swollen, red, and exquisitely painful. Initially radiographs may be negative. The acute attack may last from hours to many days. As gout progresses, it can become polyarticular, and systemic symptoms such as fever, chills, or sweats may be present. Hand and wrist involvement is common. Eventually chronic arthritis and tophi develop, with continued episodic acute attacks. In chronic gout radiographic findings include erosions with sclerotic margins, and overhanging edges of bone (Fig. 19.81). Definitive diagnosis is made by arthrocentesis and identification of crystals with negative birefringence under polarized light microscopy. For an acute attack, colchicine, indomethacin, or corticosteroids are often used. An intra-articular steroid injection is quite effective. Prophylaxis is provided by daily low-dose colchicine or indomethacin. In addition, xanthine oxidase inhibitors such as allopurinol, or uricosuric agents such as probenecid can be used to reduce serum uric acid levels. Chronic gouty arthritis is treated with selective arthrodesis of joints that are painful, or that have deformity that is affecting function. Large painful tophi, or tophi that are interfering with function can be excised.

Fig. 19.81 PA radiograph of the hand demonstrating large gouty tophi of the PIP joints, and overhanging erosions.

Fig. 19.82 PA radiograph of the left wrist demonstrating chondrocalcinosis of the TFCC and lunotriquetral ligaments consistent with pseudogout.

Crystalline arthropathy (pseudogout)

Pseudogout is another common crystalline arthropathy (see Table 19.1), and the incidence increases with age.[62] Also known as calcium pyrophosphate dihydrate deposition disease (CPPD), pseudogout is characterized by the deposition of calcium pyrophosphate crystals within hyaline and fibrocartilage. Common radiographic findings include chondrocalcinosis of the TFCC (Fig. 19.82), and scapholunate advanced collapse (SLAC) pattern arthritis. Under polarized light microscopy, calcium pyrophosphate crystals are positively birefringent and rhomboid shaped, differentiating them from urate crystals. The clinical presentation is commonly one of chronic mono-, oligo-, or polyarthritis, although acute pseudogout attacks can occur. It is also common to see chondrocalcinosis as an incidental radiographic finding, not associated with clinical symptoms. Although the knee is most frequently affected, the wrist is second. Pseudogout attacks may last substantially longer than gout attacks, extending up to 3 months' duration.[63] Although multiple medications are being studied for use in treating pseudogout, the mainstays of treatment are NSAIDs, corticosteroids, and colchicine.

Summary

Multiple diverse rheumatologic disorders exist, many of which commonly affect the hand and wrist. Although the medical management of rheumatologic diseases has dramatically improved, there are still many patients with recalcitrant pain and loss of function who may benefit from hand surgery. In most cases, arthritic pain can be effectively treated with arthrodesis or arthroplasty. Restoration of function is less reliably achieved, but is an important secondary goal. It is important for the patient to undergo a thorough medical and anesthesia workup prior to any surgery because of the many systemic manifestations associated with rheumatologic disorders.

Future directions

At times, differentiating between an acute gout attack and septic arthritis can be clinically challenging. The ability of arthrocentesis to distinguish gout versus infection may be limited by the amount of fluid obtained, or pre-existing antibiotic treatment. Recent research demonstrates that dual-energy computed tomography (DECT), also known as a "gout-map CT scan", may be used to differentiate between a joint with gout and an infected joint.[64] In addition to detecting monosodium urate crystals within a joint, DECT can be used to quantify the anatomic extent and severity of crystal deposition. The sensitivity and specificity for detecting gouty arthritis using DECT are approximately 75% and 93%, respectively.[64] Although the role of DECT in diagnosing gout requires further study, this technology shows substantial promise.

Osteoarthritis in the hand and wrist

Paige M. Fox, Brian T. Carlsen, and Steven L. Moran

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Osteoarthritis is characterized by a loss of articular cartilage.
- The development of osteoarthritis is a dynamic process that represents an imbalance between destruction and repair of the articular cartilage. It can result from trauma, such as an intra-articular fracture or a ligamentous injury that results in abnormal load-bearing characteristics, or it can be idiopathic without an identifiable cause.
- Osteoarthritis can affect the entire joint, including the articular cartilage, subchondral bone, ligaments, joint capsule, synovial membrane, and periarticular muscles and tendons.
- Patients with osteoarthritis seek treatment because of pain, loss of function, or both. However, there is often a poor correlation between the patient's symptoms and radiographic findings.
- Osteoarthritis is more common in women. In the hand, the distal interphalangeal (DIP) joints of the fingers and the carpometacarpal (CMC) joint of the thumb are most commonly affected, followed in order by the finger proximal interphalangeal (PIP) and metacarpophalangeal (MP) joints.
- Radiocarpal arthritis is most commonly a result of traumatic injury and follows a regular progression over time as seen in scapholunate advanced collapse (SLAC) and scaphoid nonunion advanced collapse (SNAC) wrist arthritis patterns.
- Treatment of arthritis is directed toward alleviating pain and improving function.
- Treatment strategies include operative and non-operative treatments. Non-operative treatments include lifestyle modification, hot and cold therapy, splinting, oral or topical non-steroidal anti-inflammatory drugs (NSAIDs), and alternative therapies (diet modification, ultrasound, transcutaneous electrical nerve stimulation (TENS), and acupuncture).
- Surgical management of osteoarthritis includes load-altering procedures, joint debridement and/or synovectomy, arthrodesis, and arthroplasty procedures.
- The appropriate type of operation varies depending on multiple factors including patient age, demands placed on the joint, the requirement for motion to perform one's activities of daily living or job requirements, patient desires, and the likelihood of success of restoring function and alleviating pain.

Introduction/epidemiology

- Osteoarthritis (OA) is a heterogeneous disease that includes conditions with different etiology, distribution, heredity, clinical presentation, and progression.
- It is characterized by mechanical and biological events that alter the homeostatic relationship of degradation and repair of the surrounding articular tissues.
- Although all joint tissues are involved, including the subchondral bone, damage to the articular cartilage is the hallmark of the disease.
- Osteoarthritis is the most common rheumatologic disorder in the world. It affects all races, sexes, and age groups.
- It is a major cause of adult morbidity. It is the cause of disability in 10% of the population over age 60.[3]
- The age-standardized prevalence of hand osteoarthritis was 44.2% in women and 37.7% in men in the Framingham OA Study.[4] DIP, PIP and thumb base arthritis were more prevalent in women while metacarpophalangeal (MCP) and wrist OA were more frequent in men.
- It is estimated that 21% of the population or 46.4 million Americans in 2005 were affected by osteoarthritis.[5]
- Symptoms of OA may include joint pain, swelling, tenderness, stiffness, and crepitus. OA is typically considered a non-inflammatory condition to differentiate it from the inflammatory arthropathies such as rheumatoid and psoriatic arthritis.
- There is no cure for osteoarthritis and no effective method of altering the progression of the disease process.

Historical perspective

Osteoarthritis is evident across species, with evidence in other mammals, amphibians, certain species of birds, and even ancient dinosaurs. The disease is likely as old as man, with evidence of its existence in prehistoric man from 2 million years ago.[1,2] The disease is considered synonymous with aging.

This chapter will review the presentation, evaluation, and treatments of osteoarthritis as it presents in the various joints of the hand and wrist. Both non-operative and operative approaches will be discussed, with particular attention to the indications and contraindications of specific treatments.

Basic science/disease process

OA is characterized by a loss of articular cartilage. It can be either primary or secondary in nature. *Primary OA* (idiopathic OA) occurs in the absence of antecedent trauma. The pathogenesis is likely heterogeneous; genetics, joint shape and underlying endocrine abnormalities can contribute. *Secondary OA* is the result of direct trauma to the joint and can occur as a result of fracture, dislocation, or infection.

In order to understand the pathophysiology of osteoarthritis, one must first consider the normal anatomy and biochemistry of the synovial joint. Normal articular cartilage consists of an extensive extracellular matrix composed primarily of proteoglycans, collagens (predominantly type II), and water. While chondrocytes compose only 1% of the volume of the cartilage extracellular matrix, they are responsible for maintaining its architecture and composition. The matrix is composed primarily of collagen, proteoglycans, proteins, and glycoproteins. Cartilage proteoglycans belong to two major classes: large aggregating molecules (aggrecans), and smaller non-aggregating molecules. The aggrecan molecule consists of a central protein core with about 100 glycosaminoglycan (GAG) side branches composed of repeating, negatively charged disaccharides. Aggrecan molecules form proteoglycan aggregates by linking with a long central hyaluronan molecule. The result is a very large molecule with 10^5 negatively charged groups. These groups fill voids in the cartilage framework and create a high osmotic pressure in the framework, providing a stiff construct resistant to compression. Non-aggregating proteoglycans and other matrix proteins serve a variety of functions in the matrix including framework stabilization, regulation of fibrillogenesis, and matrix metabolism through chondrocyte interactions.[6] Such molecules include biglycan, decorin, fibromodulin, chondroadherin, cartilage oligomatrix protein, and fibronectin. The interstitial fluid provides an important function in terms of altering the cartilage friction coefficient with changes in pressure (load).[7]

Microscopically, articular cartilage can be divided into four zones based on the cartilage matrix composition and architecture.[8] Zone 1 is the most superficial zone and is called the superficial or tangential zone. Here, the chondrocytes are flat and oriented parallel to the articular surface. The collagen is condensed and proteoglycans are sparse. The thin collagen fibers are arranged parallel to the articular surface. This construct resists shear force and has been compared to a "tough skin" that protects the underlying intermediate and deep zones.[9] In zone 2, the intermediate zone, the chondrocytes are isolated or in isogenous groups and are surrounded by oblique collagen fibers. This zone is the thickest and is rich in proteoglycans. Proteoglycans are complex macromolecules composed of a protein core with attached glycosaminoglycan chains (chondroitin sulfate and keratan sulfate). The negative charge of the glycosaminoglycans accounts for the hydration and large swelling pressure of cartilage.[10] Zone 3 is the radiate layer and includes large, round chondrocytes oriented vertically with intervening radial collagen fibers. Zone 4 is the deepest layer or calcified layer. It lies adjacent to the subchondral bone and resists shear stress between cartilage and bone.[9] Between zone 3 and zone 4 is the *tidemark* (Fig. 20.1). With age, articular cartilage becomes thin and there is relative advancement of the tidemark zone that occurs together with replacement of calcified cartilage with bone.[11] The result of this anatomic design is a shiny and slippery surface with a friction coefficient lower than any prosthetic replacement. This remarkable construct is able to withstand millions of loading cycles each year with forces that may reach up to 18 MPa.[12]

Fig. 20.1 Histological section of **(A)** normal and **(B)** abnormal cartilage. **(A)** Normal joint articular cartilage is connected to the bone through a layer of calcified cartilage. The basophilic line, or blue line, histologically separates the articular cartilage from calcified cartilage. The calcified cartilage receives nutrients through the epiphyseal vessel; the articular cartilage receives nutrients primarily through diffusion from the overlying joint fluid. **(B)** In joints affected by osteoarthritis, there is fraying in the superficial cartilage and decrease in articular cartilage thickness.

In the healthy, homeostatic state, the chondrocyte responds to the mechanical and biochemical environment by altering the synthesis and degradation its macromolecules. Two groups of enzymes function to degrade the extracellular matrix: matrix metalloproteinases (MMPs) and *a d*isintegrin *a*nd *m*etalloproteinase with *t*hrombospondin-like motifs (ADAMTS). MMPs break down collagen[13] and ADAMTS functions to break down aggrecan. The main MMP in cartilage is MMP-13 that breaks down type II collagen and the main ADAMTS in cartilage are ADAMTS-4 and ADAMTS-5.[14,15]

The regulation of matrix degradation and synthesis is poorly understood, but cytokines play an important role in both anabolic and catabolic pathways.[8,16,17] The interplay between these cytokines is complex. Anabolic activity seems to be a response of the structural needs of the matrix, as may occur in response to mechanical loading. Cytokines involved in the anabolic pathway include transforming growth factor-beta (TGF-β) and insulin-dependent growth factor I.[8] Catabolism within the matrix involves a complex cascade that includes interleukin-1, stromelysin, aggrecanase, and plasmin, in response to stimulation or inhibition by TGF-β, tumor necrosis factor, tissue inhibitors of metalloproteinases, tissue plasminogen activator, plasminogen activator inhibitor, and other molecules.[8]

Pathophysiology

Osteoarthritis involves all of the tissues around the synovial joint, including the articular cartilage, joint capsule, ligaments, subchondral bone, metaphyseal bone, and the muscles acting across the joint. However, the principle pathological change is that of loss of articular cartilage. Other changes are noted such as subchondral sclerosis, subchondral cyst formation, and marginal osteophytes.[8,18,19]

The earliest microscopic findings of OA are that of fibrillation and fraying of the superficial zone cartilage along with decreased staining for proteoglycans in the superficial and transitional zones and in-growth of blood vessels into the tidemark from subchondral bone (Fig. 20.1B).[8] Progression of the disease leads to clefts in the articular surface, fracture of the superficial cartilage, and decrease in cartilage thickness. Enzyme activation leads to further destruction of the cartilage leading to complete loss of articular cartilage exposing dense and eburnated bone.[8]

Associated with these changes of the cartilage are alterations in the subchondral bone, specifically an increased density. This increased density can be seen as a sclerotic line on radiograph. These changes may be more pronounced at the joint periphery where the new bone formation may be so exuberant as to produce osteophytes. The exact pathophysiology of osteophyte formation is not known; however, it may be related to the release of anabolic cytokines from the matrix that stimulate the abnormal bone and cartilage growth.[20,21]

The changes involving the joint also affect the periarticular tissues. The synovial membrane becomes inflamed as fragments of cartilage become embedded within them.[22] As the joint loses motion due to mechanical factors and pain, the capsule and surrounding ligaments become stiff due to myotendinous contraction and ongoing edema. The lack of motion and use can lead to muscle atrophy.[8]

Diagnosis

The most common symptoms of OA are pain, swelling, and stiffness of the affected joint. Pain is the primary feature of the condition and is the focus of treatment. Examination confirms swelling, tenderness, and limited range of motion. In the case of post-traumatic arthritis, there may be joint instability associated with previous ligamentous injury.

Symptoms can dissipate with time and are not always correlated with the radiographic severity of disease.

Fig. 20.2 Posteroanterior radiograph of the hand of a 69-year-old male showing typical bony changes seen in advanced osteoarthritis. Osteophyte formation is seen at the distal interphalangeal and proximal interphalangeal joints and trapeziometacarpal joint of the thumb. Joint narrowing is seen within the fingers as well as evidence of subchondral sclerosis.

Osteoarthritis may also be present in the absence of pain. In a classic study looking at arthritis among miners in their 40s, Kellgren and Lawrence found that only 24% of miners with radiographic OA had pain and 8% of radiographically normal knees had pain.

Radiographs are the most helpful test in making the diagnosis. In primary and secondary OA, joint spaces are narrowed radiographically due to a loss of radiolucent articular cartilage. Subchondral bone remodeling can manifest as increased density within the subchondral bone or sclerosis. Osteophytes and loose bodies may also be present (Fig. 20.2).

In 1957, Kellgren and Lawrence described a grading system for the radiographic appearance of OA.[23] Findings considered included: (1) the presence of peripheral osteophytes; (2) periarticular ossicles (commonly found in association with DIP and PIP joints); (3) narrowing of joint cartilage and subchondral sclerosis; (4) small pseudocystic areas with sclerotic walls, typically in the subchondral bone; and (5) altered shape of the bone ends. The authors then classified the arthritis into five grades[23]:

1. Normal joint
2. Doubtful
3. Minimal (but definitely present)
4. Moderate
5. Severe.

This system has been broadly applied for grading osteoarthritis in various joints; unfortunately the grading system can be ambiguous as there are no specific cut-off criteria between the grades. In a recent analysis by Schiphof and colleagues, the

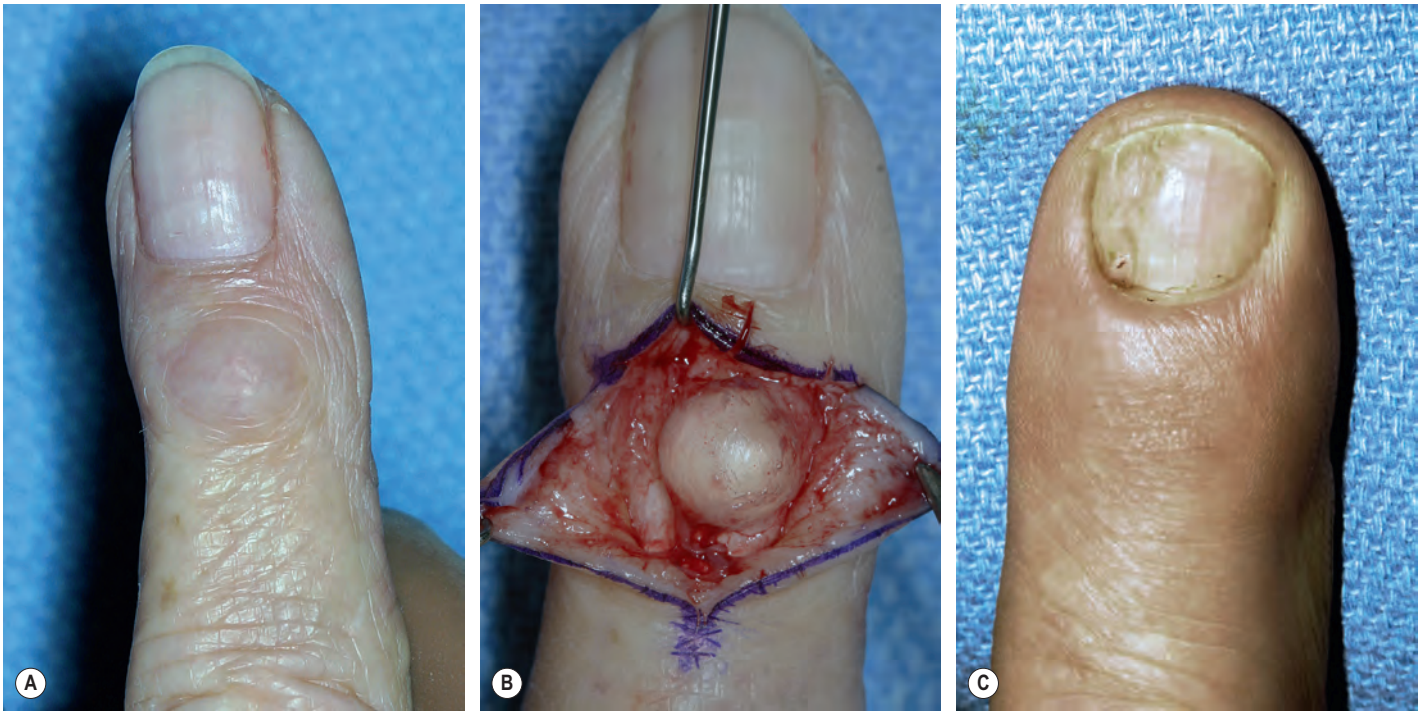

Fig. 20.3 Typical appearance of a mucous cyst in this 67-year-old female with distal interphalangeal joint osteoarthritis. **(A)** A mass is palpable over the joint. **(B)** The cyst is clearly seen at the time of surgical exploration. **(C)** Mucous cysts may also present with nail grooving, which results from pressure on the germinal and sterile matrix of the nail.

authors note inconsistency in the application of the grading system within multiple cohort studies and have recommended the development of a single validated classification system.[24]

Management of OA of the fingers

Hand and finger arthritis is one of the most common presentations of primary OA. Its onset is insidious with progressive aesthetic deformity followed by pain and functional limitation. Epidemiological studies of the joint-specific prevalence of hand arthritis consistently show the distal interphalangeal joint to be the site most frequently affected by OA, followed by the thumb CMC joint, and the PIP joint.[25] These studies typically defined OA based on the radiographic features described by Kellgren and Lawrence, which include the presence of osteophytes, joint space narrowing, subchondral sclerosis, and subchondral cysts.[23]

Distal interphalangeal joint (DIP) arthritis

Diagnosis

Osteoarthritis of the DIP joint is common and affects females more frequently than males. Clinically, patients present with enlarged joints and hard, knobby protuberances overlying the DIP joints of multiple fingers. These, so called *Heberden's nodes*, are pathognomonic for the condition and are attributed to osteophyte formation with overlying soft-tissue thickening. These should be differentiated from a *mucous cyst*. A mucous cyst is a dorsal synovial cyst, often limited to a single digit. They are often associated with lateral deviation of the distal phalanx, and a limited range of motion (Fig. 20.3).

Radiographically, joint space narrowing and osteophyte formation are common findings. However, the radiographic appearance of the DIP is not consistently associated with the patient's symptoms. Frequently, the only significant concern for the patient is the aesthetic appearance. Even patients with severe DIP deformity may have little pain or functional impairment and the presence of Heberden's nodes alone is not generally considered an indication for surgery.

Indications for surgery

The treatment of DIP OA is dictated by the severity of pain and functional limitation. Splinting allows the joint to be rested and protected from minor trauma. Splinting used in conjunction with oral or topical anti-inflammatory medication and lifestyle modification are the mainstays of non-operative treatment. This approach is usually sufficient to treat acute exacerbations of pain and swelling. Steroid injections can be attempted for temporary pain relief but are difficult to administer in such a small joint, and multiple repeated injections are not a convenient as a long-term treatment plan. When intractable pain, deformity, and misalignment are severe enough to interfere with precision pinch, oppositional pinch, and global hand function, surgery is indicated.

The surgical option for treatment of severe DIP arthritis is essentially limited to arthrodesis, which is well tolerated in the DIP position. Although implant arthroplasty is technically feasible, it is not commonly performed because of concerns of long-term joint instability.[26–30]

Biomechanical effects of DIP fusion

The normal range of motion at the DIP joint is 0–60°; however, only 15% of digital flexion occurs at the DIP and the joint only contributes 3% of the overall flexion arc of the whole finger.[31] Thus, of all finger joint fusions, DIP arthrodesis confers the least detrimental impact to hand motion, and is the well tolerated. One study of splint-simulated DIP fusion found a 20% reduction in grip strength, which was attributed to the *quadriga effect*, as a result of the limited excursion of the flexor digitorum profundus (FDP) tendon in the fused digit.[32] Significant loss of grip strength has not been shown in clinical studies.

DIP arthrodesis

Indications

The single most common indication for arthrodesis is intractable pain at the DIP joint that has failed all conservative treatments. Other less common indications include chronic mallet deformity, missed flexor tendon avulsions, or distal phalanx nonunions.

Techniques

A multitude of fixation techniques have been described,[33] including interosseous wiring,[34] percutaneous pinning, tension band wiring,[35,36] bio-resorbable pinning,[37] plating,[38] oblique lag screw fixation,[39] and axial compression screw fixation.[33,40] Regardless of the technique chosen, the joint is prepared in a similar manner and the requirements for a successful outcome are: (1) full apposition of the cancellous bone surfaces; (2) preservation of distal phalanx bone stock to allow for hardware purchase; (3) fusion in approximately 5–10° of flexion if possible; and (4) stable fixation.

Most techniques utilize a transverse skin incision overlying the joint. Oblique or axial extensions are made proximally and distally and skin flaps are raised to complete an H-shaped exposure centered over the joint. Alternatively, a midlateral or a Y-shaped dorsal incision can be used. Specific care should be taken to avoid injury to the germinal nail matrix located just distal to the extensor insertion. The extensor tendon and joint capsule are sharply divided in a transverse orientation, the collateral ligaments are divided, and the joint is maximally flexed to allow access to the articular surfaces.

With the base of the distal phalanx and the condyles of the middle phalanx exposed, a rongeur is used to remove dorsal and lateral osteophytes. The articular surfaces are decorticated until cancellous bone is visualized. Alternatively, osteotomies can be created with a small oscillating saw to achieve precise apposition of the cancellous bone. If power saws or burrs are to be utilized, copious irrigation should be maintained throughout the cutting process to avoid the risk of thermally induced osteonecrosis, which can elevate the risk of nonunion postoperatively.[41]

Interosseous wiring

Interosseous wiring involves securing the distal and middle phalanx together by means of one or two dental wires passed through bone tunnels. Interosseous wiring can be used to achieve some compression of the joint and is usually used in conjunction with K-wires for greater stability. Zavitsanos *et al*. described a technique which allows the K-wires to be completely buried, minimizing the risk of infection.[34]

K-wire fixation

After the joint is prepared, two crossed 0.045-inch Kirschner wires are passed across the joint. Alternatively, an axial K-wire and a single oblique wire can be used. A minimum of two wires needs to be used to prevent rotation. The wires are typically cut beneath the skin at the fingertip. This enables the patient to continue to use the finger in activities of daily living. The DIP joint is immobilized in a splint to protect the fusion. Once union is documented radiographically, the wires can be removed. Wire removal can be done in the office under digital block anesthesia.

Tension band wiring

With the joint surfaces prepared, two 0.045-inch K-wires are placed parallel across the joint. Distally, the pins are buried in the distal volar cortex of the distal phalanx while proximally the pins exit on the dorsal cortex of the middle phalanx. A transverse canal is made dorsal to the wires in the proximal distal phalanx. A 28-gauge dental wire is passed through this canal and secured proximally around the K-wires exiting on the dorsal proximal phalanx in a figure-of-eight fashion. The dental wire is twisted and secured and the K-wires are bent to assure the construct is as low profile as possible. The tension band construct is remarkably stable and early motion may be permitted in selected patients. If the hardware is bothersome, it can be removed after bony union.

Clinical tips

Tension band wiring

- Take down the collateral ligaments for clear visualization of the entire joint.
- A rongeur or small saw can be used to prepare the joint for fusion.
- K-wires can be placed retrograde from the joint into the middle phalanx to assure an appropriate trajectory that will capture a sufficient portion of the distal phalanx.
- After confirming the correct length of the parallel K-wires, back them out of the bone slightly, bend, and cut to length prior to gently tapping back into place. This will allow for better coaptation to the bone and make hardware irritation less likely.

Axial compression screw

A single axial compression screw (Fig. 20.4) can be used to reliably achieve DIP joint fusion. A traditional lag screw technique can be used but will result in prominent hardware at the fingertip and is discouraged. Buried headless compression screws are preferred. The technique for the use of a threaded headless compression screw initially involves preparation of the joint surfaces followed by the placement of an antegrade axial K-wire through the distal phalanx exiting at the hyponychium. The bone surfaces are then coapted in the position of fusion and the same wire is drilled retrograde back into the middle phalanx. The position of the wire and

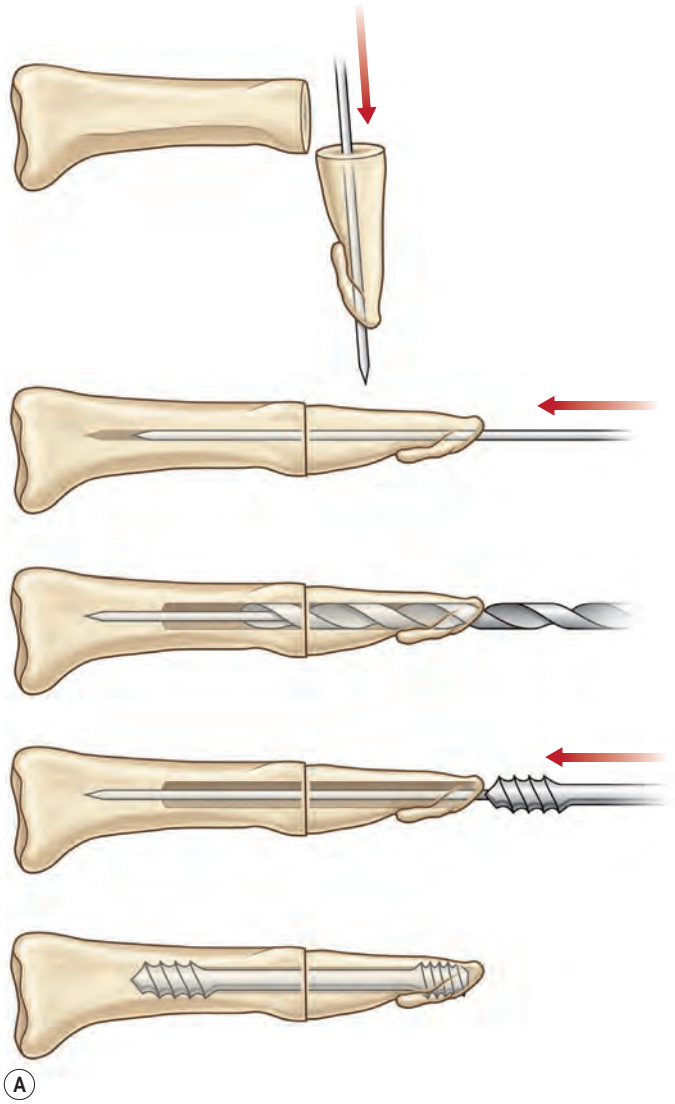

Fig. 20.4 **(A)** Technique for fusion of distal interphalangeal (DIP) joint using axial compression screw. In preparation for fusion, all articular cartilage needs to be removed from the joint surface. A K-wire is then driven retrograde out of the distal phalanx. The joint is then reduced in preparation for fusion and the wire is then driven across the DIP joint. A cannulated drill is used to prepare the bones for screw placement. The screw may then be placed over the wire to complete the fusion. **(B)** Final position of screw within joint. **(C)** DIP fusion may also be accomplished with the use of K-wires alone or tension band technique.

arthrodesis are checked fluoroscopically, and a cannulated drill is used prepare the channel for screw placement. The appropriate screw size is determined through fluoroscopic measurement, and a cannulated, fully threaded, self-tapping screw is inserted in a retrograde fashion to complete the fusion (see Fig. 20.4).

The screw should be long enough to engage the cortical isthmus of the middle phalanx. Occasionally, the intramedullary canal of the middle phalanx is too wide for the thread to engage the endosteal cortex even at the isthmus (e.g., thumb), and the chances of a stable construct are reduced. Additionally, specific attention should be paid to the anteroposterior (narrowest) diameter of the distal phalanx to ensure that the screw thread diameter is not greater than this measurement, otherwise dorsal fracturing and nail bed deformity can occur.[42]

The major advantages of this technique over other methods of DIP fusion are buried hardware and stable fixation. Immobilization time with the use of compression screws has been shown to be significantly shorter when compared to other

techniques for DIP fusion. Patients may often be splinted for only 1–3 weeks, allowing patients to return to work earlier.[43] One disadvantage of this technique is the difficulty in achieving the optimal prehensile position at the DIP as the joint is typically fused straight due to the conical shape of the screw. Other reported complications have included a single case of skin necrosis of the fingertip requiring secondary amputation[44]; this was likely due to unrecognized prominent hardware.

Complications of DIP fusion

Infection

Traditional fixation techniques for small joint arthrodesis include interosseous wiring, crossed K-wires, or a combination of these techniques. The rate of deep infection and osteomyelitis with these techniques remains up to 20% in some studies.[45] Surgeons who prefer this technique should consider burying the K-wires during the consolidation phase, as infection and nonunion rates are much lower with buried techniques are utilized.[46]

Nonunion

Reported nonunion rates for DIP arthrodesis range from 0–20%. Several studies have reported low rates of nonunion with screw techniques[44,45,47–49] as well as traditional techniques[46]; however, a clear relationship between fixation technique and the rate of nonunion has not been shown for DIP arthrodesis.[45]

Kirschner wire and interosseous wire techniques produce significantly less compression across the fusion site than compression screw techniques and compression itself has been shown to achieve more rapid fusion. In a biomechanical cadaver study comparing fixation techniques, the use of a single buried axial compression screw (Herbert screw) was shown to be superior in terms of fixation strength when compared to a combined K-wire/tension band technique.[42] Despite this biomechanical study, retrospective clinical studies have noted similar nonunion rates when comparing compression screws, interosseous wiring, and crossed K-wires techniques; it is thought that nonunion rates most closely correlate with the amount cortical bone and condition of the bone stock at the time of operative procedure.[45]

DIP arthroplasty

Distal interphalangeal joint arthroplasty is an uncommon procedure with few indications. The obvious advantage is maintained range of motion of the DIP, which may be beneficial in selected cases, e.g., in professional musicians.[30] There are few published series and these all report on the use of silicone interposition implants.[27–29] The largest series reported 38 DIP arthroplasties of which 10% were removed by 10 years. The average range of DIP motion was 33° with an average extension lag of 12°.[28]

Mucous cyst

Dorsal synovial cysts are commonly associated with DIP arthritis and develop in response to irritation of the joint by marginal osteophytes (see Fig. 20.3). Cysts slowly expand, damaging the germinal matrix, resulting in nail deformity and nail grooving. Progressive thinning of the overlying skin and recurrent inflammation are also common. Infection can be troublesome, as communication with the joint risks the development of septic arthritis and recurrently symptomatic cysts should be removed surgically.

Needle aspiration of the mucous cyst with subsequent corticosteroid injection of the DIP joint is appealing because it can be performed in the office setting with minimal morbidity.[50–52] Typically, the cyst is too small for effective needle aspiration and instead, multiple punctures are made with a 25-gauge needle and manual expression of the cyst fluid is performed. The joint may then be injected with a lidocaine and corticosteroid solution and wrapped snugly for several days. This technique has been associated with a 60% resolution of the cyst.[50] However, one must observe careful sterile technique to minimize chance of infection into the joint space.

If the cyst recurs surgical excision can be performed. Our preferred surgical technique consists of marking the margins of the cyst under loupe magnification followed by excision of the cyst and overlying attenuated skin. The underlying inflamed synovium should be debrided and associated dorsal and marginal osteophytes removed. Specific attention should be paid to preservation of the extensor insertion, which can be challenging as it may be significantly attenuated. Skin closure may require the use of local skin flaps in rare circumstances.[50,53–55]

Fritz *et al*. reported the results of surgical excision of 86 mucous cysts. Nail deformities were present in 29% of patients preoperatively.[56] Postoperative loss of extension of 5–20° at the interphalangeal (IP) or DIP joints was seen in 17% of patients. One patient developed a superficial infection and two developed a DIP pyarthrosis, eventually requiring DIP arthrodesis. A total of 7% of patients without preoperative nail deformity developed one postoperatively; however, 60% of preoperative nail deformities were improved by the procedure. Recurrence was seen in 3% of cases and other complications included persistent swelling, pain, numbness, stiffness, and radial or ulnar deviation at the DIP joint.

Proximal interphalangeal (PIP) joint arthritis

Within the hand, the PIP joint is the third most frequently affected by OA. The joint is more commonly affected in females.[25] The PIP joint has been described as the "functional locus of the finger" as it produces 85% of intrinsic digital flexion and contributes 20% to the overall arc of finger motion.[57] Despite this, a full range of motion is not absolutely necessary for good hand function, and a 45–90° flexion arc allows for most activities.

As in DIP arthritis, PIP joints affected by OA are often enlarged and painful. Patients will complain of their inability to wear or remove rings from the affected fingers. *Bouchard's nodes* are pathognomonic for PIP OA and are bony protuberances at the joint, analogous to Heberden's nodes at the DIP joint. Range of motion at the PIP joint tends to be preserved until late in the disease process. Radiographic findings include joint space narrowing, subchondral sclerosis, and osteophytes (see Fig. 20.2).

Management

Patients with occasional or minor symptoms are medicated with oral or topical non-steroidal anti-inflammatory drugs. Resting the joint by splinting in *extension* can be used to decrease pain in acute exacerbations. Intra-articular steroid injections can also be used to decrease pain but repeated injections are impractical for the long-term management of severely symptomatic patients. When non-operative management strategies are insufficient to control the patient's symptoms, PIP joint OA is usually treated surgically, with either arthrodesis or implant arthroplasty. Vascularized joint transfer is technically feasible but uncommonly practiced due to significant donor site morbidity and inferior outcomes when compared with implant arthroplasty.[58–61]

The decision for PIP arthrodesis or arthroplasty is dictated by the patient's functional needs, desires to preserve PIP motion, and the requirements for lateral stability at the joint. The ulnar three digits are important for generating grip strength. Maximal grip strength requires almost full PIP flexion to avoid the quadriga effect. The index finger's relatively independent FDP function does not impose a significant quadriga effect on the remaining digits during grasp. In comparison, the index finger is used to generate oppositional and adduction pinch strength, which requires PIP lateral stability but little PIP motion if metacarpophalangeal joint motion is preserved. Therefore, the decision for arthrodesis versus arthroplasty may be different for each digit involved. For example, arthrodesis of the index finger PIP joint provides finger stability for pinch and is well tolerated; however, for the ring and small finger PIP joints, implant arthroplasty may be preferred, as PIP joint motion in these digits is important for grip function and strength. If fusion is to be performed on the PIP joints of the ulnar three digits, care must be taken in placing the joints in enough flexion to preserve grip strength. A significant decrease in grip strength occurs when the PIP joint of the small finger is fused in less than 45° of flexion, and when the PIP joint of the middle and ring fingers are fused in less than 60° of flexion.[62]

PIP arthrodesis

PIP arthrodesis can be accomplished using the same techniques as described for DIP arthrodesis. The optimal position of PIP fusion varies according to the digit, with some authors recommending 40° of flexion for index, 45° for the long, 50° for the ring and 55° for the small finger (Fig. 20.5)[63]; however, this can be tailored according to the patient's occupation and recreational activities. Preoperative splints simulating fusion at various angles can be used to allow the patient to make a more informed decision.

Techniques

The PIP is approached dorsally through a longitudinal incision centered over the joint. The extensor tendon and joint capsule are split longitudinally and dissected radially and ulnarly. The central slip should be elevated subperiosteally off the base of the middle phalanx. The proximal origins of the collateral ligaments are divided and the joint is flexed to expose the joint surfaces. The bone ends are prepared using angled saw cuts on both phalanges. Alternatively, rongeurs or a burr can be used to create a concave–convex (cup and cone) configuration on the opposing bone surfaces. The digit is necessarily shortened by preparation of the bone surfaces. Prolapse of the volar plate in between the bone ends may result in non union; the volar plate should be resected if this occurs. Fixation can be achieved by one of the following techniques:

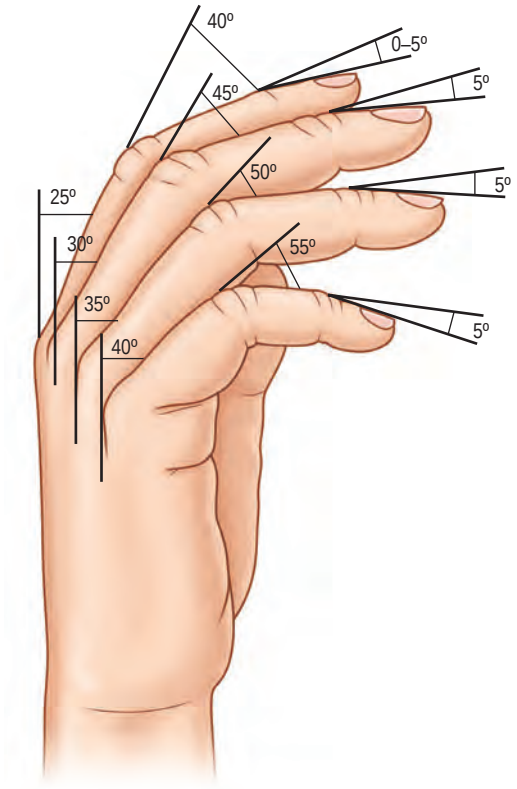

Fig. 20.5 Illustration of recommended fusion angles for distal interphalangeal (DIP), proximal interphalangeal (PIP), and metacarpophalangeal (MCP) joints. DIP fusion angles are often performed with 0–15° of flexion. PIP fusion angles increase as one moves from the index to the small finger, to correspond with the natural cascade of the hand. Recommended fusion angles for the PIP joint have been 40° of flexion for the index, 45° for the long, 50° of flexion for the ring, and 55° of flexion for the small. MCP fusion angles have been recommended to progress from 25° of flexion at the index to 40° of flexion at the small finger.

Crossed K-wire technique

After preparation of the joint, two crossed 0.045-inch or larger Kirschner wires are passed obliquely across the joint in a coronal plane. Alternatively, an axial K-wire and a single oblique wire can be used. Similar to DIP fusion, the wires can be buried beneath the skin and removed once there is radiographic union. During this time, the joint is protected in an immobilizing splint.

Tension band wire technique

Tension band wiring uses a combination of K-wires and interosseous wire to achieve moderate stability and compression. After preparation of the joint, a transverse hole is drilled through the middle phalanx approximately 5 mm distal to the osteotomy and a 0.6-mm stainless steel wire is passed through the hole. Two parallel 1-mm K-wires are inserted across the joint, and left protruding through the dorsal cortex of the proximal phalanx. The steel wire is passed around the K-wires

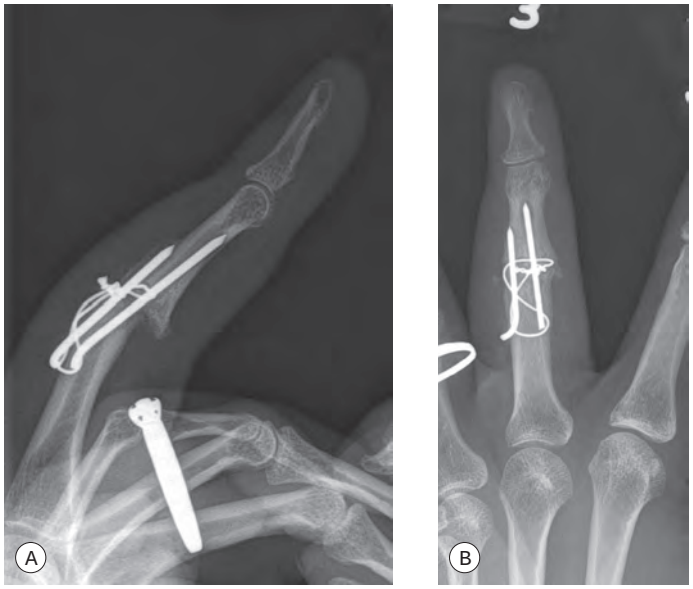

Fig. 20.6 Lateral **(A)** and anteroposterior **(B)** radiographs of a long finger following proximal interphalangeal joint fusion using a tension band technique.

in a figure-of-eight fashion and tightened to produce compression of the construct. The wire ends and K-wires should be cut short and manipulated to lie flat on the dorsal cortex and prevent extensor tendon attrition. (Fig. 20.6). The dorsal soft tissues are closed and a splint is applied. A splint is worn for protection until radiographic union.

Compression screw

Arthrodesis of the PIP joint can be accomplished by antegrade insertion of a headless compression screw across the prepared joint (Fig. 20.7A). A K-wire is used to start a hole in the dorsal cortex of the proximal phalanx and oriented obliquely in a sagittal plane. The angle of insertion should correspond to the desired angle of fusion and the wire is inserted antegrade across the joint, into the middle phalanx. The position of the entry hole in the proximal phalanx should be at least 6 or 7 mm proximal to the joint to prevent fragmentation of the dorsal cortex, which can be a complication of this technique. The K-wire is used as a guide wire for the cannulated drill sequence required for the particular screw being used (as described above for DIP arthrodesis). Fluoroscopy is used to check alignment, and to choose an appropriately sized screw that is then inserted in an antegrade fashion, with the assistant holding manual compression of the bone surfaces. The thread should reach the cortical isthmus of the middle phalanx to achieve endosteal purchase. The dorsal soft tissues are closed and a bulky splint is applied. A thermoplastic splint can replace this after 7 days, which should be worn for approximately 3 weeks. The major advantage of this method of fixation is the substantial stability of the construct, which allows early mobilization, and less likelihood of hand stiffness.

Plating

For severely osteoporotic bone, or for salvage of failed fusion attempts using other methods, PIP arthrodesis may be obtained using mini-plates (1.7 mm up to 2.7 mm). Newer plate designs allow for compression or locking screw

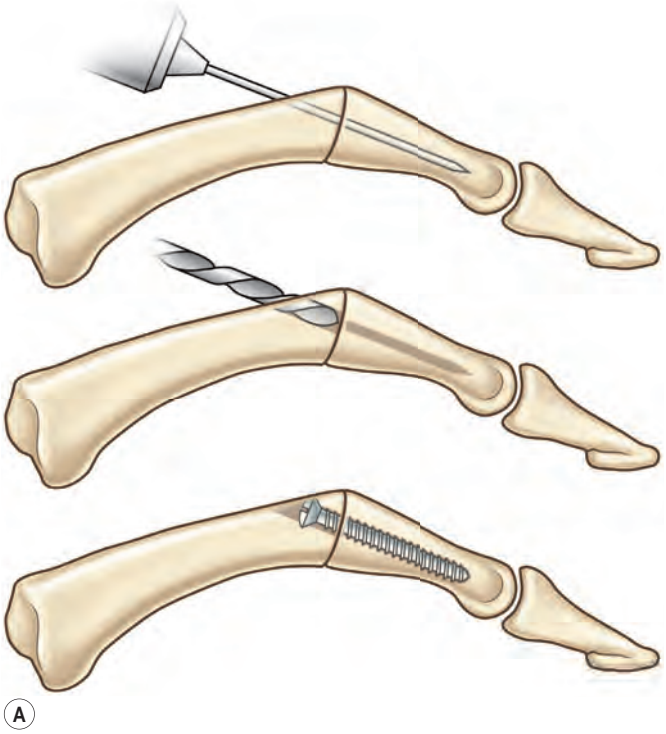

Fig. 20.7 Example of a proximal interphalangeal joint fusion with **(A)** headless compression screw and **(B)** dorsal plating technique.

placement, which can significantly improve fixation in severely osteoporotic bone. Plates are applied using standard AO technique. Pre-contouring of the plates is required to achieve the appropriate angle (Fig. 20.7B).

PIP arthroplasty

Arthroplasty will allow for some preservation of joint motion. Arthroplasty techniques consist of soft-tissue interposition, silicone spacers, and a variety of constrained and unconstrained implants. Soft-tissue arthroplasties are mentioned for historical purposes but have been largely replaced by implants, silicone or other. Techniques for soft-tissue arthroplasty have included resection of the head of the proximal phalanx,[64] volar plate interposition,[65] and perichondrial transplant arthroplasty.[66–68]

Currently, there are two popular approaches to implant arthroplasty – interposition silicone spacers including the Swanson implant (Wright Medical Technologies, Arlington, TN) and NeuFlex implant (DePuy, Warsaw, IN); and surface replacement or total joint replacement implants such as the SR-PIP implant (Small Bone Innovations, Morrisville, PA) and the PyroCarbon PIP (Integra, Plainsboro, NJ). The success of PIP implant arthroplasty is largely dependent on the condition of the surrounding soft tissues including the collateral ligaments, tendons, and volar plate. When these structures are preserved, implant arthroplasty has a higher success rate.

Silicone interposition arthroplasty

Silicone interposition implants consist of one-piece flexible, stemmed, hinged elastomer spacers that can be used in all digits after resection arthroplasty of the PIP joint. Swanson and Niebauer first devised these implants in the 1960s. The implant consists of a single silicone unit with a tapered proximal and distal stem with a central interposed flexion region, which is dorsally offset. The implant does not function as a true joint but rather a spacer that is stabilized by the fibrous capsule, which develops around the implant. The implant glides or "pistons" within the medullary canals during movement and this was originally believed to disperse forces over a broader surface area potentiating the life of the implant. Newer implant designs have maintained the same general concept but have incorporated a 30° pre-flexed hinge between the proximal and distal stems to facilitate finger flexion.

Technique

The PIP joint can be exposed by one of three surgical approaches – dorsally, laterally, or from the volar surface. We prefer a longitudinal dorsal approach in most cases, as it affords superior exposure to the joint and allows easier insertion of the implants. A 2–3 cm straight or curved dorsal incision is made over the PIP joint and continued through the center of the extensor tendon from mid-proximal phalanx until just distal to the insertion of the central slip on the middle phalanx. The two parallel halves of the central slip are then mobilized off the underlying middle phalanx. This produces radial and ulnar tendinous bands, each containing half of the central slip and a lateral band, which are allowed to sublux laterally when the middle phalanx is flexed, exposing the PIP joint. The joint is flexed to 90°, and osteophytes are removed as necessary. An alternative exposure of the PIP joint involves the use of Chamay technique, where a distally based flap of the extensor mechanism is elevated from proximal to distal (Fig. 20.8). The flap is then repaired at the completion of the surgical procedure.[69]

A micro-oscillating saw is used to make a transverse osteotomy at the distal-most portion of the flare of the proximal phalanx, just proximal to the condylar insertion of the collateral ligaments. In general, no resection of the base of the middle phalanx is necessary. Specially designed awls and broaches (specific to implant system used) are used both proximally and distally to open the intramedullary canal to allow the largest size implant. After a trial implant is inserted, the joint is taken through a range of motion to assess stability and fit and the definitive implant is placed. The soft tissues are closed and the hand and wrist are immobilized in the intrinsic plus position. Within a week, the patient is provided a dynamic splint and motion is initiated in a supervised rehabilitation program.

Surface replacement arthroplasty with non-constrained implants

The first PIP joint replacement prosthesis was described in 1959 by Brannon and Klein.[70] Numerous implant designs have since been produced and many have been abandoned due to implant failure, instability or high complication rates.[71–74] At present, the two designs available in the United States are made of metal or PyroCarbon.

Clinical tips

PIP silicone arthroplasty

- A central dorsal approach provides easy access and clear visualization of the PIP joint.
- We prefer a central incision through the extensor tendon and central slip to the Chamay approach.
- Only the cartilaginous surface of the middle phalanx needs to be removed. No formal cut is made in the middle phalanx.
- If the insertion of the central slip is disrupted during implant placement, a non-absorbable suture should be used to repair the tendon to the bone through small holes placed in the dorsal cortex of the middle phalanx prior to final implant placement.
- A minimal or no-touch technique helps decrease the risk of infection when placing the final implant. Clean smooth forceps are ideal for placing the implant.

Linscheid and Dobyns introduced the first non-constrained PIP prosthesis in 1979 and this design is still available as the SR-PIP implant.[75] The proximal component is made of a chromium–cobalt alloy with a polished articular surface, and the distal component has an ultra-high molecular weight polyethylene (UHMWPe) articular surface fixed to a titanium base and stem. The articulating surfaces are a tongue-in-groove configuration, similar to the PIP joint anatomic design. For this reason, the manufacturer has described the system as "semiconstrained." This congruency adds to the lateral stability of the joint. The titanium stems are textured and are

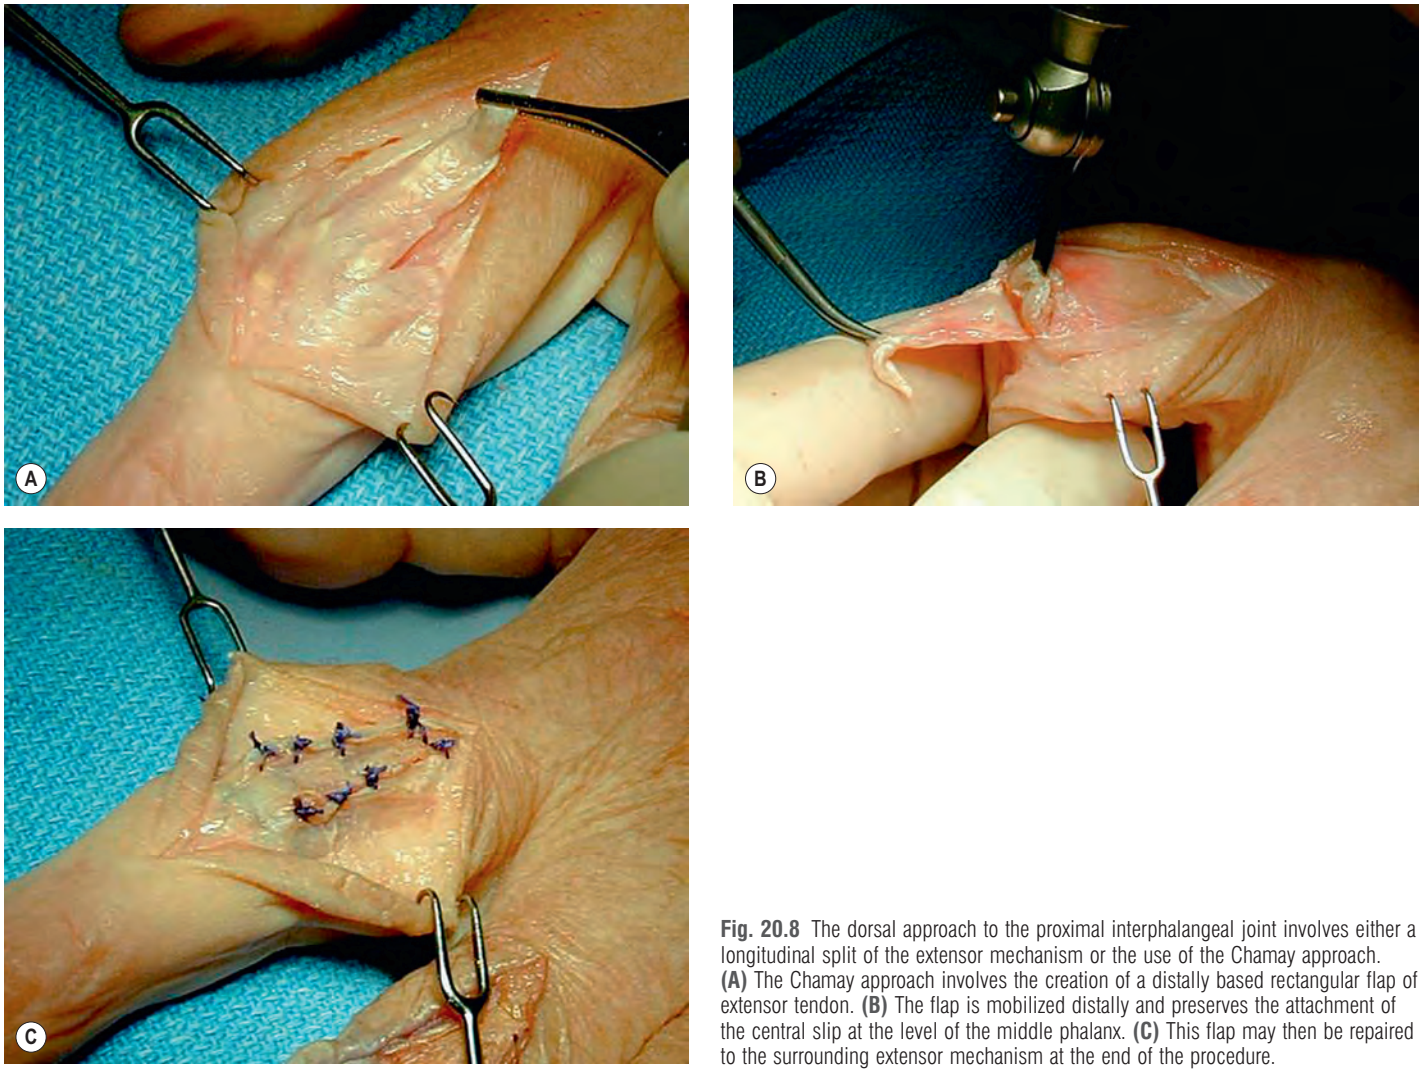

Fig. 20.8 The dorsal approach to the proximal interphalangeal joint involves either a longitudinal split of the extensor mechanism or the use of the Chamay approach. **(A)** The Chamay approach involves the creation of a distally based rectangular flap of extensor tendon. **(B)** The flap is mobilized distally and preserves the attachment of the central slip at the level of the middle phalanx. **(C)** This flap may then be repaired to the surrounding extensor mechanism at the end of the procedure.

designed to "press-fit." However, non-cemented implants have been shown to have a higher incidence of subsidence and loosening.[76]

Pyrolytic carbon implants have been developed for use in the PIP joint. Pyrolytic carbon is a substance similar to graphite, which is formed by the high-temperature pyrolysis (thermal decomposition) of hydrocarbons, and their subsequent recrystallization as a surface coating. Pyrolytic carbon is used in joint arthroplasty as a 0.5–1.0 mm coating on a graphite substrate and 1% tungsten is added to produce radio-opacity. The elastic modulus of PyroCarbon (23 GPa) is a much closer match to that of cortical bone (29 GPa), than other implant systems (titanium, 105 GPa; CoCr, 230 GPa), thus it is presumed that there should be less subsidence. The pyrolytic carbon proximal interphalangeal – PyroCarbon PIP – is a non-cemented, minimally constrained, two-component, non-linked total joint replacement implant. Joint stability is achieved as a function of the complementary shape of the component surfaces, but ultimately depends on surgical preservation of the collateral ligaments and soft tissues. Like the SR-PIP arthroplasty, the device can be cemented at the surgeon's discretion.

Both the PIP pyrolytic carbon implant system and SR-PIP arthroplasty are approved for use by the US Food and Drug Administration (FDA) as Humanitarian Use Devices (HUD). Such devices are authorized for use in PIP joint arthroplasty when the patient:

> *… has soft tissue and bone that can provide adequate stabilization and fixation under high-demand loading conditions after reconstruction; and needs a revision of a failed PIP prosthesis, or has pain, limited motion, or joint subluxation/dislocation secondary to damage or destruction of the articular cartilage.*

Because these devices are used for HUD purposes, their use requires Institutional Review Board (IRB) approval. However, once approved, the IRB does not have to review and approve each individual case.

Patient selection

A trial of non-operative management is recommended in all patients with PIP OA prior to discussing operative intervention. Unconstrained surface-replacement implants rely on the preservation of the collateral ligaments for stability. Patients with gross ligamentous instability or who have damaged their collateral ligaments may not be appropriate candidates for arthroplasty and would be better served with fusion. Evidence

of insufficient bone stock, inadequate intramedullary space, marked soft-tissue compromise, or ongoing active or chronic infection, are all contraindications to implant arthroplasty, and an alternative surgical option should be pursued. Patients should be informed that average joint motion following arthroplasty is only 40–60°, and joint motion may deteriorate over time. Preoperatively, true anteroposterior (AP) and lateral radiographs are obtained of each PIP joint so that joints may be templated for implant sizes. The index finger PIP joint is subject to significant lateral force during pinch maneuvers. Therefore the surgeon and the patient must discuss the increased potential for complications after index finger PIP arthroplasty.

Technique for non-constrained or semiconstrained PIP arthroplasty

Surface replacement arthroplasty of the PIP joint can be performed through either a dorsal, lateral, or volar approach. Our preference is for the dorsal approach as it provides excellent exposure of the joint and facilitates implant placement (Fig. 20.9). A 2–3 cm straight or curved dorsal incision is made over the PIP joint and continued through the center of the extensor tendon from mid-proximal phalanx until just distal to the insertion of the central slip on the middle phalanx. The two parallel halves of the central slip are then mobilized off the underlying middle phalanx. This produces radial and ulnar tendinous bands, each containing half of the central slip and a lateral band, which are allowed to sublux laterally when the middle phalanx is flexed, exposing the PIP joint. The joint is flexed to 90°, and osteophytes are removed as necessary.

A 0.035-inch K-wire is inserted into the dorsal third of the proximal phalanx head, and fluoroscopy is used to confirm a central position in the medullary canal. A starter awl is then used to enlarge the intramedullary canal. A cutting guide is then used to create a vertical osteotomy approximately 0.5–1 mm distal to the insertion of the collateral ligaments on the head of the proximal phalanx removing the articular cartilage. Next, the proximal phalanx is broached, until the medullary canal is filled with the largest broach possible. The lateral fluoroscopic view will be the first to show the size limitations of the intramedullary canal. Once the canal has been enlarged, a matched oblique cutting guide is used to create a back cut in the proximal phalanx, congruent with the sized implant shape. A proximal trial implant can then be inserted and checked radiographically for size and alignment.

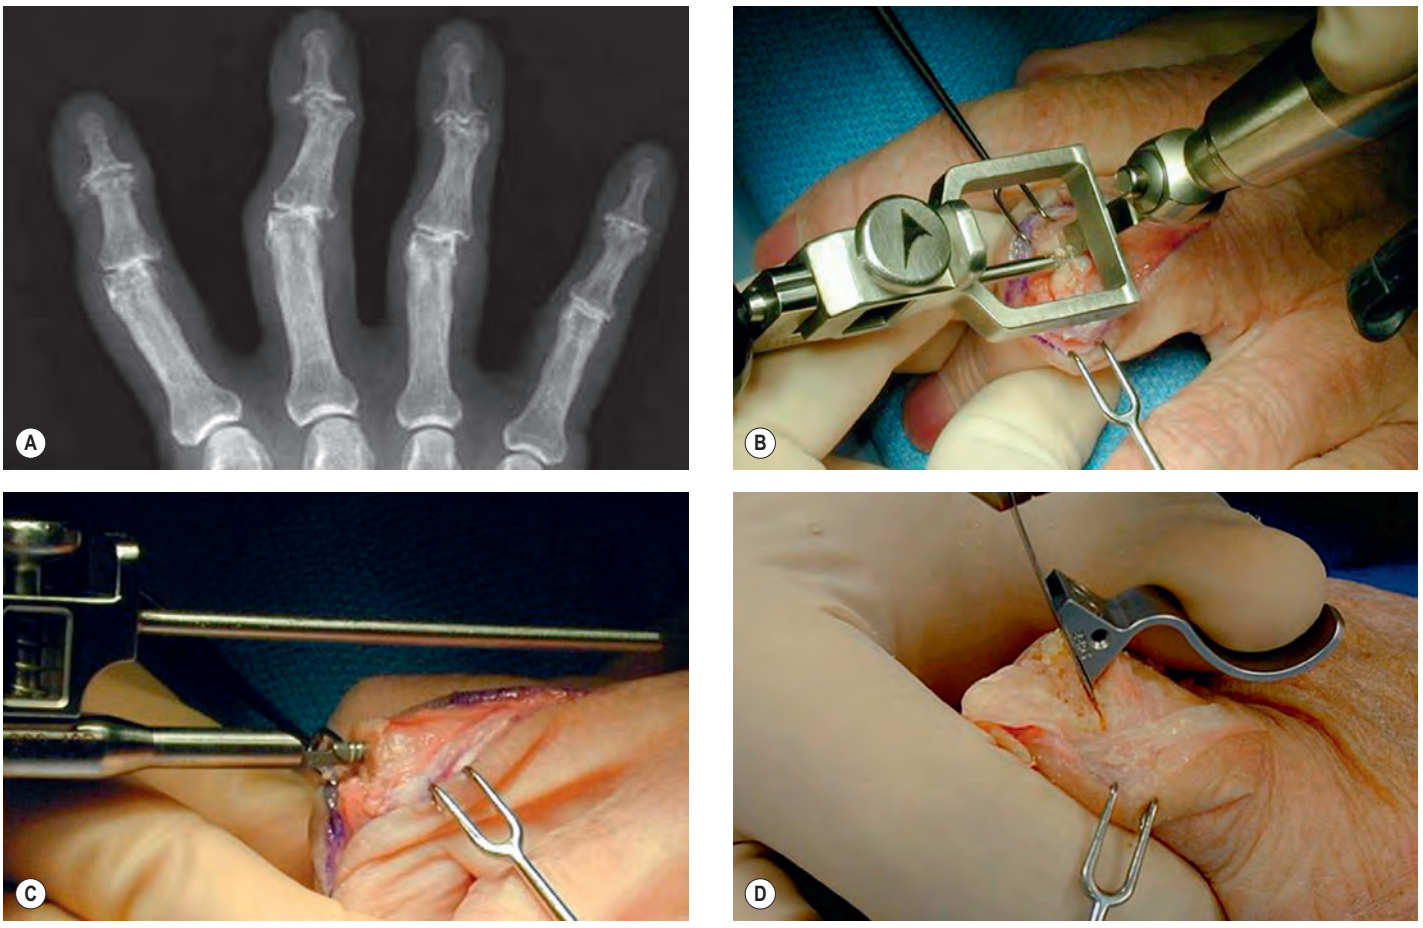

Fig. 20.9 **(A)** The posteroanterior (PA) radiograph of a 73-year-old woman with advanced osteoarthritis of the proximal interphalangeal (PIP) joints of the index through ring fingers, who has elected to undergo PyroCarbon arthroplasty of the index and long finger PIP joints. The arthroplasties are performed through a dorsal approach. **(B)** The proximal phalanx is prepared initially with the aid of a cutting guide to remove the articular surface. **(C)** A broach is used to prepare the canal of the proximal phalanx so that it will accept the implant. **(D)** A back cut is then created in the proximal phalanx so the implant can be properly seated.

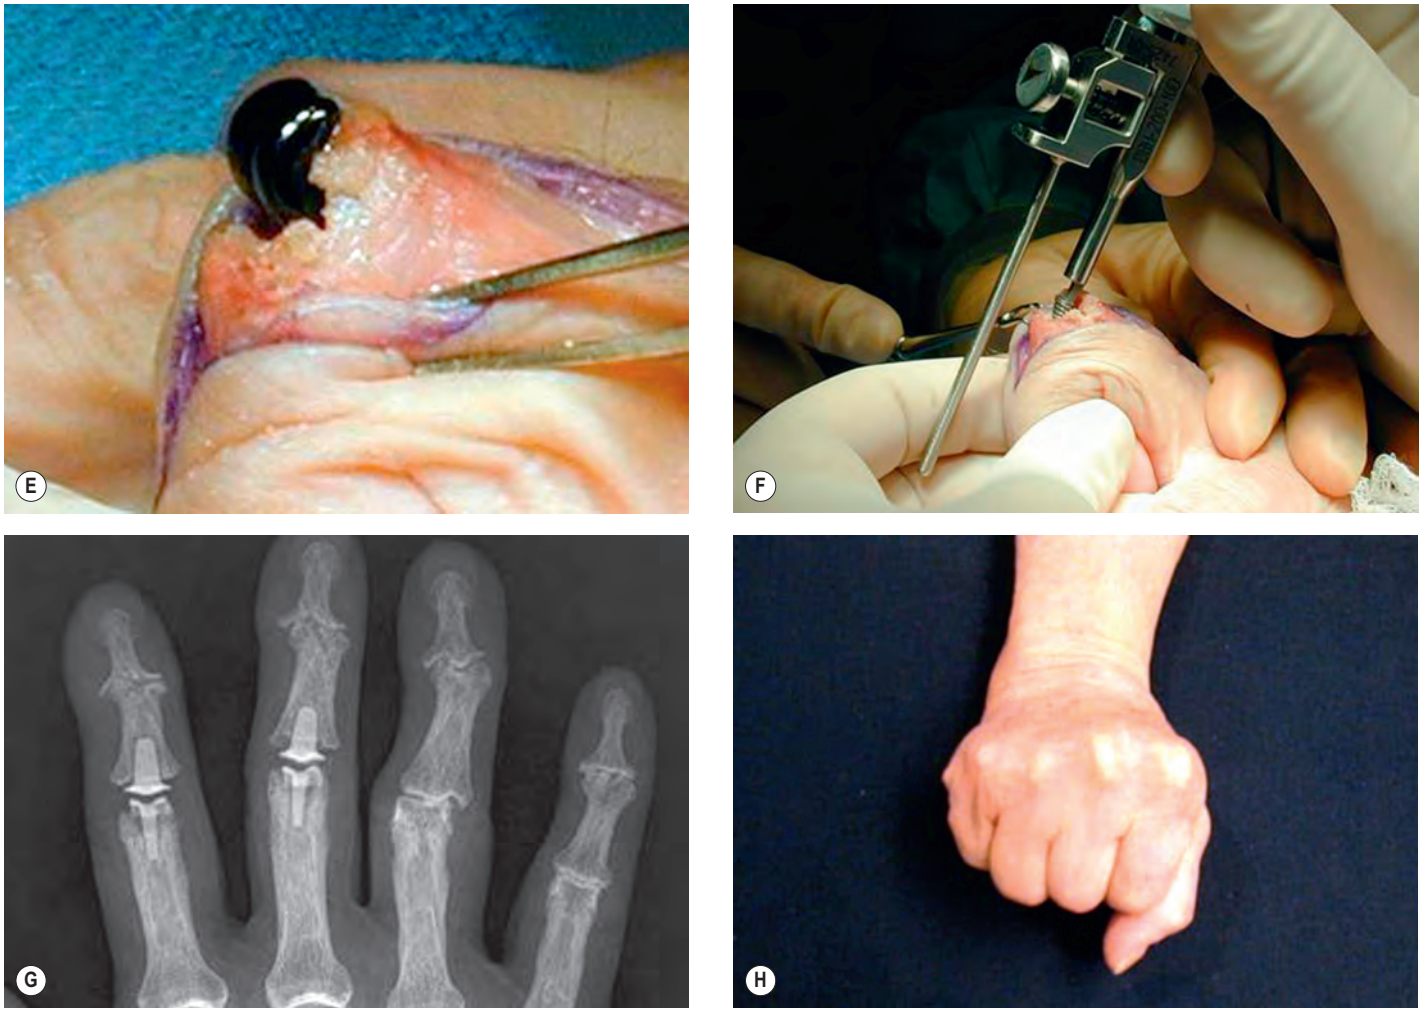

Fig. 20.9, cont'd (E) The proximal component is then trialed to assess the fit and position. **(F)** A similar procedure is then performed on the middle phalanx. **(G)** PA radiographs showing results at 1 year and functional result. The ring finger PIP was not treated because it was not producing pain and still had reasonable motion **(H)**.

Hyperflexion of the joint then exposes the middle phalanx joint surface. Preparation of the middle phalanx proceeds similarly to the proximal phalanx with the goal of inserting the largest implant possible. Due to the increased amount of cortical bone in the middle phalanx a side-cutting burr is used to facilitate implant placement. Ideally the distal implant should be the same size as the proximal implant, but implants can be mismatched one size smaller or larger if necessary. The distal trial implant is then inserted and a good press-fit is checked. Apposition of both the dorsal and volar collar of the prosthesis against the osteotomy is required for a good outcome.

Prior to final implant insertion, holes are drilled with a fine K-wire into the dorsal bony ridge on the middle phalanx and non-absorbable sutures are placed to attach the central slip back to the bone. The distal implant is inserted and impacted, followed by the proximal implant, and the central slip is reconstructed using the previously placed sutures. If the collateral ligaments have been compromised during the implant placement, collateral ligament-stabilizing sutures should be placed to prevent ulnar or radial laxity or hyperextension. The remainder of the tenotomy is closed longitudinally and the skin is closed with non-absorbable sutures. A padded dorsal, blocking splint is applied in a neutral position.

Postoperative therapy for PIP arthroplasty

Patients must adhere to strict hand therapy follow-up for approximately 10 weeks following surgery and this should be discussed preoperatively, as poor therapy compliance will lead to poor outcome (Fig. 20.10).[77] Hyperextension of the PIP joint must be avoided at all costs, and we therefore do not pursue complete joint extension, preferring to accept a 5–10° flexion deformity, as hyperextension will lead to joint dislocation.

During the first 2 weeks postoperatively, the patient is splinted or casted in full extension and minimal motion is allowed at the PIP joint. Strict elevation is encouraged to manage swelling. The plaster splint is removed after 10–14 days and sutures are removed and the patient is allowed to start a short arc motion protocol allowing for 30° of flexion at the PIP joints. Flexion is gradually increased each week to

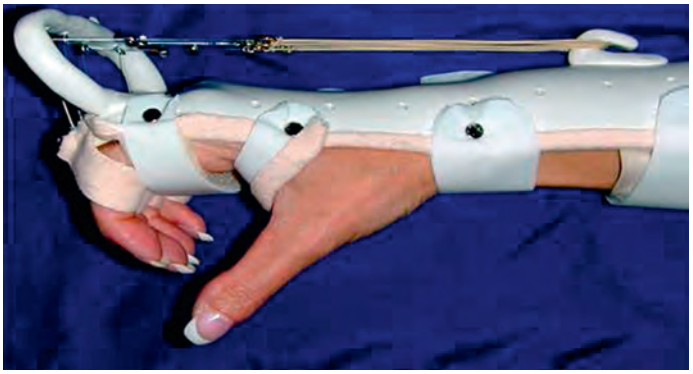

Fig. 20.10 The typical splints used when rehabilitating the proximal interphalangeal (PIP) joints following surface-replacement arthroplasty. The PIP joints are allowed protected flexion with passive extension for the first several weeks following surgery.

achieve a goal of 70–90° of flexion by 6 weeks. Resting splints are discontinued after 6 weeks if there is no extension lag and active flexion is encouraged with no limits. Isolated pinching, deviation, and rotation should be avoided during the rehabilitation phase. Buddy tapping may be used to increase motion of stiff joints.

Outcomes and complications of PIP arthroplasty

Successful implant arthroplasty of the PIP joint affords obvious benefits over arthrodesis; however, despite multiple advancements in implant design, uniformly predictable results have been difficult to achieve.[78] The major complications from PIP arthroplasty continue to be implant failure, instability, and loss of motion. Pellegrini and Burton compared arthrodesis and silicone and metal arthroplasty in 43 patients, and noted better pinch strength in the arthrodesis group, especially in the index finger. Few revisions were necessary in the silicone arthroplasty group; however, seven patients underwent revision of the metal prosthesis in order to improve lateral stability. All of these failed and required revision, and the authors concluded that arthrodesis remains the treatment of choice for the index finger, and silicone arthroplasty for the ulnar digits.[79]

Silicone implants have been used for PIP replacement for over 40 years with several large series reported in the literature. Pain relief tends to be good and the degree of functional improvement and patient satisfaction is high; however, very few series report improvement in range of motion. The reported incidence of implant fracture with silicone arthroplasty is variable, ranging from 5–44%, and rotational malalignment and lateral deviation may occur with longer follow-up.[80–82] The first large series of silicone interposition arthroplasty was reported by Swanson in 1972.[83] He reviewed 148 implants and there were no major complications. The series was later expanded to report 424 PIP joint arthroplasties. In this series, complete pain relief was achieved in 98% of patients, with an average increase in the arc of PIP motion of 10°.[84] Complications included bone resorption in 1.2% of cases and implant fracture in 5%. More recently, Takigawa *et al*. reviewed 70 implants with an average follow-up of 6.5 years and reported pain relief in 70%, improvement in extension from 32° to 18°, but no change in total active motion of the PIP joint.[85] Complications included fractures in 15% of the implants, and nine joints required revision. Patients rated their outcome as good in 25 joints, fair in 27, and poor in 18.

Lin *et al*. reviewed their experience of 69 PIP silicone arthroplasties done through a volar approach.[81] There was an improvement in the extension deficit from 17° to 8° but no improvement in overall arc of motion. Complete resolution of preoperative pain was noted in 67 of 69 joints and complications were observed in 12 joints, including five implant fractures and three cases of implant malrotation. More recent studies by Namdari and Weiss reported 4-year outcomes of 16 joint replacements using the pre-flexed NeuFlex silicone implant.[86] After an average 4-year follow-up, the mean range of motion was 61°, with 0° of extension lag. Pain relief was excellent or good in 84% and overall patient satisfaction was rated at 90%. Pettersson *et al*. compared this new implant with a traditional silicone implant design, and found better patient satisfaction but otherwise similar results.[87] Silicone interposition PIP arthroplasty remains popular and is often used as a benchmark comparison for newer surface-replacement implants such as metal or PyroCarbon systems.

The outcomes of metal surface-replacement arthroplasty was reported by Linscheid *et al*., where they described the outcomes of 66 cemented CoCr–UHMWPE surface-replacement prostheses with an average 4.5-year follow-up.[71] In this study, the average arc of motion improved from 35 to 47°, and total pain relief was achieved in 85%. There were a significant number of complications, including five swan-neck deformities; five unstable joints; coronal deviation in four joints, and 12 joints required re-operation.

Jennings and Livingstone reviewed 43 metal surface-replacement PIP arthroplasties with an average follow-up of 37 months, and found no change in arc of motion and a 25% revision rate.[88] Revision arthroplasties were generally performed for loosening of the components. They found a significantly higher loosening rate for uncemented components (39%) when compared with cemented components (4%). Johnstone *et al*. reported similar findings in their study.[76] Johnstone and colleagues noted a higher incidence of subsidence and component loosening in newer generation implants which were not cemented.[76] Luther *et al*. recently reported an average 27-month follow-up on 24 SR-PIP arthroplasty.[89] They found that 14 joints required re-operation (58%), including four that required removal. Despite this, 70% were satisfied with their final functional results.[89]

The results of pyrolytic carbon arthroplasty for proximal interphalangeal joint replacement have been the subject of several recent studies.[90–94] Bravo *et al*. published the largest and most comprehensive study to date.[91] A total of 50 PIP PyroCarbon joint replacements were performed in 35 patients. The minimum follow-up was 27 months. The average age at the time of surgery was 53 years. Joints replaced included the index,[15] middle,[18] ring,[10] and small.[7] The mean preoperative range of motion was 40°, mean pinch and grip measurements were 3 and 19 kg, respectively, and the mean preoperative pain score was 6 by visual analog scale (0–10). Postoperatively, mean range of motion improved to 47°, mean pinch and grip measurements were 4 and 24 kg, respectively. Despite these modest improvements, the mean postoperative pain score was 1 and overall patient satisfaction was high

(80%). Fourteen joints required additional procedures and the revision arthroplasty rate was 8%. There were no cases of implant infection. Notably, radiographic evidence of subsidence was noted in 20 joints although there was no apparent loosening.

Tuttle *et al*. also reported a retrospective series of 18 joint replacements in eight patients.[93] The average active range of motion was unchanged, however there were no cases of lateral instability. Complete resolution of preoperative pain was apparent in only eight cases. Complications included two dislocations evident at the first office visit; five contractures (with a motion arc of <35°), and eight squeaky joints. Wijk *et al*. reported 2-year follow-up on 53 PIP PyroCarbon arthroplasty procedures.[94] Range of motion and grip strength were unchanged postoperatively; however, pain relief and occupational performance were improved and patient satisfaction was high. Revision surgery was required in seven patients, including two who required subsequent arthrodesis.

Chung *et al*. evaluated 14 patients (21 joints) prospectively. The mean arc of motion at 12 months was 38°, grip and pinch strength both improved postoperatively. Patient-rated outcomes were studied by questionnaire, showing a significant improvement in pain, satisfaction, and aesthetic outcome.[58]

Herren *et al*. performed 17 PyroCarbon PIP joint arthroplasty procedures for osteoarthritis, which were followed prospectively for a mean of 20.5 months.[95] All patients noted significant pain relief with a reduction in mean preoperative pain score of 7.6 on a 10-point visual analog scale, to 1.3 at final follow-up. One patient required a revision procedure because of implant migration. Nunley *et al*. performed five PyroCarbon PIP arthroplasties on younger patients with post-traumatic arthritis.[92] These were followed prospectively for 1 year and were found to have no statistically significant improvement in pain or motion arc, however grip strength increased significantly postoperatively.

Watts *et al*. reviewed outcomes and complications of 97 joints after pyrocarbon PIP arthroplasty with a minimum 2-year follow-up.[96] Thirteen percent of digits required a revision at an average of 15 months postoperative. There were no significant differences in preoperative and postoperative range of motion. Overall joint survivorship was 85%.

Branam *et al*. have published a study comparing the outcomes of pyrolytic carbon implants with silicone implants for PIP arthroplasty.[90] This retrospective study compared outcomes of 19 PyroCarbon implants with 23 silicone implants. Although differences in final motion arc and pain relief were statistically insignificant, coronal plane deformity was more prevalent, and more pronounced in patients who had silicone arthroplasty. Overall it is apparent that both joints provide benefits with regard to pain relief and preservation of some motion. The superiority of one type of implant over another has yet to be determined.

More recently the idea of hemiarthroplasty for management of PIP joint arthritis has become a reality. Pettersson *et al*. reviewed their experience with 42 fingers in 38 patients undergoing PIP joint hemiarthroplasty.[97] While there was significant improvement in the Disabilities of the Arm, Shoulder and Hand (DASH) and visual analog pain scales, there was no significant change in grip, pinch, or range of motion. Only four joints required revision for failure. Average follow-up at 4.6 years was overall promising.

OA of the metacarpophalangeal (MCP) joint

Anatomy and biomechanics

The MCP joint is a multiaxial condyloid joint that allows for flexion, extension, abduction, adduction, and a limited degree of circumduction. Circumduction or rotation is not a motion under active control, but is allowed for passively by the intrinsic joint mechanics. The joint contributes to 77% of the total arc of finger flexion.[98] The metacarpal head has been described as having a unique "cam" shape. However, this description is not true to its mechanical reality. A cam is mechanical link that translates rotational motion into linear motion or vice versa, typically with a rotating *eccentric* wheel. However, the head of the metacarpal is *round* and, therefore, the analogy is not valid. The circular metacarpal head is offset volar to the axis of the metacarpal shaft, which does result in differential tension of the collateral ligaments in flexion and extension. The unique three-dimensional shape of the head, being wider on its volar aspect, adds to the collateral ligament tension in joint flexion and limited lateral motion in this position. On the other hand, when the MCP joint is extended the collateral ligaments are lax and there is maximal abduction and rotation of the joint in this position.

The MCP joint capsule is composed of areolar tissue dorsally that is loosely reinforced by the extensor tendon and the sagittal band.[99,100] Laterally, the collateral ligaments support the joint, while the volar plate provides volar support. The intrinsic muscles provide only modest, secondary capsular support. The ulnar and radial proper collateral ligaments are fan-shaped, thick, and wide, arising from the dorsal aspect of the metacarpal head and inserting into the volar aspect of the proximal phalanx. The accessory collateral ligaments are located volar to the origin of the proper collateral ligaments on the metacarpal head and interdigitate with the proper collateral ligaments distally. The collateral ligaments play a major role in stabilizing the MCP joint in all directions of joint displacement. The accessory collateral ligaments contribute primarily to abduction–adduction and rotational stability, while the volar plate prevents dorsal dislocation of the joint when fully extended. The dorsal capsule provides a very modest contribution to stability when the joint is in distraction and at the extremes of supination and pronation.[99,100]

OA affects the MCP joint less commonly than other hand joints and is usually secondary to injury or trauma, e.g., intra-articular fracture, septic arthritis, chronic repetitive trauma in setting of heavy labor occupations, and occasionally in metabolic disorders such as hematochromatosis.[101–103] MCP OA usually affects the index and middle fingers.[101,102] Conservative treatment with splinting, hand therapy, non-steroidal anti-inflammatory drugs, and steroid injections is the first-line treatment of MCP OA. Surgery is indicated for stiffness and/or pain that are refractory to non-operative treatments.

Resection and resurfacing arthroplasty

Resurfacing arthroplasty involves the resection of diseased metacarpal cartilage and bone, followed by the placement of

soft tissue into the joint space to prevent direct bone contact. This procedure was used historically to treat MCP OA but now is reserved as a salvage procedure for cases of failed implant arthroplasty. Tupper[104] described the use of the volar plate for interposition arthroplasty. The volar plate is detached proximally from the metacarpal head before the diseased cartilage and bone of the metacarpal head is resected. This distally based volar plate is then attached to the dorsal edge of the osteotomy by means of sutures preplaced through drill holes in the metacarpal. Before the joint capsule is closed, the collateral ligaments are reattached using horizontal mattress sutures preplaced through drill holes on the sides of the distal metacarpal.[105,106] Other resection/interposition arthroplasty techniques using tendon and interosseous muscles have been described by Vainio[107] and Riordan and Fowler,[108] although not specifically for OA.

Costal perichondrium may also be used for joint resurfacing. After harvesting the perichondrium and cutting it to the size and shape of the joint surface, the perichondrial graft is secured by means of a horizontal mattress suture. There are limited and variable reports on the outcomes of using rib perichondrium for resurfacing arthroplasty.[67,109] A study by Seradge[67] noted poor outcomes in patients over 40 years of age and uniform failure in cases of reconstruction after septic arthritis. He concluded that such patients constitute a contraindication for the procedure. If perichondrium is to be used it should be oriented with the deep surface facing the joint as this is the chondrogenic surface. Similarly if the retinaculum or volar plate are used for resurfacing, the synovial (deep) surface should be oriented facing the joint.[109]

MCP Implant arthroplasty

MCP implant arthroplasty is most commonly used in patients with rheumatoid arthritis. These patients tend to have a lower demand on the hands and therefore make implant arthroplasty more appealing (Fig. 20.11). In distinction to patients with rheumatoid arthritis, patients with OA of the MCP joint tend to have preservation of the collateral ligaments and fewer issues with soft-tissue imbalance and thus can be excellent candidates for implant arthroplasty of the MCP joint. Contraindications for MCP arthroplasty are similar to PIP arthroplasty. The index finger MCP joint can be considered for arthroplasty, even in a manual laborer. MCP joint prostheses can be grouped into one of four basic groups: hinged designs, flexible (silicone) prostheses, surface-replacement prostheses, and PyroCarbon implants.

Hinged prostheses

Metal-hinged prostheses are rarely used today. The 1953, Brannon and Klein prosthesis was the first prosthesis to be used for MCP arthroplasty.[70] This simple, uniaxial metal prosthesis resulted in bone resorption with subsequent finger shortening and loss of range of motion. In the 1970s and 1980s, the hinge implants evolved into multiaxial designs made of metal, polymers, or ceramics. The two-component ball-and-socket Griffith-Nicolle prosthesis[110] and ceramic prostheses[111,112] were strong enough to prevent fracture, but postoperative range of motion was too limited for adequate joint function.[110]

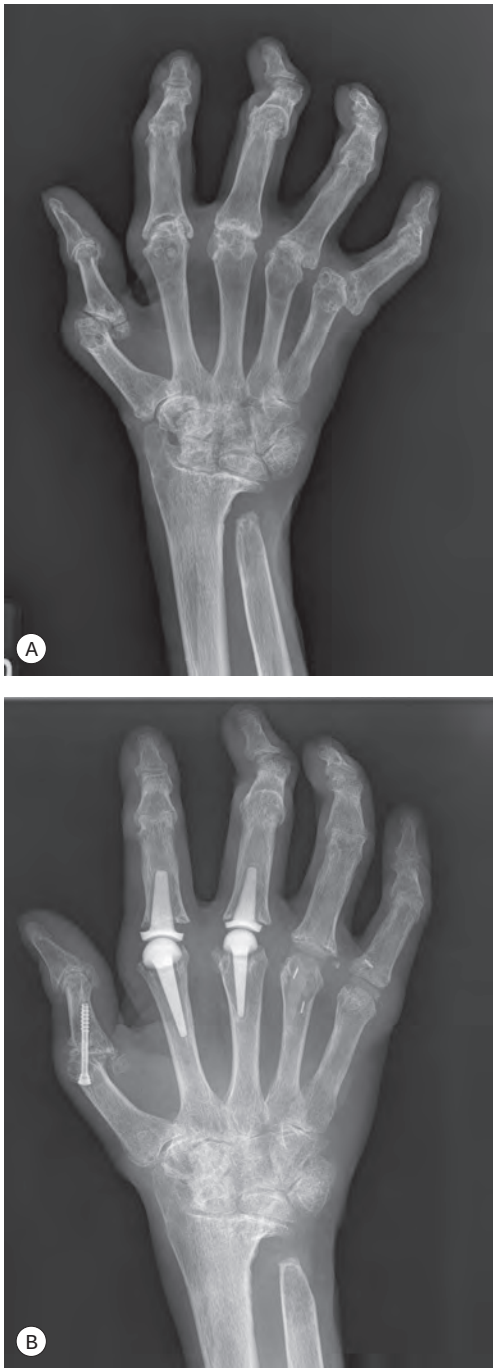

Fig. 20.11 **(A)** Anteroposterior (AP) radiograph of a 62-year-old woman with longstanding history of rheumatoid arthritis. She complains of metacarpal phalangeal (MP) joint pain at all fingers and the thumb. She has previously undergone a Darrach procedure to control distal radioulnar joint arthritis. Radiographs show evidence of advanced arthritis at the MP joint of the thumb, index, long, ring, and small fingers. In addition, there is evidence of ulnar deviation of the long, ring, and small fingers. While there is radiocarpal arthritis, the patient has no pain at the wrist and the wrist shows no evidence of radiographic instability or radial deviation on the AP radiograph. **(B)** AP radiograph 6 months after surgery to address MP arthritis. Patient has undergone a thumb MP joint fusion using a compression screw, PyroCarbon joint replacement at the long and index finger MP joints, and silicone joint arthroplasty at the ring and small MP joints. Silicone arthroplasty was chosen for the ring and small finger because of poor soft tissue at the collateral ligaments. The silicone implant, unlike the PyroCarbon implant, does not rely on the collateral ligaments for radial and ulnar stability due to its constrained design.

Silicone constrained prostheses

The Swanson prosthesis was the first silicone MCP joint prosthesis and has been in use since the 1960s.[113] This prosthesis has been widely used and studied, although primarily for rheumatoid arthritis (RA). The silicone elastomer is cross-linked, which creates a rubber-like form to the implant. The implant acts as a dynamic spacer and not a true joint. The prosthesis is held in position by a process of fibrous encapsulation, instead of osteointegration.[113] The prosthesis does not flex at the central hinge section until the joint has been flexed beyond 45°. Instead, in early flexion, the implant bends at the interface between the stem and the hinge.[114] This results in a high incidence of stem fracture. Beckenbaugh reported a fracture rate of 26% at 2.5 years when using the original Swanson MCP prosthesis. After this study, the silicone elastomer used in the prosthesis was modified to increase its tear propagation strength and its fatigue-crack growth resistance, and a newer, "high performance implant" was released.[115] Kirschenbaum *et al*.[116] reported a 10% fracture rate within 8.5 years of insertion of the modified Swanson implant. Fracture rates of around 5–7% have been reported at 2–5-year follow-up.[117,118] Interestingly, many of these fractures do not require treatment as they go unnoticed by the patients.[116] Other complications with the implant have included implant deformation and silicone synovitis.[116,119,120]

The clinical experience with the Swanson implant in patients with RA constitutes the main body of the literature on this implant. However, Rettig *et al*.[121] reported their experience with silicone MCP arthroplasty in the setting of OA. While the experience in RA can shed some light on the management of patients with OA, the outcome of silicone arthroplasty in this population is likely to be different than patients with OA. They reported 100% patient-reported overall improvement with a mean MCP flexion of 59°. This small study consisted of 12 patients and 14 MCP joints. In contrast to the literature on Swanson implant failures in the setting of MCP RA, this study, albeit small, demonstrated no Swanson implant fractures in patients with OA.

The limitations of the Swanson implant in patients with RA have motivated the development of new silicone implant designs like MCP Soft Skeletal Implant (Small Bone Innovations, Morisville, PA) and the NeuFlex implant (DePuy, Warsaw, IN). Studies are promising for the NeuFlex implant, an anatomically neutral silicone implant with a block-hinge design and a preformed 30° resting angle that approximates the relaxed MCP position. The logic for this design is that with the finger in repose, there is no stress on the implant, contrary to the Swanson design. *In vitro* studies also suggest that the NeuFlex implant has greater longevity than the Swanson implant before fracture.[122] Weiss *et al*.[123] compared MCP joint mechanism after NeuFlex, Swanson and Sutter (previously made by Avanta) arthroplasty and found that the mechanics of the NeuFlex implant most closely matched that of an intact MCP joint. Only one study[86] specifically examines the *in vivo* use of NeuFlex implants in OA of the MCP joint. At 4-year follow-up, NeuFlex implants were associated with a mean flexion arc of 65°, a mean extension lag of 3°, no implant fractures, and high patient satisfaction.[86] Despite the limitations of the Swanson MCP prosthesis, it remains the current "gold standard" to which other implants are compared. Not only is it effective in relieving pain and improving motion arc, but it is also relatively cheap and easy to place and remove (Fig. 20.12).[124–126]

Fig. 20.12 Example of silicone metacarpophalangeal arthroplasties of the index and long finger in a 63-year-old woman who was suffering from post-traumatic arthritis.

Surface-replacement prostheses

Silicone implants are inadequate in patients who place a higher demand on the MCP joint due to employment or lifestyle. Surface-replacement prostheses are more appropriate in such patients unless the soft tissue around the MCP joint is inadequate to offer implant stability.[127–130] Surface-replacement prosthetics attempt to recreate normal joint anatomy. They vary in their design: a single-component silicone implant with a Dacron-coated stem[127]; a non-joined, two-component Pyrolite carbon implant[128]; a four-component polyethylene-titanium implant[129]; or a three-component titanium plate-silastic hinge implant.[130] Studies on surface-replacement prostheses are small, consisting mainly of RA patients, with short postoperative follow-up. With the exception of a 20% fracture rate with the Hagert prosthesis, the surface-replacement prostheses are associated with a high patient satisfaction, resolution of pain, improved cosmetic appearance, average range of motion of 47–60°, and a low fracture rate.[127–130] The main problem with these implants is instability and dislocation.[128]

Kung *et al*. developed a stable surface-replacement arthroplasty implant based on cadaveric evaluation of normal MCP joint articular geometry.[131] The implant is a non-constrained, two-component implant with a hemispherical cobalt–chrome alloy metacarpal component with and an ultra-high molecular weight polyethylene phalangeal component. The head has lateral volar contours that increase lateral stability during

flexion. Also, its arc of rotation is greater than that of an anatomical joint to decrease the risk of palmar subluxation. The stem of each component may be "press-fit" or secured into the intermedullary canal with bone cement. When mechanically tested at different angles, axial loads, and directions of motion, this semiconstrained MCP joint implant demonstrates more intrinsic stability than cadaveric MCP joints.[131]

PyroCarbon arthroplasty

Pyrolytic carbon, formed by the pyrolysis of a hydrocarbon gas, has an elastic modulus similar to cortical bone.[132] This makes the material ideal for implant–bone stress transfer, potentially reducing implant wear and subsidence.[132] The implant is stabilized by appositional bone growth and does not require cement fixation.[133] PyroCarbon implants require minimal bone resection and preserve the collateral ligaments allowing for greater distribution of compressive forces. However, such nonconstraint prostheses are more likely to sublux or dislocate, especially in the setting of suboptimal soft-tissue support. It is for this reason that these implants are less stable in patients with RA. Cook *et al*. reported a 70% 16-year implant survival for the early PyroCarbon implant design. The patients in that study, the majority of whom had RA, had good outcomes.[134] A short-term study by Nunez and Citron[135] specifically focuses on the use of the implant in patients with OA; after a mean follow-up of 2.2 years, 10° of motion was gained, pain significantly improved, and there were no cases of implant failure. In 2007, a study by Parker and colleagues reported similar range of motion as previous reports.[134,136] A systemic review of the literature, however, suggests that PyroCarbon prostheses may provide no significant advantage over the Swanson implant with regard to postoperative motion and that complication rates of both implant designs may be similar.[58] Overall, PyroCarbon arthroplasty has been shown to decrease pain, improve extension lag, and improve grip and pinch strength.[134,136]

Technique for MCP joint arthroplasty with PyroCarbon implant

Prior to surgery AP and lateral radiographs are used to template the size of the implants needed for the surgical procedure, keeping in mind that most routine radiographs are magnified by 3%. The MCP joint is exposed through a longitudinal incision; alternatively, if several joints are to be replaced, a transverse incision can be made, as in the case of RA. The extensor mechanism is split centrally; alternatively, it can be mobilized from the radial or ulnar aspect of the sagittal bands (Fig. 20.13). If the extensor mechanism is divided from the sagittal bands for joint exposure, these structures will need to be reconstructed and the extensor mechanism must be centralized at the completion of the case.

Once the joint is exposed, a starter awl is used to identify the intramedullary canal of the metacarpal. An alignment guide is placed within the intramedullary canal and the cutting guide is attached to the alignment guide. Using the cutting guide, a 27.5° back cut is created into the metacarpal head. The guide is then removed and the remaining osteotomy is completed by hand. The cutting plane of the guide is positioned 1.0–2.0 mm distal to the dorsal attachments of the collateral ligaments. Upon completing the metacarpal osteotomy, the proximal phalangeal base is prepared in a similar manner; however, the cutting plane is positioned 0.5–1.0 mm distal to the dorsal edge of the proximal phalanx and is tilted 5° distally from vertical. It is strongly recommended that a conservative osteotomy (limited to the joint's articular surfaces) be performed initially to avoid damage to the collateral ligaments. Additional metacarpal and proximal phalanx can always be removed later if the joint space is too small to accommodate the implants.

Following completion of the osteotomies, the proximal phalanx is broached to accommodate the largest implant. The metacarpal is then broached to match the proximal phalanx. Trial components are then inserted and checked using fluoroscopy. Motion should allow for approximately 10–15° of hyperextension and full flexion. Impaction grafting with autograft or allograft can be used if there is any concern about implant seating against the intramedullary bone. When satisfied with the preliminary appearance of the trial implants and the MCP joint motion, the trials are removed, and permanent implants are press-fit into the intramedullary canals. Unlike the PIP PyroCarbon joints, the MCP implants should not be mismatched for size, as this may produce edge wear on the implant. Care must be taken to assure the correct axial rotation of the component by verifying that the dorsal surface of the component is parallel to the dorsal surface of the proximal phalanx. To prevent volar subluxation or dislocation of the implant, a capsular repair is performed and the extensor tendon is centralized.

Postoperatively, the hand is placed in a volar splint with the wrist at 10–15° of dorsiflexion and slight ulnar deviation; the MCP joints are placed in full extension, and the PIPs may be left in slight flexion (5–10°). Short arc (30°) MCP joint flexion is started on day 5–10. Flexion is increased weekly by 20° until full flexion is obtained. Nighttime and resting splints are worn for 6 weeks keeping the joint in full extension when not exercising to minimize and resultant extension lag (Fig. 20.14).

MCP arthrodesis

Current implant arthroplasty techniques have made MCP arthrodesis a final resort in the treatment of MCP OA. MCP arthrodesis can be very debilitating, particularly if the other joints of the fingers have limited motion due to OA. Arthrodesis can be considered whenever arthroplasty is not possible due to inadequate soft-tissue support or significant damage to the metacarpal or proximal phalanx bone stock. In general, the MCP joints should be fused in increasing flexion starting with 25° of flexion for the index finger and adding an additional 5° of flexion for each finger as one advances in an ulnar direction (Fig. 20.15). In preparation for arthrodesis, good cancellous-to-cancellous bone contact is essential and this may be achieved in a "ball-in-socket" or a flat surface configuration. There are many techniques for arthrodesis of the MCP joints. Intramedullary olecranon bone[137] and prosthetic pegs[138] have been described. Some 97–99% fusion rates have been reported with crossed Kirschner pin stabilization.[139,140] In contrast, intraosseous wiring is associated with a 9% nonunion rate[141] and an 8% nonunion was reported with AO screw arthrodesis.[142] Arthrodesis with miniplates has been reported

Fig. 20.13 Technique for use of PyroCarbon metacarpophalangeal (MCP) joint arthroplasty. **(A)** posteroanterior (PA) radiographs of a 63-year-old male with osteoarthritis of the MCP joint, as demonstrated radiographically by joint narrowing of the index and long finger MCP joints. **(B)** The surgical exposure is obtained through a longitudinal incision over the MCP joint. **(C)** The joint surfaces are prepared with a cutting guide similar to proximal interphalangeal joint arthroplasty. After the articular cartilage has been removed, the proximal phalanx is broached in preparation for implant placement. Broach position is verified with intraoperative fluoroscopy. **(D)** A similar procedure is performed on the metacarpal. **(E)** The final implants are placed and the extensor mechanism is reconstructed with braided suture with the finger held in extension. **(F, G)** Final position of the implants on PA and lateral radiographs 6 months following the surgery.

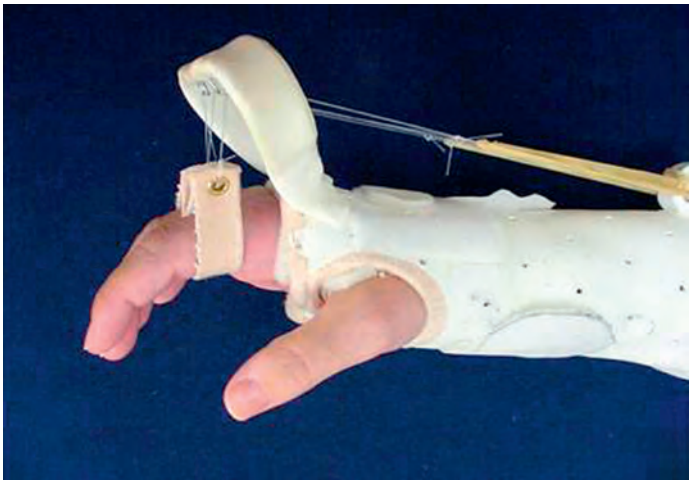

Fig. 20.14 Splint design for rehabilitation of surface-replacement arthroplasty at the metacarpophalangeal joint.

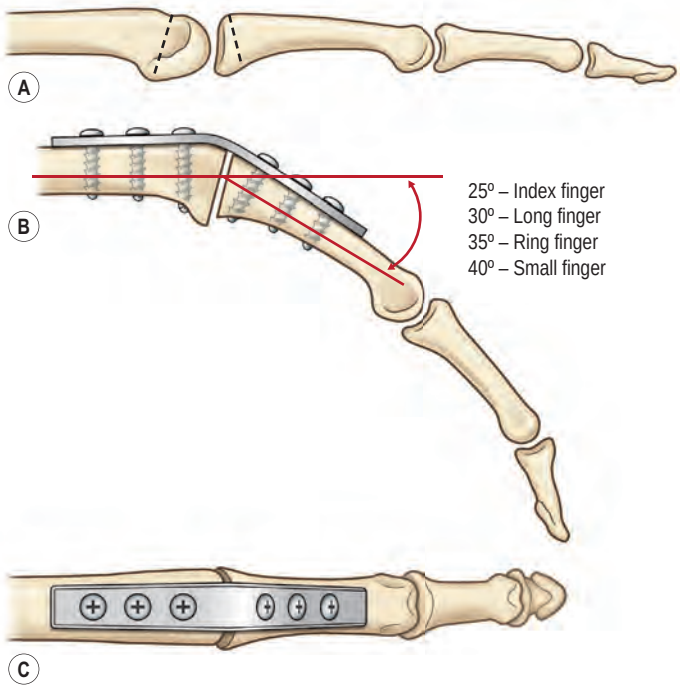

Fig. 20.15 Metacarpophalangeal (MCP) joint fusion can be achieved with various techniques. Angled cuts in the proximal phalanx base and MCP head allow one to maximize surface contact and create appropriate fusion angles. MCP fusion angles increase as one moves from the index finger to the small finger. Recommended fusion angles for the MCP joints have been 25° of flexion for the index, 30° for the long, 35° of flexion for the ring and 40° of flexion for the small.

to achieve 96% fusion rates (Fig. 20.16).[143] Alternatively, tension band arthrodesis allows for another means of fixation with acceptable fusion rates.[144,145] Tension bands can transform distracting flexor tendon forces across an arthrodesis site to compressive forces dorsally, that stabilize the arthrodesis.

Clinical tips

MCP PyroCarbon arthroplasty

- Splitting the extensor tendon longitudinally down the middle provides good visualization of the entire joint throughout the procedure without the need to reposition the tendon.
- Be sure that the hole created in the metacarpal head for placement of the cutting guide is centrally located with an appropriate trajectory down the middle of the metacarpal medullary canal.
- Protect the collateral ligaments during the proximal and distal cuts. These structures are critical to avoid joint instability.
- Use imaging to confirm the correct trajectory when broaching.
- Impaction grafting is valuable to create a tight fit between the prosthesis and bone.

Vascularized joint transfer/ costochondral replacement

Although not commonly performed, the MCP joint can be replaced with a free vascularized or pedicled transfer of another joint. When compared to implant arthroplasty, vascularized toe transfer is less effective in improving postoperative arc of motion.[58] Thus, in cases of OA of the MCP joint, vascularized joint transfers are only indicated in patients where implant arthroplasty is contraindicated or has already failed, in young manual workers where implants have a high failure rate, and/or in cases where there is inadequate bone stock for

Fig. 20.16 Oblique radiograph of the index finger demonstrating an metacarpophalangeal joint fusion obtained with a dorsally applied mini-plate.

implant arthroplasty.[146] Vascularized joint transfers are also recommended in children, as it is the only procedure that preserves the epiphyseal growth plate and allows for some longitudinal growth.[58] Better functional results in MCP joint reconstruction can be seen with the use of the second metatarsophalangeal joint.[147] After harvesting the flap, the whole second ray should be amputated for rapid recovery of normal gait. A small dorsalis pedis flap can be raised for any associated hand skin defects.

OA of the thumb

The thumb accounts for 50% of overall hand function and, as such, it is the most important digit in the hand.[31] Arthritis of the thumb can occur at the IP, MP, or trapeziometacarpal (TM) joints. Arthritis of the interphalangeal joint is managed in a manner similar to that of the finger DIP joints as described above. One needs to decide the degree of flexion in which to fuse the joint and the method of fixation (K wires, 90–90 interosseous wiring, or headless compression screw fixation). The technique of joint debridement and fixation is essentially the same as with the finger DIP joints. Similarly, mucous cyst formation can be a complication of IP joint arthritis of the thumb. This is managed similar to a manner identical to that described for DIP arthritis above.

MCP joint arthritis of the thumb

Osteoarthritis of the thumb MCP joint is relatively uncommon and frequently the result of injury, particularly chronic radial or ulnar collateral ligament injury.[148] While arthroplasty may be an appropriate option for the thumb MCP joint in rheumatoid arthritis, MCP arthrodesis has been the standard of care for OA of the thumb MCP joint for more than 50 years.[149] MCP thumb joint fusion is well tolerated due to the large degree of motion at the thumb CMC joint. As with the IP joint of the thumb, MCP joint fusion can be accomplished by a variety of techniques that have been outlined above, such as tension band wiring, crossed K-wires, or plate fixation. The primary decision is what position the joint should be fused. The position must be functional, that is, it should facilitate opposition to the fingers and not hinder the ability to oppose to the tip of the ring finger or small finger. This typically means fusing the joint in slight (15°) of flexion.[149] However, fusing the joint in slightly more flexion (20–40°) takes some work out of opposition for the CMC joint and may decrease the load across this joint and therefore be protective against the development of OA at this location or at least slow its progression.[149]

Trapeziometacarpal arthritis

Etiology and epidemiology

Osteoarthritis of the TM joint of the thumb is very common, with a reported age adjusted prevalence of 7% in men and 15% in women.[150] In a retrospective study of patients presenting with distal radius fracture, the prevalence of TM arthritis rose steadily after age 40, with 91% of patients over 80 demonstrating arthritic changes (85% of men and 94% of women over age 80). While many patients remain relatively asymptomatic, a subset of patients will develop debilitating pain, thumb weakness, and instability, severely limiting hand function. Many treatment options exist, including NSAIDS, splinting, and corticosteroid injections.[151–154] When conservative options fail, surgical treatment should be considered.

The effect of basal thumb OA on disability and mortality is modest, and as such, it is likely underdiagnosed in clinical practice.[150] Basal thumb arthritis usually involves the carpometacarpal joint, but the scaphotrapeziotrapezoid (STT) joint can also become involved. Combined CMC/STT disease is twice as likely to be symptomatic than isolated CMC arthritis.[155] Males with thumb arthritis are more likely to be symptomatic than females.[156]

Epidemiological studies suggest that basal thumb arthritis is most common in postmenopausal women. While the prevalence of radiographic thumb carpometacarpal OA among men is 7%, it is more than double that (15%) in women[150] and quadruple that in the postmenopausal population.[155] The discrepancy is not as wide when considering only symptomatic disease; 5% of men and 7% of women over the age of 70 years suffer from symptomatic basal thumb OA.[156] Among postmenopausal women with radiographic evidence of basal thumb arthritis, the majority have isolated CMC disease; 6% have isolated STT disease; and 23 % have combined CMC/STT.[155] The gender differential seen in this disease may be explained by anatomic differences in the joint. Female CMC joints have greater reciprocal articular surface curvatures and lower degree of surface congruity, resulting in smaller contact areas with greater stresses.[157] Hormonal factors may also contribute to the development of basal thumb OA in females. Spector *et al*.[158] found an increased risk for the disease in women who had a hysterectomy. Interestingly, the relationship is not demonstrable with other hand joints, putting the validity of this relationship into question.[159]

Other risk factors for thumb CMC OA have been extensively studied. Obesity is a strong determinant of thumb CMC OA in both sexes.[150,160,161] Obesity causes OA by increasing the load on weight-bearing joints; however, the first CMC is not a weight-bearing joint. Obesity may predispose to CMC osteoarthritis via non-mechanical, biological mechanisms related to elevated serum lipids.[162] Unlike weight-bearing joints,[163,164] there is no independent association between thumb CMC OA and diabetes or hypertension.[159] Furthermore, while an association between thumb CMC OA and OA in weight-bearing joints has been reported by some investigators,[165–167] others have dismissed this relationship.[150] While thumb CMC OA is not specifically associated with heavy physical activity,[159] it is clearly associated with occupations requiring repetitive thumb use (especially in the absence of enough rest breaks) and occupations that expose the thumb to greater than normal forces.

Family history is another strong predictor in the development of thumb CMC OA. In a classic twin study, Spector[168] provided clear evidence of a genetic link for the development of TM OA in females. Jonsson and colleagues[169] went on to suggest that the genetic influence increased with the severity of the disease.

Anatomy and biomechanics

The TM joint comprises the articulation between the trapezium and the base of the thumb metacarpal. The trapezium and first metacarpal base have reciprocal concavoconvex

surface, which resembles a biconcave saddle joint.[170] The trapezial surface is concave in an ulnar–radial direction and convex in a dorsopalmar direction. Reciprocally, the base of the first metacarpal is convex in an ulnar–radial direction and concave in a dorsopalmar direction. The radius of curvature of the metacarpal base is 34% greater than that of the trapezium and is thought to predispose to joint incongruity and instability.[171] The trapezial surface flattens and transforms from a saddle type to a semicylindrical type joint with advancing arthritis.[172] The scaphotrapezial (ST), trapeziotrapezoid and trapezium-index metacarpal joints are also considered as part of the basal joint of the thumb and can become involved in late stage OA.

Due to the bony incongruity and large cantilever forces, the CMC joint relies heavily on static ligamentous restraints for stability. Up to 16 ligaments have been identified[171,173]; however, the there are five major internal ligamentous stabilizers of the trapeziometacarpal (TMC) joint; these ligaments are the dorsal radial ligament, posterior oblique ligament, first intermetacarpal ligament, ulnar collateral ligament, and the anterior oblique ligament. The dorsal radial ligament prevents lateral subluxation. The posterior oblique ligament provides stability in flexion, opposition, and pronation. The first intermetacarpal ligament (IML) is taut in abduction, opposition, and supination; it holds the first metacarpal tightly against the second metacarpal. The IML is joined by the ulnar collateral ligament, which prevents lateral subluxation of the first metacarpal on the trapezium and controls for rotational stress. The fifth and most important ligament is the volar anterior oblique ligament (AOL) with its deep (dAOL) and superficial (sAOL) components. The ligament arises form the volar tubercle of the trapezium and inserts on the volar aspect of the thumb. The AOL is taut in extension, abduction, and pronation; it controls pronation stress and prevents radial translation. The dAOL serves as a pivot point for the TMC joint and guides the metacarpal into pronation while the thenar muscles work in concert to produce abduction and flexion. These fibers limit ulnar translocation of the metacarpal during palmer abduction while working with the sAOL to constrain volar subluxation of the metacarpal (Fig. 20.17).[170,171,173]

The TM joint surface allows for biaxial movements – flexion/extension of the CMC and palmar abduction/adduction.[170] Capsular laxity allows for rotation of the metacarpal on the trapezium. Combined flexion, palmar abduction and rotation allow for opposition.[170] Cooney *et al*. radiologically demonstrated that the average total motions of the TM joint (defined as motions of the first metacarpal with reference to the third metacarpal) is 53° of flexion–extension, 42° of abduction–adduction, and 17° of axial rotation (pronation–supination).[174]

Diagnosis and classification

The diagnosis of TM OA is usually made from the history and physical examination. Radiographs are used to stage the disease. When evaluating a patient with thumb base pain, the differential diagnosis is broad and includes: flexor carpi radialis (FCR) tendonitis, de Quervain's tenosynovitis, inflammatory arthritides, rheumatoid arthritis, gout, pseudogout, gamekeeper's thumb, radial sensory neuritis, and radiocarpal or STT arthritis.

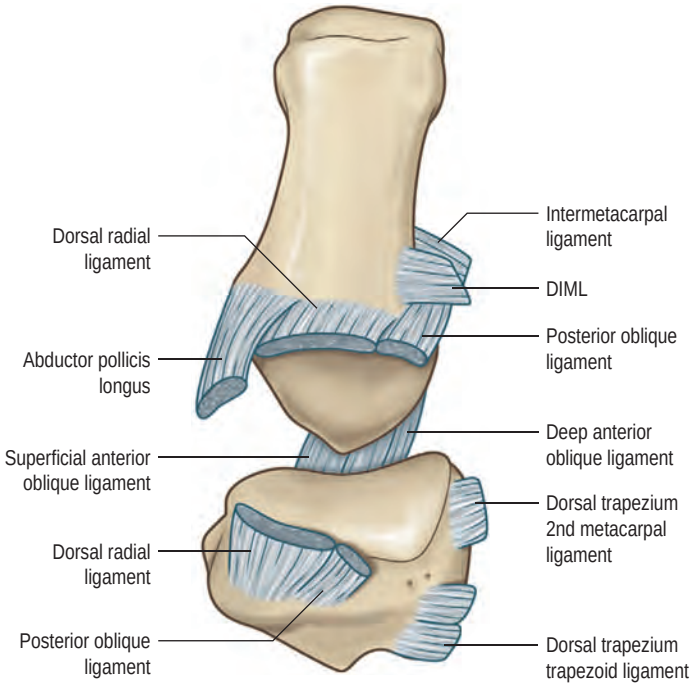

Fig. 20.17 Diagram of the trapeziometacarpal joint looking from dorsal to palmar. A portion of the dorsal radial ligament (DRL) and posterior oblique ligament (POL) have been removed to show the palmar ligaments. The most important ligaments for thumb stability are the DRL, POL, ulnar collateral ligament (not depicted), first intermetacarpal ligament (IML), and the anterior oblique ligament, deep and superficial heads (DAOL, SAOL). DIML, dorsal intermetacarpal ligament.

Basal joint arthritis typically presents in females 50–70 years old who complain of worsening thumb pain interfering with activities of daily living. Patients often complain that activities requiring opposition or pinch grip, such as opening jars or carrying heavy objects between the thumb and fingers, produce pain at the base of the thumb. Complaints of stiffness or pain at rest are usually indicators of late stage disease. On physical examination, patients may show the following signs[175,176]:

1. *Shoulder sign*: classically reveals squaring or prominence at the base of the thumb (dorsoradial subluxation secondary to ligamentous laxity and the pull of abductor pollicis longus (APL) on the base of the metacarpal).
2. *Point tenderness* at the CMC joint.
3. *Grind test*: pain on axial compression with rotation of the metacarpal on the trapezium is pathognomonic of CMC arthritis.
4. *Distraction test*: pain on thumb metacarpal base rotation and axial traction may be present in early stage disease due to joint capsule inflammation.
5. *Adduction deformity*: in later stages of the disease, the metacarpal adopts an adducted posture and the patient may develop a subsequent contracture of the first webspace.
6. *Hyperextension deformity*: as a result of the adduction deformity or severe joint stiffness, there may be a

compensatory hyperextension deformity of the thumb MCP joint.

7. *Thumb weakness*: pinch strength is almost always diminished and functional hand width is often narrowed.
8. *Carpal tunnel syndrome*: up to 43% of patients with TM OA may have evidence of median nerve compression on nerve-conduction studies.[177] The prevalence is even higher in women, worker's compensation patients, and those with diabetes mellitus. Given this high association, one should take great care to diagnose coexistent carpal tunnel syndrome in patients scheduled for basal joint surgery. If present, carpal tunnel syndrome can be treated at the same time of TM OA surgery.[177]

AP, lateral, and oblique radiographs of the TM joint can be used to confirm the diagnosis and stage the disease. TM stress views (30° posteroanterior (PA) view with the patient forcefully pushing the radial aspects of their thumb tips against each other) can help assess the degree of joint subluxation and joint space loss.[178] Stress views also demonstrate the ST joint and the index finger TM joint very well. The Robert's view (AP view with the hand hyperpronated) also provides a clear image of all four trapezial articulations.[175] Only 28% of women who have radiographic signs of isolated TM arthritis and 55% of women with pantrapezial arthritis admit to symptoms of thumb arthritis, thus radiographic changes must always be correlated with physical signs prior to developing any treatment plan.[155]

There are two frequently used classification systems for CMC arthritis. The Eaton classification (Table 20.1)[178] is most commonly used and is based on radiographic features alone. Individual symptoms may not correlate with the Eaton stage. In comparison, Burton classification (Table 20.2) is based on clinical and radiographic findings.[179,180]

The Eaton classification of TM OA follows the progressive changes that occur with progression of disease. In stage I, the joint appears normal or slightly widened, associated with effusion or ligamentous laxity. In stage II there is slight narrowing of the joint associated with cartilage loss. Joint debris such as loose bodies and osteophytes may be seen, but measure less than 2 mm in size and sclerotic changes are minimal. In stage III, the joint space is markedly narrowed or obliterated, subchondral sclerosis and cystic changes are apparent, dorsal subluxation is variably seen, and osteophytes and debris exceed 2 mm in size. The STT joint is spared (normal) in stage III. However, in stage IV, there is pantrapezial arthritis with STT joint involvement in addition to those changes seen in stage III (Fig. 20.18).[178]

Table 20.1 **Eaton classification**

Stage	Radiographic characteristics
Stage I	Normal or slightly widened trapeziometacarpal joint Trapeziometacarpal subluxation up to one-third of articular surface Normal articular contours
Stage II	Decreased trapeziometacarpal joint space Trapeziometacarpal subluxation up to one-third of articular surface Osteophytes or loose bodies <2 mm
Stage III	Decreased trapeziometacarpal joint space Trapeziometacarpal subluxation > one-third of articular surface Osteophytes or loose bodies ≥2 mm Subchondral cysts or sclerosis
Stage IV	Involvement of the scaphotrapezial joint or less commonly the trapeziotrapezoid or trapeziometacarpal joint of the index

(Data from Eaton RG, Littler JW. Ligament reconstruction for the painful thumb carpometacarpal joint. *J Bone Joint Surg Am*. 1973;55:1655–1666.)

Table 20.2 **Burton classification**

Stage	Findings
Stage I	Pain Positive grind test Ligamentous laxity Dorsoradial subluxation of CMC joint
Stage II	Instability Chronic subluxation Radiographic degenerative changes
Stage III	Involvement of the scaphotrapezial joint or less commonly the trapeziotrapezoid or trapeziometacarpal joint of the index
Stage IV	Stage II or III with degenerative changes of the MCP

CMC, Carpometacarpal; MCP, metacarpophalangeal.

Non-operative treatment

Splinting alone may be effective in early stage disease. Reconstructive procedures aimed at providing pain relief, as well as restoring thumb motion and strength, are usually necessary in the later stages. Regardless of stage at presentation, all patients should undergo a trial of conservative management prior to operative intervention. This includes activity modification, splinting, NSAIDs, and steroid injections.

Teaching patients to avoid aggravating activities of the thumb improves their pain control and overall function.[181] Patients should be advised to avoid twisting, lifting, gripping, and pinching movements. Joint protection by dividing stress among multiple hand joint and using assistive devices preserves the integrity of the joint structure and improves joint function, both in the short and the long term.[182,183] Patients may be taught home hand exercises that aim to strengthen the thenar muscles, the abductor pollicis longus, and the extensor pollicis longus (EPL). These exercises counter the flexion–adduction force of the adductor pollicis muscle, prevent adduction contracture of the first webspace, and improve grip strength and global hand function.[182,184,185] The use of a joint protection arthritis education program with educational–behavioral teaching methods has proven beneficial in adherence, pain, disease status, and functional ability in arthritis patients.[183] Such strengthening exercises, however, should only be recommended to patients with early stage OA without significant pain.

Fig. 20.18 Radiographs of Eaton stage I–IV trapeziometacarpal (TMC) osteoarthritis. **(A)** An example of stage I arthritis displaying a slightly widened TMC joint space due to ongoing synovitis. **(B)** An example of stage II arthritis with joint space narrowing and small osteophyte formation. **(C)** An example of stage III showing significant joint destruction and osteophyte formation but preservation of the scaphotrapeziotrapezoid (STT) joint. **(D)** An example of stage IV arthritis with narrowing and arthrosis at both the TMC and STT joints.

Splinting rests the joint and holds it in a position of maximum surface contact, thus increasing joint stability and diminishing mechanical stress.[186,187] This often decreases the associated acute inflammation and pain enough that an adequate level of function returns. A long opponens splint holds the thumb in palmar abduction with the MP joint in 30° of flexion and pronation and the wrist in 15° of extension. This shifts the center of pressure dorsally and away from the palmar side of the CMC joint that is susceptible to OA.[187] A short opponens splint by definition does not immobilize the wrist. A modified short splint that only immobilizes the CMC is also commercially available.[186] Although the long and short splints are equally effective, patients tend to prefer the less bulky design of the short splints.[188] Splints may be prefabricated neoprene or custom-fitted thermoplast.[189,190] While some authorities prefer the individualization and rigidity offered by the custom-fitted thermoplast splints,[190] neoprene splints offer greater pain relief and are generally preferred by patients over the more rigid splints.[189] Patients are instructed to wear the splints whenever they feel basal thumb pain, whether it is day or night.[189] After 3–4 weeks, patients may notice a decreasing need for splinting. Recently, however, a randomized European trial suggested that patients with thumb CMC OA may need to be splinted longer (several months) before one can actually see significant improvement in their overall pain and disability.[191]

Medical therapy for basal thumb OA includes NSAIDs and intra-articular steroids. Systemic and topical NSAIDs help reduce synovitis, but they do not halt or reverse disease progression. There is no difference in the effectiveness of currently available NSAIDs.[192] Intra-articular steroid injections can be used to resolve synovitis refractory to activity modification, splinting, and NSAID therapy. When followed by 3 weeks of splinting, a 40% success rate for subjective symptom

improvement has been reported.[193] While steroid injections seem to offer short-term pain relief in early basal thumb OA,[194] their long-term effectiveness is uncertain.[195] Steroid injections should not be more often than two to three times a year and should be used cautiously in very early stage disease as they can potentially accelerate arthritic degeneration. As demonstrated in a small 2004 randomized controlled trial, patients with stage IV disease are unlikely to benefit from steroid injections.[152] With increasing evidence that hyaluronic acid contributes to joint hemostasis[196] and reduces pain in patients with knee OA,[197] investigators have studies injections of hyaluronic acid into the thumb CMC joint. While studies suggest that hyaluronic acid may result in some basal thumb pain relief, there is no evidence that its effectiveness is superior to that of steroids.[198] Interestingly, a recent prospective, randomized, double-blinded trial[199] studying hyaluronic acid and steroid injections found no improvement in pain, strength, range of motion, or disability with either when compared with placebo. However, this study did not exclude patients with advanced stage disease, and follow-up was limited to 26 weeks.

The technique for CMC injection is straight-forward; however, advanced disease associated with large osteophytes and distorted anatomy may present a challenge. The landmark for thumb CMC joint injections is the dorsoradial aspect of the proximal end of the first metacarpal.[190] The thumb is opposed against the little finger so that the proximal end of the first metacarpal is palpable. Traction is applied to the thumb in order to widen the CMC joint space. The CMC joint is then injected using a 25-gauge needle. The needle is inserted at a point proximal to the prominence at the base of the first metacarpal on the palmar side of the extensor pollicis brevis and the abductor pollicis longus tendons. The needle is advanced distally until it penetrates the joint capsule.[190] Fluoroscopy can be used if the joint anatomy is distorted. The anatomical snuffbox should be avoided because it contains the radial artery and superficial radial nerve. Several corticosteroid preparations are commercially available. Betamethasone is water soluble and does not leave intra-articular precipitates behind. About 1.5 mL of a 50/50 mix of betamethasone and 1% lidocaine without epinephrine may be used.[190]

Surgical procedures for stage I disease

Surgery for TM arthritis is indicated in patients with persistent pain, instability, and decreased function refractory to conservative therapy. The type of procedure used is dictated by disease severity, depending primarily on whether the cartilage of the CMC joint is unaffected (stage I) or shows signs of degeneration (stages II–IV). Attritional changes in the beak ligament cause hypermobility and synovitis that precede any cartilaginous degeneration.[200] The palmar articular cartilage neighboring the beak ligament is subject to compressive forces in early disease. Attrition of the beak ligament results in dorsal translation of the contact area with subsequent cartilage degeneration.[201] The goal of surgery in early stage of disease is to stabilize the joint, preventing further subluxation, and to offload the palmar cartilage, preventing further degeneration.[202] Surgical procedures that are appropriate for such early stage CMC arthritis include arthroscopy, metacarpal abduction–extension osteotomy, and volar ligament reconstruction.

Thumb CMC arthroscopy

Not only is arthroscopy diagnostic in cases of basal thumb arthritis, but also it can serve as primary therapy in early disease or as adjunctive therapy in advanced stages.[203,204] Thumb CMC arthroscopy is viewed as a less invasive therapeutic intervention. Synovectomy, debridement, and thermal shrinkage capsulorrhaphy of the beak ligament may all be performed arthroscopically. Synovectomy and debridement are appropriate for early stage disease that failed conservative therapy.[203,204] Arthroscopic intervention is not recommended for more advanced disease with significant cartilage loss. Menon[205] described arthroscopic interposition arthroplasty (using tendon, fascia lata, or Gore-Tex patch) with excellent results. Badia, however, cautions against arthroscopic interposition arthroplasty for stage III disease in young, active patients (who may benefit more from arthrodesis) and in low-demand patients (who may benefit more from trapeziectomy with or without ligament reconstruction).[203,204]

Thumb CMC arthroscopy is usually performed under regional anesthesia with tourniquet control. A total of 5–8 lb of longitudinal traction is applied on the thumb using a single finger trap. Joint distension is achieved by injecting 5 mL of normal saline into the joint under direct palpation. A radial portal (1-R) and an ulnar portal (1-U) are usually needed. The radial portal is placed just radial to the APL tendon, and the ulnar one is placed ulnar to EPL tendon. The dorsal radial ligament, posterior oblique ligament, and the ulnar collateral ligament are best evaluated using the radial portal. The ulnar portal allows for better assessment of the beak ligament.

A short barrel, 1.9-mm 30° arthroscope and a full-radius shaver with suction are utilized.[203,204] A radiofrequency probe may be used to perform the synovectomy, the chondroplasty (in cases with focal cartilage wear), or the thermal capsulorrhaphy (in patients with ligamentous laxity). Performing an arthroscopic trapeziectomy in stage III disease requires burring away the articular cartilage and removing subchondral bone down to a bleeding surface. This increases joint space and allows for hematoma formation, optimizing tendon graft placement and adherence. A volar slip of APL or palmaris longus may be used as a tendon graft and is inserted into the joint space via a portal. The joint is protected in a thumb spica splint for 1–5 weeks depending on the pathology and the intervention.

Dorsal wedge extension osteotomy

The volar compartment of the CMC joint is where compressive forces localize when the thumb is in its functional position of flexion and adduction.[201] One way to unload this compartment in early disease is to perform a dorsal, closing wedge osteotomy of the thumb metacarpal that extends and abducts the metacarpal away from the trapezial joint surface. Pellegrini and his colleagues[206] were the first to evaluate the biomechanical efficacy of a 30° dorsal wedge osteotomy. Their data suggested that the procedure is successful at offsetting the subluxing forces acting on the base of the metacarpal. This procedure was found to not only shift the joint load dorsally[206] but also tighten the dorsoradial ligament and reduce overall joint laxity.[207] In a cadaveric model of extension osteotomy, Shrivastava *et al*. demonstrated that the procedure reduced laxity in all directions (40% reduction in the dorsal–volar

direction, 23% reduction in the radial–ulnar direction, 15% reduction when distracted, and 15% reduction in pronation–supination).[207] Because of the changes it creates in the articular forces, the procedure is contraindicated in cases of global joint instability and cases of non-reducible subluxation.

The technique for a dorsal wedge extension osteotomy is described by Tomaino.[208,209] After establishing regional anesthesia and Esmarch bandage exsanguination, tourniquet control is applied, and a 3 cm dorsal incision is made from the base of the thumb metacarpal distally. The dorsal sensory branch of the radial nerve and lateral antebrachial cutaneous nerve as well as the extensor pollicis longus tendon are identified and protected. The CMC joint is identified using a 25-gauge needle. A transverse arthrotomy may be performed to document normal joint surfaces if the radiographs are questionable or if there is crepitance on examination.[208,209] One centimeter distal to the joint, subperiosteal, circumferential dissection of the metacarpal is obtained. Using a microsagittal saw, a partial transverse osteotomy is performed in this location down to the volar cortex. A new saw blade is used to make a 30° osteotomy 5 mm distal to the first one. The two osteotomies are connected at the volar cortex completing a dorsally based 30° wedge of bone that is removed. The distal metacarpal is extended and compressed against the base. The reduction is secured in place with K-wires[208] or two 11×8 staples.[209] Plates or tension band technique can be used for fixation as well. The periosteum and skin is then closed, and a thumb spica splint is placed for 10 days. A thumb spica cast (with the interphalangeal joint left free) is then placed for an additional 4 weeks. At around 6 weeks postoperatively, the cast is replaced with a forearm-based thumb spica Orthoplast splint, and the patient is instructed to start gentle TM motion. Osteotomies heal at an average of 7 weeks. Unless union is delayed, grip and pinch exercises are started 8 weeks postoperatively.[208,209]

Pain relief and improved hand function following extension osteotomy are likely related to both load transfer and increased joint stability. Some 80% of patients have good–excellent long-term pain relief.[202] At 2.1-year follow-up, grip and pinch strengths increase by an average of 8.5 and 3.0 kg, respectively.[208] At 6.8-year follow-up, 82% of patients have normal grip and pinch strengths.[202] This procedure also has the added benefit of correcting any adduction contracture that may be present. Overall long-term patient satisfaction with this procedure is reported at 91–93%.[202,208]

Volar ligament reconstruction

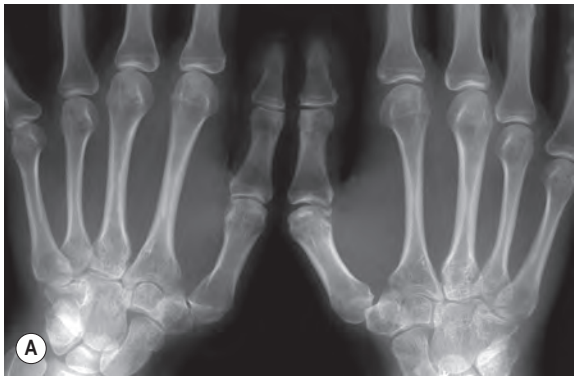
Since volar ligamentous laxity contributes to CMC joint instability and degenerative disease progression, early basal thumb OA can be addressed surgically by reconstructing the volar ligaments. Eaton and Littler described a technique for reconstructing the volar ligaments by passing the radial half of the FCR tendon through the base of the thumb metacarpal and then suturing it to the APL tendon. The procedure was initially described for the treatment of late disease[178]; however, subsequent reports have confirmed the efficacy of the procedure in early disease.[210,211] This procedure is viewed by many as the first of choice for early disease when there is only early chondromalacia.[211] The presence of STT OA precludes use of this procedure. This technique has been reported to slow the radiographic progression of the disease in up to 94% of female patients at 15-year follow-up.[211] This compares favorably with the 17% reported radiographic prevalence of stage III–IV disease in postmenopausal women in the general population.[155] While it eliminates long-term pain in only 29% of patients, patients with persistent pain tend to have only mild pain and are generally satisfied with the procedure. The technique appears to be less effective in men and patients involved in worker compensation claims.[211]

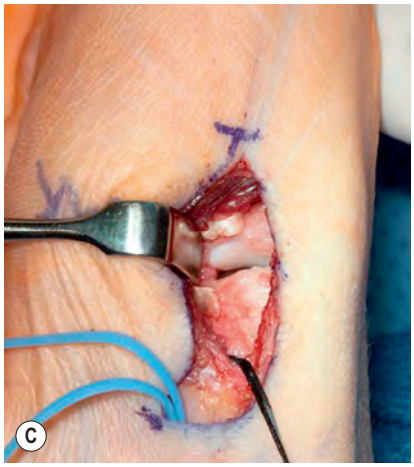
Technique for Eaton–Littler procedure

Adequate thumb CMC joint exposure for volar ligament reconstruction usually necessitates a modified Wagner incision, which is a longitudinal incision that is located parallel to the long axis of the thumb metacarpal at the interval between the glabrous palmar and non-glabrous dorsal skin (Fig. 20.19). The dorsal sensory branch of the radial nerve and branches of the lateral antebrachial cutaneous nerve crossing the operative field must be identified and protected. The radial edge of thenar muscles is elevated extraperiosteally off the metacarpal, exposing the trapezium, the metacarpal base and the CMC joint. The interval between EPL and extensor pollicis brevis is developed to expose the dorsal cortex of the metacarpal base. Using handheld awls or a cannulated drill over a K-wire, a tunnel is made in the metacarpal base in a dorsal to volar direction (perpendicular to the axis of the thumbnail, 1 cm distal to the dorsal surface of the joint aiming volarly just distal to the insertion of the beak ligament, and parallel to the articular surface). A 28-gauge stainless steel wire, or Hewson suture passer, is passed through the tunnel from volar to dorsal and is used to pass the tendon through the bone.[212]

After incising the FCR tendon sheath longitudinally, the ulnar half of the FCR tendon is split longitudinally with a heavy suture.[212] The tendon slip is harvested using multiple transverse incisions on the volar forearm from the level of the wrist to the level of the musculotendinous junction. The tendon is divided proximally and delivered through the subfascial plane into the distal incision. The split is completed distally to the level of the trapezium. The FCR tendon slip is then delivered through the metacarpal base in a volar to dorsal direction using the previously placed wire or tendon passer. After the tension is set, the tendon is secured to the periosteum of the dorsal cortex using 3-0 braided synthetic suture. The tendon is then secured beneath the APL tendon. The remaining tendon is directed volarly, looped around the FCR tendon, sutured to the FCR tendon, and finally redirected dorsally where it is sutured beneath the APL tendon. Although not absolutely necessary, the CMC joint may be further secured with K-wires. Finally, the thenar muscles are reapproximated, and the skin is closed.

Postoperatively, the thumb is immobilized in a short arm thumb spica cast for 4 weeks. After that, the thumb is protected in a thermoplast long opponens splint which is removed for hand therapy. Active and active-assisted range of motion of wrist, thumb CMC, MP, and interphalangeal joints are performed in hand therapy. Palmar abduction is started before radial abduction. During the first 2 weeks out of cast, opposition and flexion to the index and long fingers are encouraged. Strengthening is begun after 4 weeks of cast removal. This is started with minimal resistance putty and then gradually increased to unrestricted activity by 3 months postoperatively.[212]





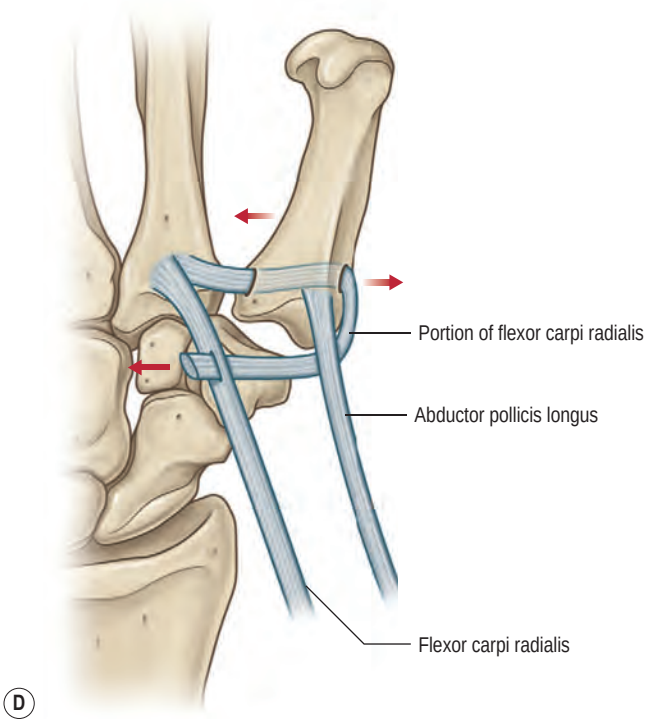


Fig. 20.19 Stress views of a 28-year-old female with right thumb pain and grade I radiographic changes **(A)**, showing evidence of joint instability of the right trapeziometacarpal (TMC) joint. **(B)** The patient elected to undergo an Eaton–Littler procedure for stabilization of the TMC joint. The procedure is performed through a modified Wagner incision, which is a longitudinal incision parallel to the long axis of the thumb, in the interval between the glabrous and non-glabrous skin. **(C)** Vessel loop is around the radial artery. The TMC joint is easily exposed through the incision. **(D)** A strip of the flexor carpi radialis is then passed through a bone tunnel parallel to the base of the thumb metacarpal. **(E)** An anteroposterior radiograph of the thumb showing restoration of TMC joint congruity.

Procedures for stage II–IV disease

In stage II–IV disease, there is loss of articular cartilage. In such cases, joint salvage will not provide adequate pain relief. Surgical procedures to manage more advance disease can be grouped into four major categories, which include: (1) trapeziectomy; (2) trapeziectomy with soft-tissue arthroplasty; (3) arthrodesis; and (4) replacement of the TM joint (prosthetic arthroplasty). The goal of surgery is to reduce pain while maintaining thumb strength and motion.

Trapeziectomy alone

Complete excision of the trapezium is the earliest described surgical procedure for CMC arthritis. It was first described by Gervis in 1947 at the Royal Society of Medicine.[213] His work was published the next year in the *Postgraduate Medical Journal*.[214] The procedure has been shown to be effective at resolving joint pain.[215–217] The improvement in thumb pain allows for improvement in hand function despite some loss in grip and pinch strengths. Historical concerns with this procedure include the possibility of proximal migration of the thumb metacarpal producing painful metacarpo-scaphoid impingement[218–221] and thumb instability.[216,222,223] This has led to the development of stabilization and suspensionplasty procedures in an attempt to return more thumb stability and prevent metacarpal subsidence.[221] Loss of trapezial space height has not been directly correlated with loss of grip or pinch strength.[218,219] In addition, prospective studies have failed to show any difference in function or metacarpal subsidence when comparing simple trapeziectomy to soft-tissue procedures[224,225] while partial trapeziectomy can be done, excising the whole bone is important in cases of STT disease.

Surgical technique for simple trapeziectomy

A dorsal approach to the thumb is usually employed.[220,226] Blunt dissection is undertaken down to the first dorsal compartment and then continued dorsoulnarly to the radial artery. The artery and radial sensory nerves are dissected off the underlying CMC joint. The joint space can be identified by palpation and opened with a longitudinal capsulotomy that is ulnar to the first dorsal compartment, starting 5 mm on the metacarpal base and extending proximally until the scaphotrapezial joint is encountered. Longitudinal traction on the thumb may help visualization in cases of severe subluxation. The trapezium is identified by visualization of the saddle joint and the metacarpal base. Confirmation may be obtained with fluoroscopy. The trapezium is removed piecemeal from within the surrounding capsule using a rongeur, a knife, an elevator, or an osteotome. Attention to the FCR tendon at the base of the wound is paramount to avoid inadvertent injury. The wound is irrigated, and all small bone fragments are removed before closing the capsule and skin.[218,224]

Postoperatively, the thumb is immobilized for 6 weeks, after which the patients are instructed to start range of motion exercises as they wean from using an elastic bandage splint over the course of 4 days. Activity is advanced as tolerated over another 10 days. Patients who, at that point, cannot touch the small finger metacarpal head with the tip of their thumb are referred to hand therapy.[226]

A variation of the simple trapeziectomy approach is trapeziectomy and distraction arthroplasty, also referred to as *hematoma arthroplasty*, as blood is thought to fill the space left by the removed trapezium, eventually forming scar.[220,226] A standard trapeziectomy is performed followed by temporary K-wire fixation of the thumb in a position of distraction, palmar abduction, and opposition for about 4 weeks. A single 1.6-mm (0.062-inch) K-wire is inserted percutaneously through the thumb and index metacarpal bases. The fixation is intended to promote dense hematoma formation and scarring in the area of the excised trapezium, hence reducing thumb subsidence. Transverse wire placement is preferred over a longitudinal as the latter may allow the thumb metacarpal to slide proximally along the wire into the trapeziectomy space.[220,226] Unfortunately, as reported by Gray and Meals in 2007,[217] such fixation does not seem to prevent thumb subsidence. However, the procedure is associated with an 82% rate of pain resolution with an average of 11% and 21% increase in pinch and grip strengths, respectively. These results are equivalent to that of the more complex tendon interposition techniques. Despite its effectiveness, unless the patient is a low-demand elderly patient who does not have metacarpal subluxation,[227] some authorities do not recommend hematoma arthroplasty as a primary treatment and suggest that it be avoided in young patients who require strong grasp and pinch strengths for work.[216,228] However, recent comparative studies and a Cochrane review recommend trapeziectomy alone for the treatment of CMC arthritis since outcomes are similar among the different techniques but complications and costs are lower with trapeziectomy alone.[224,225,229]

Trapeziectomy with ligament reconstruction and/or tendon interposition

Several procedures for tendon interposition arthroplasty are available (Video 20.1 ▶). These procedures consist of a complete or partial trapeziectomy and interposition of tendinous tissue in the trapeziectomy void. The different operations described for biological arthroplasty are distinguished by: (1) the choice of tendon used to fill the trapeziectomy void and prevent thumb subsidence, and (2) the choice of method used to stabilize the thumb following trapeziectomy. An attempt to reconstruct the intermetacarpal ligament anchoring the thumb metacarpal to the index metacarpal is known as *suspension arthroplasty*.

Froimson's fascial arthroplasty is one of the first described interposition arthroplasties that did not include any element of ligament reconstruction. After a standard trapeziectomy, half of the FCR tendon is harvested, rolled up in an "anchovy" fashion, and used to fill the trapeziectomy space. Froimson[230] reported a 90% rate of pain relief at 88-month mean follow-up, but pinch power was reduced by 30%. Radiographically, the procedure resulted in a 50% decrease in the interval between the first metacarpal base and the scaphoid, but clinically the thumb shortening was minimal.

Burton and Pelligrini[228] described a thumb ligament reconstruction performed with the radial half of the FCR tendon routed through the base of the thumb metacarpal, and the remaining length of the tendon was placed in the trapeziectomy void. This procedure has become known as the *ligament reconstruction and tendon interposition procedure*, or LRTI, and is one of the most common trapeziectomy soft-tissue reconstructive procedures performed (Fig. 20.20). At a mean 2-year follow-up, grip and pinch strengths increased 19% compared

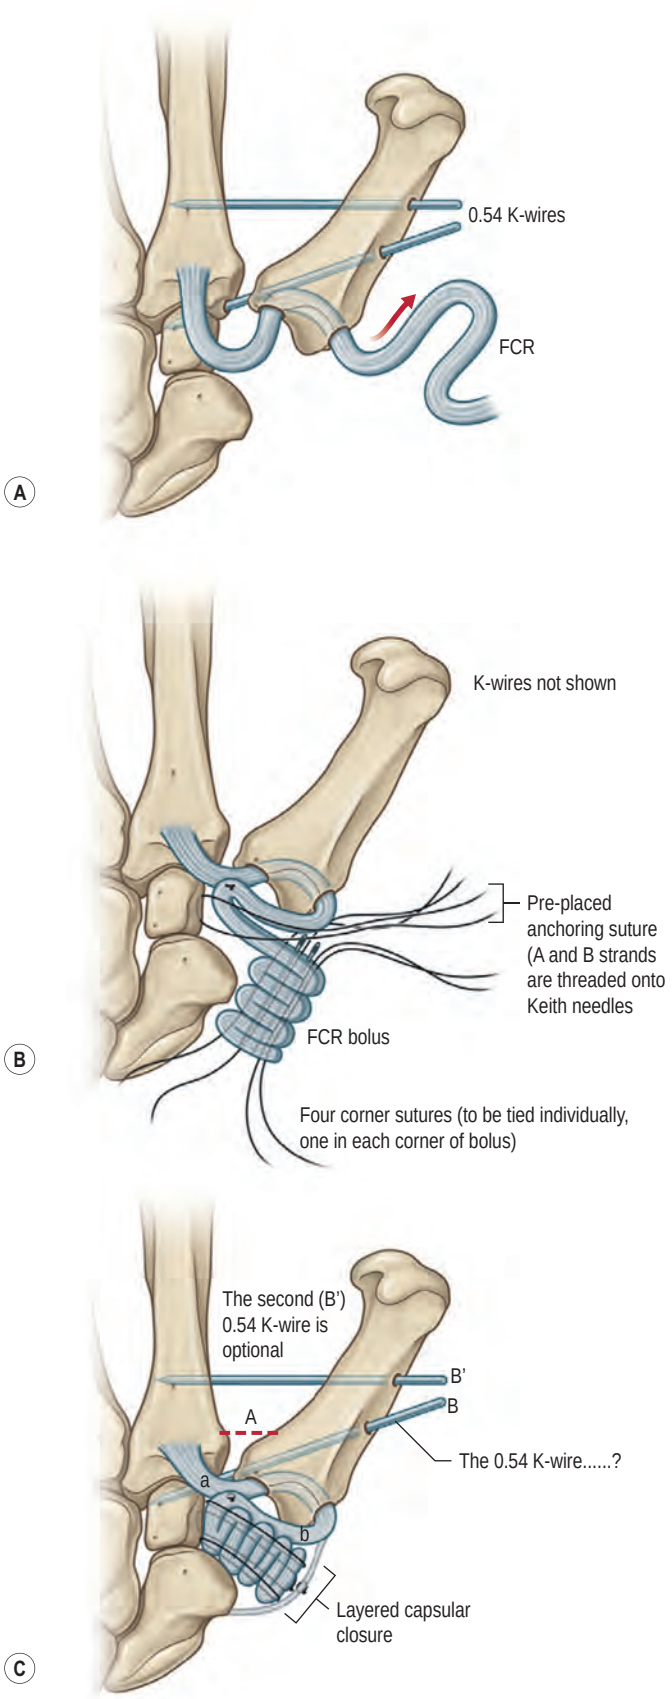

Fig. 20.20 The Burton and Pelligrini procedure begins with the removal of the trapezium, followed by the harvest of a portion of the flexor carpi radialis tendon (or whole tendon, as illustrated). **(A)** The tendon is passed through a drill hole created in the base of the metacarpal in a volar to dorsal direction. **(B)** The tendon is then sewn to itself to stabilize the metacarpal base of the thumb. **(C)** The remaining tendon is then placed into the space left by the resected trapezium to function as an interpositional spacer.

with preoperative values.[228] At 9-year follow-up, thumb function improved further (grip strength 93%, tip-pinch strength 65%, and key-pinch strength 34%), suggesting that the procedure is not only durable but also improves thumb function for several years postoperatively.[231] Loss of trapezial space averaged 11% at 2 years[228] and 13% at 9 years postoperatively,[231] despite the interposition of a portion of the FCR tendon.

Another variation on LRTI is the Brunelli procedure.[180] Described in 1989, Brunelli utilized one of the slips of the APL tendons for the ligament reconstruction. The tendon is divided proximally, leaving its insertion intact. It is then passed through a tunnel created in the base of the thumb and index metacarpals and sutured to the second and third carpometacarpal ligaments. Tendon interposition may be achieved using a palmaris longus graft. Like ligament reconstruction with FCR, this form of ligament reconstruction has also been advocated for use in early (stage I) disease without performing a trapeziectomy.[180]

Other modifications to the trapeziectomy procedure have included the use of tendon slings or *suspensionplasties*. Suspensionplasties are thought to resist the sagittal plane collapse that occurs when the weakened arthritic thumb is loaded during pinch.[221] Weilby described a suspensionplasty that avoids the use of bony tunnels by simply weaving a slip of FCR around the APL and remaining FCR in a figure-of-eight fashion (Fig. 20.21).[232] The procedure has been reported to relieve pain in 92% patients.[233] It affects thumb mobility in 12% patients, and while it improves grip and pinch strengths, recovery usually takes 3–6 months.

Exposure for the Weilby suspensionplasty is accomplished using the modified Wagner incision previously described. The radial artery and sensory nerve are identified and protected. A radial slip of FCR is released at the level of its myotendinous junction and freed all the way distally to base of the metacarpal. A capsulotomy of the CMC joint is performed and followed by a trapeziectomy. If the scaphotrapezoidal joint appears arthritic on traction of the index and long fingers, a proximal trapezoidectomy is performed.[221] The thumb is then held in distraction and radial abduction, making sure the base of the first metacarpal is in line with the base of the second metacarpal. The slip of the FCR is then passed through a slit in the APL tendon. The tendon is then secured at its insertion through the APL. The remaining tendon is then passed in a figure-of-eight fashion around the APL and remaining FCR to form a firm sling at the base of the metacarpal. The tendon construct is secured with sutures and then the capsule and skin are closed.[232] This procedure may be performed alternatively with a slip of the APL passed through a slit in the FCR (see Fig. 20.21).[234]

At around 10 days postoperatively, a cast replaces the thumb spica splint for another 3 weeks. The patient is placed in a custom-made thumb spica splint when range of motion exercises are started at around 4 weeks postoperatively.

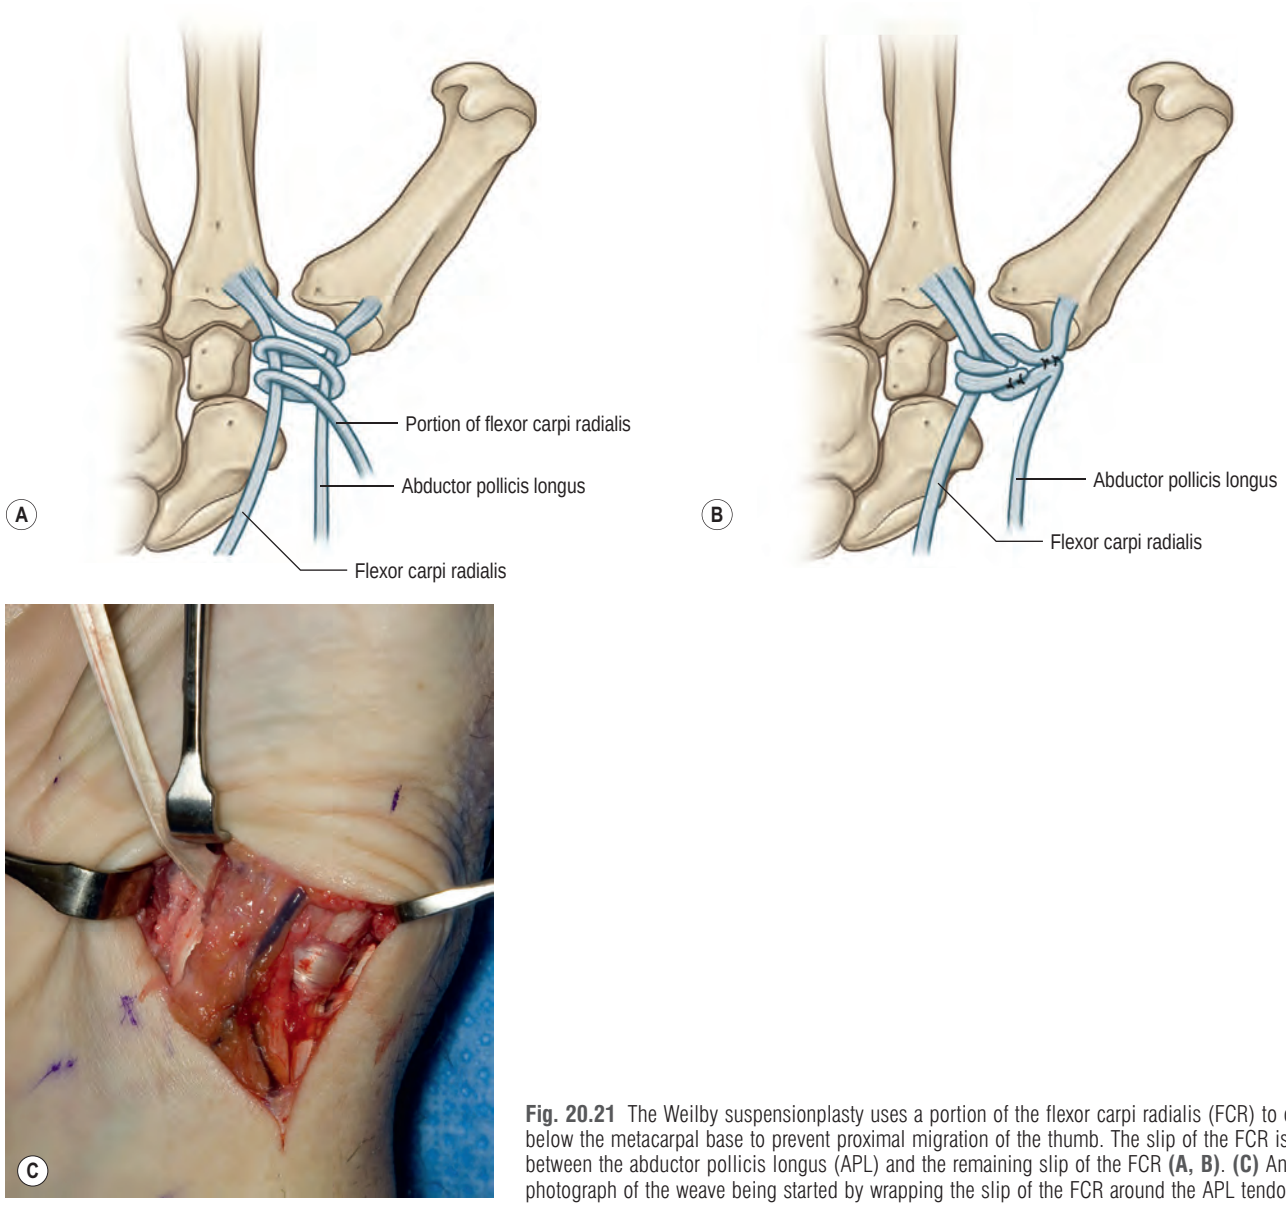

Fig. 20.21 The Weilby suspensionplasty uses a portion of the flexor carpi radialis (FCR) to create a sling below the metacarpal base to prevent proximal migration of the thumb. The slip of the FCR is wrapped between the abductor pollicis longus (APL) and the remaining slip of the FCR **(A, B)**. **(C)** An intraoperative photograph of the weave being started by wrapping the slip of the FCR around the APL tendon.

Strengthening and opposition across the palm are delayed until around 8 weeks postoperatively. The splint is then weaned by 10 weeks.[221]

Despite variation in surgical technique, there seems to be minimal outcome differences between simple trapeziectomy, trapeziectomy with ligament reconstruction, and LRTI. When compared in a 2004 prospective randomized trial,[235] no difference in grip strength, pinch strength, or thumb subsidence was noted at 8.2-month follow-up between patients who underwent trapeziectomy and ligament reconstruction alone and patients who underwent ligament interposition as well. A randomized control trial published in 2014 compared the LRTI technique of Burton and Pellegrini to the Weilby in 79 patients. While the LRTI group had less pain and better Patient-Related Wrist and Hand Evaluation (PRWHE) at 3 months, these differences did not persist to 12 months, at which point both groups had similar results.[236]

A 2009 Cochrane review[229] included nine studies involving 477 patients undergoing various procedures for basal thumb OA. The review concluded that, "while no procedure appears to be superior over another in terms of pain, physical function, patient satisfaction, or range of motion, there is insufficient evidence at this time to be certain." The review, however, did demonstrate that LRTI, when compared to simple trapeziectomy, is associated with 12% more adverse effects (including scar tenderness, tendon adhesion or rupture, sensory change, or complex regional pain syndrome type 1). The small number of studies included in this review and each study's unclear risk of bias have raised some doubts with regard to these results.

Prosthetic arthroplasty

Silicone arthroplasty for the TM OA was introduced independently in the late 1960s by Swanson[237] and Niebauer.[238] The procedure had the theoretical advantage of minimizing proximal migration of the thumb metacarpal after trapeziectomy. Early reports showed good results in the short

term[237,239]; however longer follow-up noted a high incidence of dorsoradial subluxation.[240] Subluxation continued to be a problem even after modifications in technique and implant design.[237,239,240] Reports of implant wear, silicone synovitis, and bone erosion also started emerging in the late 1980s.[241] With implant wear, investigators noted a 50% loss of implant height (especially on the ulnar border of the implant) at 4-year follow-up.[242] A 16% revision rate for silicone synovitis was also noted. Because of these complications, silicone implant CMC arthroplasty fell out of favor with most surgeons. Recently, however, Bezwada and colleagues[243] showed that osteolysis, implant wear, and subluxation did not directly correlate with clinical or subjective outcomes. In their study, they reported an 84% rate of patient satisfaction with and no radiographic evidence of synovitis.

Comparative studies are few, but in 2005, Taylor *et al*.[215] performed a retrospective comparison between patients undergoing silicone arthroplasty, resection arthroplasty (with and without ligament reconstruction), and arthrodesis for the treatment of TM OA. Taylor found no significant differences in the clinical outcomes between silicone arthroplasty and resection arthroplasty over 5-year period. In this study, the arthrodesis group was found to have a higher re-operation rate.[215] While the follow-up may not be long enough to document clinical deterioration of silicone implants,[244] this study suggests that silicone arthroplasty may be a reliable option for disabling, refractory basal thumb OA, especially in the low-demand patient. A newly developed one-piece silicone implant that has been shown to be biomechanically superior to LRTI may expand the current indications for silicone arthroplasty in CMC OA.[245]

Other types of TM arthroplasty have included metallic prostheses mainly of a ball-and-socket design.[246] Constrained TM joint prostheses are more prone to loosening, while non-constrained prostheses dislocate more easily.[246] The de la Caffiniere implant (ball-and-socket, cemented, semi-constrained prosthesis) is probably the most widely used and most studied.[247] The implant has a cobalt–chromium ball inserted into the shaft of the metacarpal and a polyethylene cup placed in the trapezium. Outcome studies have shown that patients with preoperative complaints of pain or instability do better than those with preoperative stiffness as their major complaint.[247] The implants have a 72–89% 16-year implant survival rate, with higher prevalence of loosening of the trapezial component and a greater need for revision surgery in working-age men.[248,249] In lieu of a silicone prosthesis, this implant may be considered in women over the age of 60 years for whom joint stiffness is not a main complaint.[246,250]

Other TM joint prostheses have produced high failure rates over time and have fallen from favor due to loosening, heterotopic bone formation and subsidence.[251–253] More recent implant designs have focused on metacarpal resurfacing in hopes of producing a *hemiarthroplasty*. The PyroCarbon metacarpal replacement hemiarthroplasty (Integra, Plainsboro, NJ) has shown promise in grade II and III disease. Subluxation of the implant, however, is a likely complication if the trapezial cup is made too shallow (Fig. 20.22).[254]

Fig. 20.22 Example of a PyroCarbon arthroplasty of the thumb trapeziometacarpal joint.

Trapeziometacarpal arthrodesis

With the success of the above reconstructive techniques, arthrodesis is now usually reserved for young (<50 years) high-demand patients who wish to maintain grip strength or as a salvage procedure for failed reconstructions. Although a previous report has suggested that mild pantrapezial arthritis is not an absolute contraindication for TM arthrodesis,[255] most authorities feel that the procedure should not be performed in the setting of STT arthritis.[256–258] The optimal position to fuse the joint is 35° of radial and palmar abduction with 15° pronation and 10° of extension.[259] This position replicates the position of the thumb in a fully clenched fist with the distal phalanx of the thumb resting on the middle phalanx of the index finger. Methods for CMC arthrodesis include slotted bone grafts, cerclage wiring, tension band wiring, staples, K-wire fixation, and screw fixation.[259] Screw and plate fixation has a higher rate of complications requiring hardware removal.[260]

Technique for arthrodesis

The surgical exposure for CMC arthrodesis (Fig. 20.23) is similar to that of a trapeziectomy. The base of the thumb metacarpal is delivered into the incision by flexing and adducting the shaft.[259] The eburnated articular cartilage and

Fig. 20.23 Example of a trapeziometacarpal joint fusion.

bone of the trapezium and metacarpal base are removed, exposing the cancellous bone. Surfaces are molded to allow for maximum bone contact between the two ends. If K-wires are being used, three 0.045 wires are usually needed, with one wire placed parallel to the long axis of the bones and the other two crossing at 15° to the axis. The K-wires should not extend proximal to the trapezium unless the trapezium is too osteopenic to hold stable fixation. K-wires are usually removed 6–8 weeks postoperatively. Postoperatively, patients are immobilized in a thumb spica until fusion is confirmed radiographically.[259]

Successful fusion will result in diminished thumb opposition and an inability to lay the hand flat.[259] Normal MP and ST joints, however, can compensate well for this limitation to allow for a functional thumb range of motion post-fusion. Post-fusion, MP joint and ST joint motions can increase by 75% and 25%, respectively.[256]

Common complications of CMC arthrodesis include nonunion, progression to peritrapezial arthritis, and symptomatic hardware requiring removal.[259] Radial sensory neuritis may also occur. Many nonunions are asymptomatic. Symptomatic nonunions may be treated with repeat arthrodesis, simple trapeziectomy, or LRTI.[259] In the literature, radiographic nonunion rates range from 6–12.5%,[255,258,261–264] with one study reporting a nonunion rate as high as 50%.[265] There appears to be no correlation between nonunion rates and the use of bone grafts.[266] Rizzo and colleagues recently reported on the outcomes of 126 patients following TM arthrodesis. Over the average follow-up period of 11.2 years, the incidence of radiographic STT arthritis was noted to be 31% and MP arthritis was identified in 12.7% of patients.[266] Despite these high values, none of the patients with radiographic MP arthritis were symptomatic and only 6% of patients with STT arthritis were symptomatic.[266]

Despite its disadvantages and complications, patient satisfaction with TM arthrodesis is usually high, with adequate recovery of pinch and grip strength postoperatively. While some have reported satisfaction rates as low as 60–78%,[261,264] most studies report a satisfaction rate >90%.[257,265,267] Although arthrodesis is generally recommended for younger patients, the procedure actually has favorable outcomes in patients over 50 years as well.[268]

OA of the wrist

Etiology

Osteoarthritis of the wrist may be primary (idiopathic) or secondary. Causes of primary OA include avascular necrosis of the lunate or scaphoid (Kienbock's or Preiser's disease, respectively), which can lead to degenerative changes throughout the wrist in later stages.[269,270] Congenital deformities, such as Madelung's deformity, can alter articular load patterns at the ulnocarpal, radiocarpal, and distal radial ulnar joints leading to the development of wrist OA. Perhaps the most common idiopathic OA of the wrist is that involving the STT joint. Epidemiologic studies note a very high incidence of STT arthritis in the general population. A radiographic and anatomic study by North and Eaton demonstrated an incidence of STT arthritis in 34% of wrists.[271] Another cadaver study reported the incidence of STT arthritis in 83% of cadaver wrists.[272]

Secondary causes of osteoarthritis of the wrist usually are related to trauma, with scapholunate ligamentous injury, distal radius fractures, and scaphoid fractures contributing most frequently to the development of secondary radiocarpal OA. Scapholunate interosseus ligament injury can lead to a progressive form of carpal instability, which may lead to the development of *scapholunate advanced collapse* (SLAC) arthritis.[273,274] In 1984, Watson and Ballet published a review of 121 wrist radiographs with degenerative arthritis due to scapholunate advanced collapse.[273] This pattern accounted for 55% of all wrists with degenerative changes and was the most common pattern of wrist arthritis. They found that arthritis initially involved the radial styloid (stage 1) and scaphoid waist, then progressed to involve the proximal scaphoid and scaphoid fossa of the radius (stage 2), with arthritis finally being identified in the midcarpal joint at the lunocapitate articulation (stage 3).[273] Other authors have added a fourth stage, which describes pan-carpal arthritis with diffuse involvement of the radiocarpal and midcarpal joints, with or without involvement of the distal radioulnar joint (Fig. 20.24).[275–277]

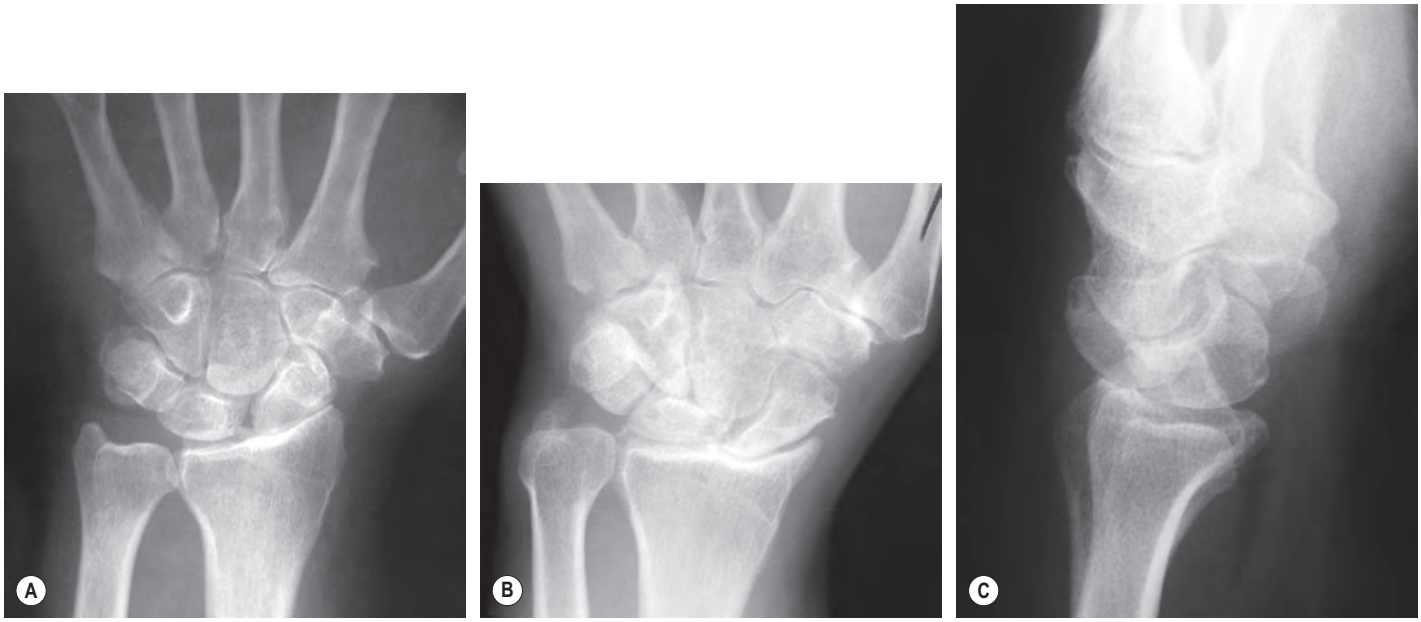

Fig. 20.24 Examples of scapholunate advanced collapse (SLAC) arthritis. **(A)** An example of stage II SLAC changes. There is evidence of advanced arthritis at the radial styloid and radioscaphoid fossa, but the midcarpal joint is still relatively free of arthritic changes. **(B)** A posteroanterior radiograph of a wrist with stage III SLAC changes. In addition to arthritis at the scaphoid fossa, there is narrowing of the capitolunate articulation, and midcarpal arthritis. **(C)** A lateral wrist radiograph in the same patient showing significant midcarpal instability with a dorsal intercalated segment instability (DISI) pattern.

The important point to note about SLAC arthritis is that the radiolunate joint is typically spared.[274–279] However, a recent publication by Lane *et al*. suggests that in a minority of cases (5–6% of SLAC wrists), the lunate fossa may be arthritic as well.[280] For this reason, it is important to assess the lunate fossa before committing to a particular reconstruction.

Wrist or forearm fracture can also lead to osteoarthritis of the wrist. The cause can be related directly to damage to the articular surface of the joint with an intra-articular fracture, with or without malunion. Alternatively, extra-articular distal radius fractures can result in malunion leading to abnormal joint wear.[281,282] Extra-articular distal radius fracture malunion can result in radial shortening, loss of radial inclination, loss of volar tilt, supination of the distal fragment, or radial or ulnar translation of the distal fragment. Each of these malunion patterns can result in abnormal load patterns across the wrist or adaptive malalignment deformities that can resemble instability patterns.[281,283] The end result of the abnormal load and wear may be osteoarthritis. In a classic report of intra-articular distal radius fractures, Knirk and Jupiter report 91% incidence of arthritis on late follow-up if there was any degree of articular step-off after fracture reduction and 100% incidence of arthritis (8/8) if there was >2 mm step-off of the articular surface.[284] Only 11% of those wrists with a congruent articular reduction developed arthritis at late follow-up. The presence of wrist arthritis within this study adversely affected the clinical outcome.

The final major cause of wrist OA is the sequela of untreated or mal-united scaphoid fractures. It is estimated that between 5% and 10% of all scaphoid fractures will fail to heal.[285] Scaphoid nonunion can lead to a pattern of carpal instability similar to that seen with scapholunate ligament injury.[286] Like the SLAC wrist, scaphoid nonunion can lead to wrist arthritis in a predictable pattern and is termed *scaphoid nonunion advanced collapse* (SNAC) arthritis.[279,285,287] There are three stages of SNAC arthritis that have been adapted from the description by Ruby *et al*.: stage I involves arthritis at the radial styloid and scaphoid articulation[279,287,288]; stage II involves progressive degeneration of the radioscaphoid articulation and scaphocapitate joint; stage III includes the pathology found in stages I and II but with progression to include the lunocapitate articulation (Fig. 20.25).[279,288]

Patient evaluation

Evaluation of the patient with suspected wrist arthritis begins with a careful history and physical examination. Important aspects of the history include the mechanism of original injury, quality and location of the pain, and exacerbating and alleviating factors. It is important to note what measures the patient has already tried to treat the pain, such as splinting, steroid injection or NSAIDs. It is important to determine the degree to which the pain is affecting the patient's lifestyle and work, as this will dictate the decision to treat with non-operative methods or proceed to wrist salvage. This is an important consideration as surgery may require a significant investment by the patient in terms of time off work due to immobilization and a potential loss of wrist motion. For these reasons, it is often advisable to see the patient on more than one occasion and sometimes follow them for years before embarking on a reconstruction. In the meantime, pain is managed with non-operative means such as splinting, NSAIDs (oral and/or topical), and periodic steroid injections.

A critical evaluation of PA and lateral wrist radiographs is essential. In doing so, one should get a sense of the etiology of the OA, whether secondary or primary. One must note which articulations are involved and which are spared as this will dictate what surgical options are available, i.e., involvement of the lunocapitate articulation in the SLAC wrist.

Fig. 20.25 A posteroanterior wrist radiograph of a patient with stage II scapholunate advanced collapse (SLAC) arthritis.

Involvement of the lunocapitate articulation should give one pause before proceeding with a proximal row carpectomy reconstruction as this will leave an arthritic capitate head behind to articulate with the lunate fossa. In this situation, a midcarpal fusion, such as a scaphoidectomy and four-corner fusion may be more appropriate. Further imaging such as a computed tomography scan, magnetic resonance imaging, or bone scan is not part of the routine evaluation, but may be indicated in select situations to evaluate for early signs of midcarpal arthritis. Another helpful diagnostic adjunct is a selective injection of lidocaine, with or without steroid, into the joint in question. This test can be potentially useful for diagnosis as well as treatment. A study by Bell *et al*. looked at the diagnostic utility of midcarpal lidocaine (with or without corticosteroid) injection in patients with chronic wrist pain.[289] They noted that patients with chronic wrist pain had an improvement in grip strength with the injection, whereas normal volunteers had a reduction in grip strength. In addition, those patients with an improvement of >6 kg or >28% improvement over baseline had a 73% sensitivity and 70% specificity of having intracarpal pathology at arthroscopy.

Surgical treatment

Surgery is directed at elimination of pain at the arthritic joint through debridement (radial styloidectomy), denervation (neurectomy), arthroplasty, or partial or total wrist arthrodesis. The specific treatment is carefully selected based on the patient's symptoms, expectations, pattern of arthritis, and functional demands. Biomechanical data is available to help predict the range of motion that may be expected with proximal row carpectomy, midcarpal joint fusion, and radiocarpal joint fusion.[290,291] Based on these studies, midcarpal fusion can result in a wrist with 50–67% of the motion of the normal side, radiocarpal fusion will provide only 33–40% of contralateral motion. If the distal pole of the scaphoid is removed following a radioscapholunate fusion, an additional 15–20% of motion is possible. Proximal row carpectomy can preserve 50–75% of contralateral wrist motion.[276]

Technique for dorsal approach to the wrist

The surgical approach to the wrist should account for the likelihood of future additional procedures should the selected initial treatment option fail. A total wrist fusion represents the ultimate salvage for wrist arthritis. Since this is typically performed through a longitudinal dorsal wrist incision in line with the third metacarpal, this approach is recommended for limited salvage procedures, such as partial wrist arthrodesis. Following the skin incision, full-thickness flaps are raised in an ulnar and radial direction. The extensor retinaculum is opened over the third extensor compartment and the extensor pollicis longus tendon is transposed. The retinaculum is raised in a radial and ulnar direction. The second and fourth compartment tendons are retracted and the dorsal wrist capsule is exposed. A ligament sparing incision is made in the capsule (Fig. 20.26).[292,293] The incisions create a radially based flap in line with the dorsal radiotriquetral ligament and dorsal intercarpal ligament. This approach gives excellent exposure of the midcarpal joint as well as the scaphoid.

Radial styloidectomy

For patients with early SLAC arthritis where arthritis is confined to the radial styloid, radial styloidectomy may be performed as a conservative palliative procedure, either in isolation or in combination with other another procedure. Radial styloidectomy is usually performed subperiosteally through the anatomic snuffbox. It is important to preserve the volar attachment of the radioscaphocapitate ligament during the procedure, which inserts into the radial styloid. If more than a 6–10 mm of styloid is removed, the radioscaphocapitate ligament origin will be significantly compromised, possibly resulting in ulnar translation of the carpus.[294–296] The radial styloid fragment may be used as a bone graft for concomitant fusion procedures.

Neurectomy

Total denervation of the wrist is associated with improved pain without loss of motion and with minimal morbidity and convalescence.[297–299] Partial denervation of the anterior interosseous nerve (AIN) and posterior interosseous nerve (PIN) is possible through a single dorsal incision.[300] This procedure has been shown to provide partial relief of wrist pain in cases of radiocarpal arthritis at an average of 31 months after surgery.[301] In a study of 20 patients, performed by Weinstein and Berger, only three patients required additional procedures for pain relief following AIN/ PIN neurectomy. Most patients in this study continued to have some wrist pain, but the majority (90%) were significantly improved. Prior to proceeding with neurectomy, patients should undergo a selective AIN/PIN block with long-acting anesthetic to verify that pain relief will be adequate. This allows the patient to assess the level of relief that may be expected from the denervation procedure.[301]

Proximal row carpectomy

Proximal row carpectomy (PRC) is an option when the proximal capitate articular surface and the lunate fossa of the radius are preserved (Fig. 20.27). In other words, there is no arthritis at the midcarpal joint or radiolunate joint. PRC

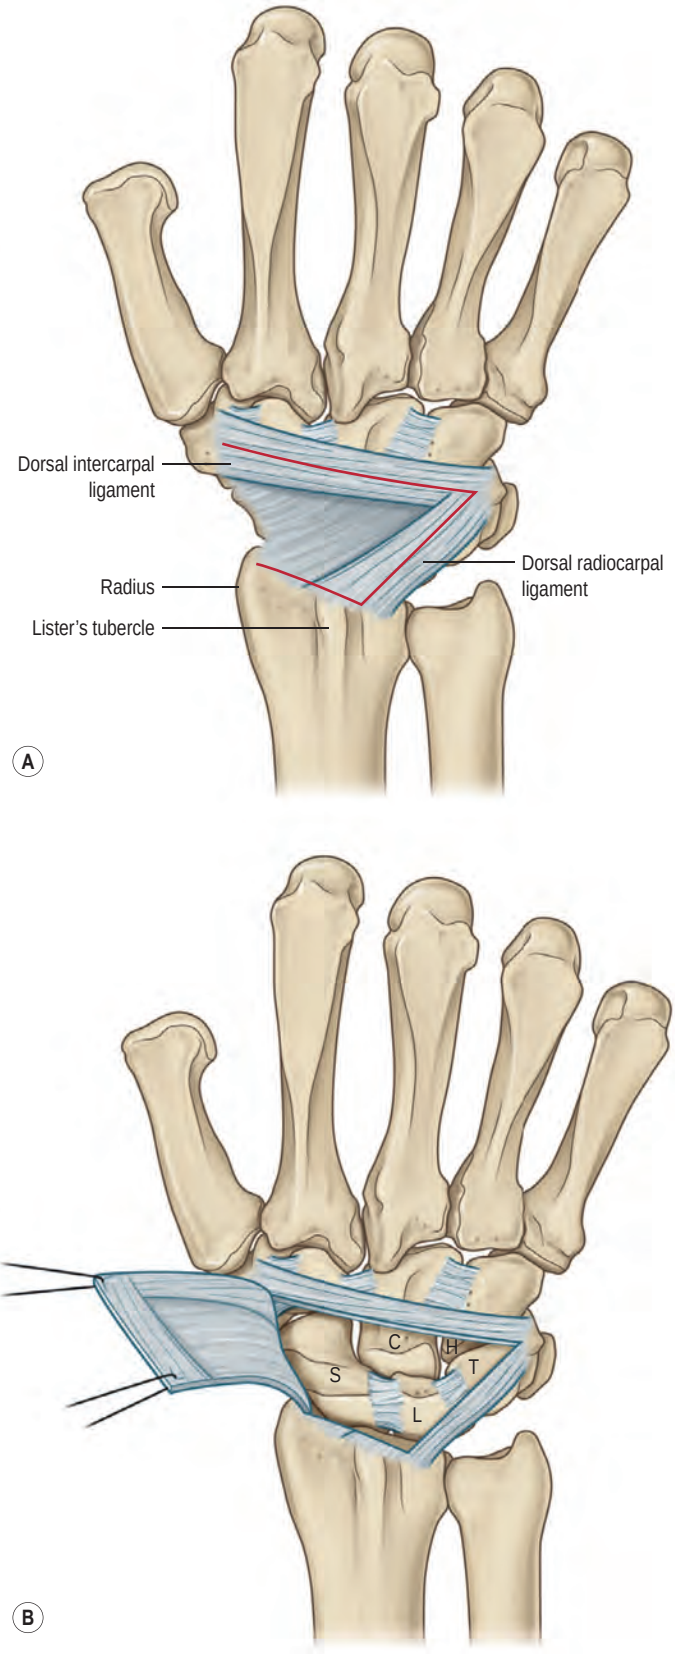

Fig. 20.26 Dorsal exposure to the wrist bones is accomplished through the use of a ligament-sparing capsulotomy. **(A)** A triangular shaped flap is designed over the dorsum of the wrist capsule extending from the Lister's tubercle to the triquetrum and back to the upper third of the scaphoid. **(B)** The capsulotomy runs in line with the fibers of the dorsal radioscaphocapitate ligament and the dorsal intercarpal ligament. S, scaphoid. L, lunate. C, capitate. T, triquetrum. H, hamate.

Fig. 20.27 A posteroanterior wrist radiograph of a proximal row carpectomy (PRC). A PRC involves the removal of the scaphoid, lunate and triquetrum. The lunate fossa of the radius and the articular surface of the capitate should be free of arthritic changes to maximize the outcome of this procedure.

entails removal of the entire proximal carpal row (scaphoid, lunate, and triquetrum) and results in the wrist functioning as a simple hinge joint. The capitate articulates with the lunate facet of the radius. The radius of curvature of the lunate fossa is larger than that of the capitate head and there is resultant incongruity at the new articulation. This incongruity may lead to articular wear between the capitate head and radius.

Proximal row carpectomy has some advantages over intercarpal fusions. It does not require a lengthy period of immobilization for an arthrodesis to heal. Krakauer *et al*. have compared proximal row carpectomy with intercarpal fusion.[302] They found that carpectomy preserved better motion, an average arc of 71° versus 54° for limited arthrodesis. Both types of procedure preserved reasonable strength and reduced pain.

There is limited data on long-term outcomes after PRC. Jebson and colleagues reported on 20 patients, 11 of who underwent PRC for osteoarthritis. Two patients in this series required wrist arthrodesis for persistent pain. The remaining 18 patients were evaluated at an average of 13 years following surgery. The average wrist range of motion and the average maximal grip strength was 63% and 83%, respectively, of the opposite extremity. Sixteen of the 18 patients had returned to their previous employment. Flattening of the capitate was present in 33% of patients and 22% of patients had some evidence of moderate to severe radiocapitate arthrosis. However, this finding did not correlate with patient satisfaction, wrist pain, or function.[303] DiDonna and colleagues have also published similar findings in a long-term outcome study of PRC with a minimum of 10-year follow-up. There were four failures (18%) requiring fusion at an average of 7 years following initial surgery. The average flexion extension

arc was 72° with and average grip strength of 91% of the contralateral side. Of the 18 wrists that did not fail, all patients were either satisfied or very satisfied with the procedure, with an overall DASH score of 9. Degenerative changes were seen in 14 of 17 wrists at the radiocapitate articulation at follow-up. However, like the findings by Jebson, this did not correlate with symptoms.[304]

Four-corner fusion

Scaphoidectomy and four-corner fusion represents another method for treating midcarpal and radial-sided wrist arthritis (Fig. 20.28). This procedure entails excision of the scaphoid and fusion of the midcarpal joint (lunate, capitate, triquetrum, and hamate). This procedure does not require preservation of the lunocapitate articulation and therefore may be appropriate in more advanced stages of the SLAC/SNAC wrist; however, it does require preservation of the radiolunate articulation.[280] In 1984, Watson presented outcomes of his "SLAC procedure" for the SLAC wrist.[273] Although this SLAC wrist procedure was initially proposed to be used with a silicone scaphoid implant, scaphoid excision without an implant works equally well and avoids the long-term risk of silicone synovitis. Potential advantages of four-corner fusion over PRC include: the retention of the native radiolunate interface; and preservation of the lunate and capitate preserves carpal height, which arguably maintains the resting muscle tension across the wrist, preserving grip strength.[273,274]

Several studies have examined the functional outcome following four-corner fusion.[302,305–309] Ashmead *et al*. reported on 100 cases, of which final wrist flexion–extension arc averaged 53% of the contralateral side and final grip strength averaged 80% of the contralateral side. Nonunion occurred in only 3% of patients; 51% of patients had total resolution of wrist pain, while 15% continued to have pain with daily activities or at rest.[305] More recently, Neubrech *et al*. reported on over 500 four-corner fusions with greater than 10-year follow-up. Forty (6.7%) fusions required conversion to complete wrist arthrodesis while 11% of patients required revision surgery. Fifty-six patients returned for follow-up exam an average of 14 years after initial surgery. They had an average flexion–extension arc of 62.5% and an average grip strength of 84.9% compared to the unaffected wrist.[309]

Techniques ensuring successful outcome have focused on adequate decortication of the four bony surfaces and correction of the dorsiflexed lunate to re-establish a collinear relationship between the lunate and capitate. Failure to correct lunate position can lead to limited wrist extension, hardware abutment, and pain.[305,306] The use of bone graft has not been shown to clearly correlate with fusion rates, nor has hardware choice; however, hardware complications have been noted with pins, staples, and circular plates.[302,307,310] In Vance *et al*.'s study, nonunion and impingement occurred in 48% of cases treated with circular plate fixation in comparison to a 6% rate with traditional fixation (K-wires, staples, or compression screws). Plate fixation was also associated with a higher rate of patient dissatisfaction.[310]

A variation of four-corner fusion can involve capitolunate arthrodesis alone. Early attempts using this limited arthrodesis were associated with high rates of nonunion, most likely due to a smaller bony contact areas for successful bony fusion.[311–313] These results were significantly improved by Calandruccio and colleagues, who combined capitolunate fusion with scaphoid and triquetral excision.[314] This procedure may provide for more wrist motion than four-corner fusion but long-term data is still pending.

Fig. 20.28 A posteroanterior radiograph showing an example of a scaphoidectomy and four-corner fusion. This wrist salvage option is indicated if there is evidence of arthritis at the midcarpal joint and the scaphoid fossa.

Total wrist arthrodesis and total wrist arthroplasty

In advanced arthritis where longstanding changes have resulted in injury to the midcarpal joint and the lunate fossa, wrist arthrodesis and wrist arthroplasty may be the only options for wrist salvage. Arthroplasty may be an enticing option because of the potential for motion preservation; however, the normal wrist functions through complicated interactions at multiple articulations across the wrist joints. It is impossible for a prosthesis to duplicate this complexity of motion and strength.[315] Therefore, there is a compromise that occurs for motion at the expense of strength. For these reasons, wrist arthroplasty is carefully selected only for those patients with low-demand wrists or who have a fusion of the contralateral wrist.[316] Patients with rheumatoid arthritis as opposed to osteoarthritis of the wrist tend to match the patient profile more appropriately for total wrist arthroplasty. The choice of wrist arthroplasty is dependent on the patient's age, activity level, and status of the contralateral wrist.

Total wrist arthrodesis represents the ultimate salvage procedure for all types of wrist arthritis. It involves fusion of the radiocarpal, midcarpal and third carpometacarpal joint. Total wrist arthrodesis is an established method of achieving pain relief and maintaining strength in patients without alternative options such as those with pan-carpal arthritis. This procedure is typically performed with the use of a dorsal

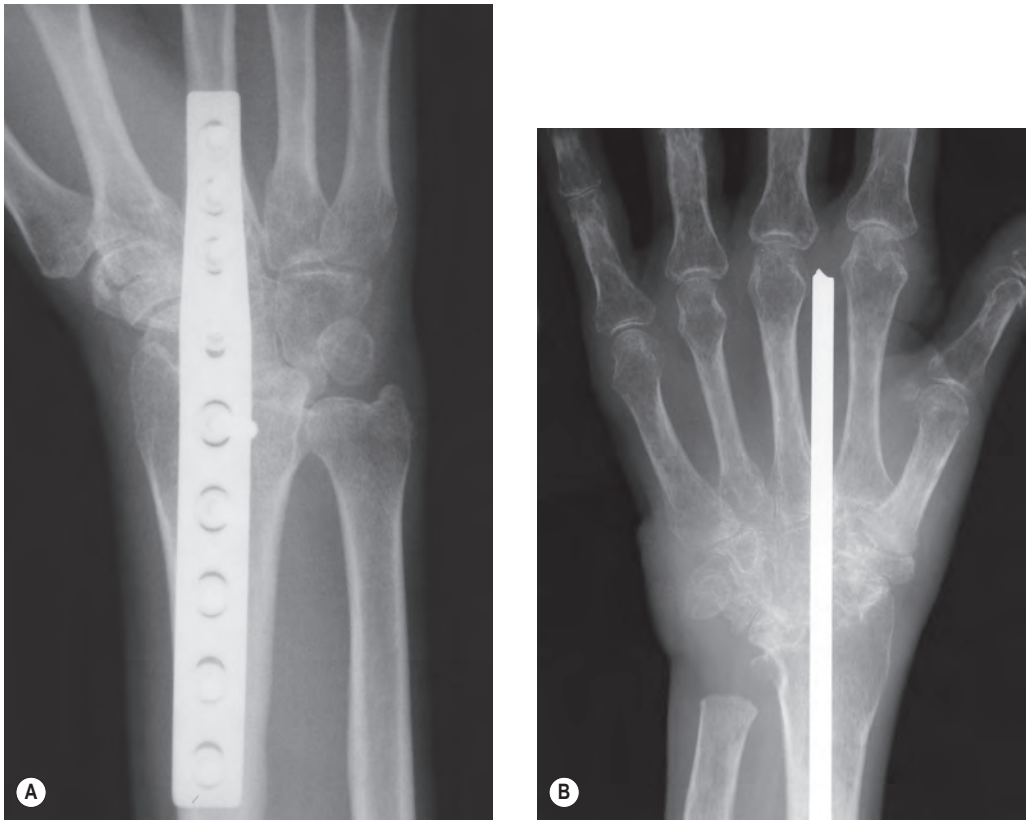

Fig. 20.29 **(A)** A complete wrist fusion may be accomplished with either the use of a dorsal plate or **(B)** the use of large intramedullary pins.

wrist fusion plate, but alternative methods have also been described using pins alone. Because the distal radioulnar joint (DRUJ) is not involved in a standard wrist fusion, forearm rotation is still possible. The ideal position for wrist fusion is in mild extension with mild ulnar deviation. This position maximizes grip strength (Fig. 20.29).

Wrist fusion is usually performed through a dorsal incision centered over the fourth extensor compartment. Decortication of the radiocarpal joint, midcarpal, and third finger CMC joint have been recommended to obtain solid fusion throughout the carpus. Alternatively, a proximal row carpectomy can be performed and the capitate can be fused to the lunate fossa of the radius. This technique can be beneficial for cases of profound wrist contractures, where decreasing the carpal height may allow for improvement in wrist position; however, it dramatically decreases the area of bony contact through which the fusion may occur. Bone graft is not necessary if good opposition between the bone ends is achieved, but in difficult cases bone graft may be acquired from the iliac crest, radial styloid, or any bones that are removed from the carpus at the time of fusion. During plate fixation, screws are ideally placed within the shaft of the third metacarpal and shaft of the radius. It is often possible to place additional screws into the capitate for additional fixation. Pin fixation, which lacks the rigidity of plate fixation, is usually achieved by placing long Steinmann or Rush pins through the intermetacarpal space of the index/long and long/ring fingers. Following fusion, the wrist is placed into plaster immobilization for 6–8 weeks, or until bony consolidation is seen on plain radiographs.

Future directions

The likely future direction of osteoarthritis treatment is cartilage replacement or regeneration. Articular cartilage has a limited capacity for regeneration and repair when damaged, due to its primarily avascular nature. Blood or bone marrow, which would usually enter an injured site and provide support for healing, do not arrive to the site of cartilage damage. Microfracture and drilling techniques are based on improving the blood flow to an area of injured cartilage to increase healing factors that may allow for cartilage regeneration.

Tissue engineering, which involves the use of scaffolds, cells, and stimulating factors (alone and in combination), is a potential avenue for treating cartilage damage.[317] Multiple clinical trials have shown early promising results for cartilage repair. Collagen-based, hyaluronic acid-based, and fibrin-based matrices have all been examined.[318–320] However, each material has its limitations and drawbacks. For example, cell migration is limited in fibrin-based matrices while collagen-based gels require placement under a periosteal cover to avoid displacement. More recently, interest has shifted toward three-dimensional tissue-engineered constructs.[321] In this emerging technology, cells can be laid down layer by layer into the preformed shape necessary to replace the area of damage. The layered cell organization more closely mimics native cartilage structure. Despite the significant advances in tissue engineering, this technology remains limited in clinical application today but provides hope for the future of osteoarthritis treatment.

Long-term outcomes of trapeziometacarpal arthrodesis in the management of trapeziometacarpal arthritis. *J Hand Surg Am*. 2009;34:20–26. *The authors performed a 33-year retrospective study of trapeziometacarpal (TMC) arthrodeses performed at Mayo Clinic. Amongst 241 procedures reviewed, they included 126 thumbs with adequate pre- and postoperative clinical and radiographic data at an average 11-year follow-up. They report improvement of preoperative pain scores, oppositional and appositional pinch strength, and grip strength ($p < 0.01$). There was no significant change of any thumb motion arc. Nonunion rate was 13% and was unrelated to the use of bone grafting. Radiographic progression of STT arthritis was seen in 39 thumbs, only eight of which were symptomatic. This study presents detailed long-term outcomes of TMC arthrodesis, providing level IV evidence for the management of TMC arthritis.*

283. Linscheid RL, Dobyns JH, Beabout JW, et al. Traumatic instability of the wrist. Diagnosis, classification, and pathomechanics. *J Bone Joint Surg Am*. 1972;54:1612–1632. *This is a seminal article from 1972 that presents the foundation for study of carpal instability. The authors describe wrist instability that develops as a result of scapholunate and other carpal ligament injuries in addition to instability from fracture dislocations, scaphoid fractures, and fractures of the distal radius and ulna. They provide the earliest comprehensive dialogue of the diagnosis of carpal instability. The article includes clinical and radiographic data, a detailed discussion of the biomechanics of carpal instability, and proposal of the now accepted classification of dorsal and palmar intercalated segment instability. The radiographic parameters and nomenclature presented in this article remain in use today. The article has been recognized as a "classic orthopedic reference" and a summary was republished in the* Journal of Bone and Joint Surgery *in 2002.*

304. DiDonna ML, Kiefhaber TR, Stern PJ. Proximal row carpectomy: study with a minimum of ten years of follow-up. *J Bone Joint Surg Am*. 2004;86:2359–2365. *The authors retrospectively evaluate the long-term results of 22 proximal row carpectomy procedures performed for the treatment of scapholunate advanced collapse, scaphoid nonunion with advanced collapse or Kienbock's disease. Outcomes were assessed by means of follow-up radiographs, objective measurement of motion and grip strength, and the DASH questionnaire. Their surgical technique is reviewed and results at a minimum 10-year follow-up (average 14 years) are presented. There were four failures (18%) at an average of 7 years, all of which occurred in patients younger than 35 years. The authors report a wrist motion arc of 72° and grip strength of 91% of that of the contralateral side in the 18 (82%) successes. They conclude that proximal row carpectomy is a viable motion-preserving procedure for advanced carpal arthritis that provides satisfactory long-term results in most patients, and advise against it in patients younger than 35 years.*

An anatomic study of the stabilizing ligaments of the trapezium and trapeziometacarpal joint. *J Hand Surg Am*. 1999;24:786–798. *This article provides a comprehensive and well-illustrated description of the ligaments stabilizing the trapezium and TMC joint. An anatomic study of 37 cadaver hands was performed identifying 16 ligaments with attachments at this important joint. Insertions, fiber orientations, and positions producing ligament tension are described for each ligament. A discussion of the biomechanical role and clinical relevance of the most important ligaments is presented.*

211. Freedman DM, Eaton RG, Glickel SZ. Long-term results of volar ligament reconstruction for symptomatic basal joint laxity. *J Hand Surg Am*. 2000;25:297–304. *This is a 15-year follow-up study of 24 pre-arthritic hypermobile TMC joints that underwent volar ligament reconstruction for symptomatic ligament laxity, after failed conservative therapy. At final follow-up, 17 patients (71%) complained of intermittent or daily pain, seven patients (29%) had no pain, and only two joints (8%) progressed to stage III radiographic arthritis. The authors present a thorough review of clinical, radiographic and intraoperative characteristics in relation to long-term clinical and radiographic outcomes of the procedure. They conclude that volar ligament reconstruction is indicated for the painful hypermobile TMC joint and limits the progression of degenerative arthritis.*

Trapeziectomy for trapeziometacarpal joint osteoarthritis: is ligament reconstruction and temporary stabilisation of the pseudarthrosis with a Kirschner wire important? *J Hand Surg Eur Vol*. 2009;34:312–321. *This is a randomized prospective study comparing two surgical treatment options for basal thumb arthritis. A total of 61 thumbs underwent trapeziectomy, LRTI, K-wire immobilization and 6 weeks of splinting and 67 thumbs underwent trapeziectomy alone and 3 weeks of immobilization with a soft bandage. Outcome measures included pain, DASH scores, and thumb and grip strengths, which were all assessed at 3 and 12 months. Detailed results are presented and no significant difference between the procedures was detected in any of the outcomes measures.*

266. Rizzo M, Moran SL, Shin AY. Long-term outcomes of trapeziometacarpal arthrodesis in the management of trapeziometacarpal arthritis. *J Hand Surg Am*. 2009;34:20–26. *The authors performed a 33-year retrospective study of trapeziometacarpal (TMC) arthrodeses performed at Mayo Clinic. Amongst 241 procedures reviewed, they included 126 thumbs with adequate pre- and postoperative clinical and radiographic data at an average 11-year follow-up. They report improvement of preoperative pain scores, oppositional and appositional pinch strength, and grip strength ($p<0.01$). There was no significant change of any thumb motion arc. Nonunion rate was 13% and was unrelated to the use of bone grafting. Radiographic progression of STT arthritis was seen in 39 thumbs, only eight of which were symptomatic. This study presents detailed long-term outcomes of TMC arthrodesis, providing level IV evidence for the management of TMC arthritis.*

Diagnosis, classification, and pathomechanics. *J Bone Joint Surg Am*. 1972;54:1612–1632. *This is a seminal article from 1972 that presents the foundation for study of carpal instability. The authors describe wrist instability that develops as a result of scapholunate and other carpal ligament injuries in addition to instability from fracture dislocations, scaphoid fractures, and fractures of the distal radius and ulna. They provide the earliest comprehensive dialogue of the diagnosis of carpal instability. The article includes clinical and radiographic data, a detailed discussion of the biomechanics of carpal instability, and proposal of the now accepted classification of dorsal and palmar intercalated segment instability. The radiographic parameters and nomenclature presented in this article remain in use today. The article has been recognized as a "classic orthopedic reference" and a summary was republished in the* Journal of Bone and Joint Surgery *in 2002.*

Proximal row carpectomy: study with a minimum of ten years of follow-up. *J Bone Joint Surg Am*. 2004;86:2359–2365. *The authors retrospectively evaluate the long-term results of 22 proximal row carpectomy procedures performed for the treatment of scapholunate advanced collapse, scaphoid nonunion with advanced collapse or Kienbock's disease. Outcomes were assessed by means of follow-up radiographs, objective measurement of motion and grip strength, and the DASH questionnaire. Their surgical technique is reviewed and results at a minimum 10-year follow-up (average 14 years) are presented. There were four failures (18%) at an average of 7 years, all of which occurred in patients younger than 35 years. The authors report a wrist motion arc of 72° and grip strength of 91% of that of the contralateral side in the 18 (82%) successes. They conclude that proximal row carpectomy is a viable motion-preserving procedure for advanced carpal arthritis that provides satisfactory long-term results in most patients, and advise against it in patients younger than 35 years.*

Scapholunate advanced collapse wrist salvage. *J Hand Surg Am*. 1994;19:741–750. *The authors present a substantial series of 100 scaphoid excisions and four-corner fusions with an average 4-year follow-up. Long-term subjective, clinical, and radiographic data is presented. At the time of follow-up, 91% of cases had significant improvement in pain levels, and no patient described their pain as worse. Flexion/extension averaged 72° and grip strength was 80% that of the contralateral side. Nonunion occurred in only three cases and only two instances of radiolunate destruction were noted, both in conjunction with ulnar translation of the carpus. Outcomes with and without the use of silicone scaphoid spacers were found to be similar.*

The stiff hand and the spastic hand

David T. Netscher, Kenneth W. Donohue, and Dang T. Pham

Access video and video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Flexion and extension contractures may result from contractures of structures volar or dorsal to the joint, capsular/pericapsular structures, and bony deformity.
- Non-operative treatment is more effective in the early phase following injury and includes splinting, extremity elevation, compression gloves, moist heat, and ultrasound.
- Surgery is indicated for residual flexion contractures refractory to non-operative measures.
- Checkrein ligament release is key in proximal interphalangeal (PIP) joint flexion contracture surgery.
- Postoperative splint application maintains surgical correction.
- Salvage procedures for PIP joint flexion include disarticulation at the PIP joint or bone shortening with PIP joint fusion.
- In the spastic hand, non-surgical treatment for cerebral palsy includes splinting, occupational therapy, intramuscular botulinum toxin A, and intrathecal baclofen.
- Surgical treatment of spasticity is also indicated in specific situations.

Introduction

Hand stiffness arises as a result of flexion and extension contractures of the small joints of the hand. Limitation of extension or flexion may be both active and passive or active alone. The appropriate treatment should be decided following clinical evaluation of what tissue needs to be addressed. This chapter will first outline the general principles of evaluation and treatment of contractures, followed by specific treatment of spasticity.

The stiff hand

Diagnosis/patient presentation

Flexion contracture (Fig. 21.1)

Hints and tips

Clinical assessment

- Active versus passive range
- Joint lag versus joint contracture
- Anatomic structure – skin, fascia, pericapsular, bone
- "Seesaw" effect across two joints
- Intrinsic and extrinsic contractures

This may result from tightness in one or more of the structures on the palmar aspect of the joint[1,2]:

- Skin: Contracture from scarring results from lacerations or palmar burns.
- Palmar fascia: Dupuytren contracture is the classic example.
- Flexor tendon sheath: Shortening and contracture may occur.
- Flexor tendon: This is due to tendon shortening or tendon adhesions. Temporary joint fixation in a particular position with locking and release by painful manipulation may result from a trigger finger within the tendon sheath but also may occur within the joint, especially at the metacarpophalangeal (MP) joint (intracapsular tumors, loose bodies, osteophytes, articular surface distortions).

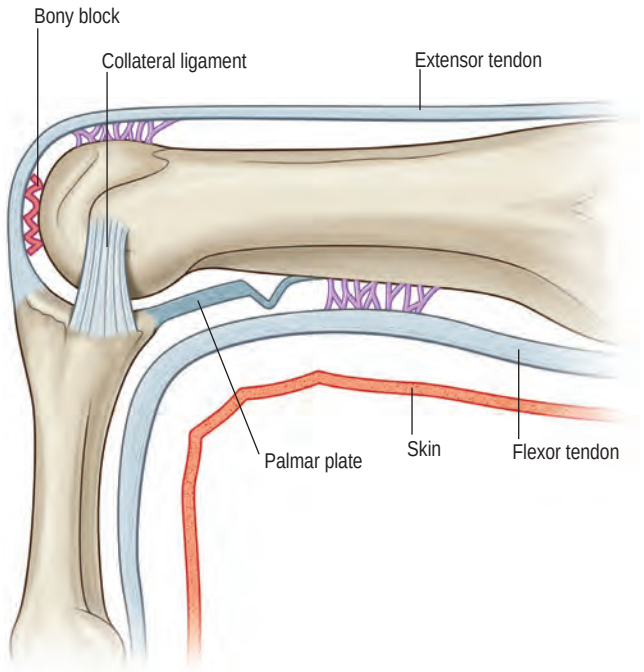

Fig. 21.1 Flexion contracture may result from tightness of structures volar to the joint, including skin, flexor tendon sheath, tendons, volar palmar plate, and accessory collateral ligaments. In addition, a bone block may impede joint motion, whereas dorsal tendon adhesions may limit the ability to extend the joint.

Capsular and pericapsular structures

Collateral ligament

The collateral ligament at the PIP joint is taut in all positions of the joint and collateral ligaments are taut in flexion only at the MP joints.[3] Thus, collateral ligament shortening never produces a flexion contracture at either joint. However, collateral ligament adherence to the lateral aspect of the proximal phalanx when the finger is flexed, does play a role in PIP joint flexion contracture.

Volar plate

When other structures are the primary cause of the flexion contracture, the volar plate becomes contracted at an early stage, especially at the interphalangeal joints.

Accessory collateral ligaments, transverse retinacular ligaments, and intrinsic tendons

Contracture of accessory ligaments, adherence of fibers of the transverse retinacular ligament to the collateral ligaments, and adhesions of intrinsic tendons in the lumbrical canals may cause flexion of MP joints.

Dorsal adhesions

Generally with flexion contracture, tightness of structures on the flexor aspect of the joint exists. However, joint extension may sometimes be prevented by incongruity of articular surfaces or adhesion of dorsal capsule or of an extensor tendon to the articular surface of the head of the proximal bone. In such a case, there is not only a flexion contracture but also limitation of flexion.

Bone

Bone block or exostosis can also cause flexion contracture.

Extension contracture

Limitation of flexion (extension contracture) (Fig. 21.2) can be caused by one or more structures on the dorsal aspect of the joint.[1,2] However, they too can result from a "jamming" effect of volar structures that block flexion, such as a bone block or palmar plate adhesions.

Skin

This usually results from scar contracture.

Long extensors

Tendon shortening or adhesions limit joint flexion. With extensor tendon adhesions, active extension of the joint is limited or absent, and active extension falls short of passive extension.

Intrinsic muscles

Intrinsic contracture may follow ischemia, or muscle fibrosis may occur for non-ischemic reasons (rheumatoid arthritis, cerebral palsy). The "intrinsic plus" position of the hand is one in which the fingers are flexed at the MP joints and extended at the interphalangeal joints.[3] A "saddle deformity"[4] results from adhesions between lumbrical and interosseous muscles. With active intrinsic contraction, painful impingement on the deep transverse metacarpal ligament occurs with limitation of flexion (the transverse metacarpal ligament is the "saddle" and the two muscles are the "legs of the rider").

Capsular and pericapsular structures

Dorsal capsule

The dorsal capsule may become scarred and contribute to extension contracture.

Collateral ligaments

Adhesions to the head of the proximal bone may limit flexion. In contrast to flexion contracture, which is more common in interphalangeal joints (especially proximal), stiffness in extension from collateral ligament shortening is more likely at MP joints. Collateral ligaments at the MP joints are relaxed in extension and taut in flexion.[5] Loss of MP joint flexion can come about simply from immobilization in the incorrect, extended position. Collateral ligaments are at their tightest (the cam arc effect of the metacarpal head) at a range between 70° and 90° flexion.

Volar plate

Flexion is prevented by volar plate adhesions to the palmar surface of the proximal bony head. Palmar plate adhesions and collateral ligament tightness may both be causes of MP joint extension contracture.[1] They may be distinguished from each other. If the collateral ligaments are contracted, finger abduction–adduction in extension (normally about 45°) is greatly reduced. When palmar plate is the sole cause, attempted passive flexion produces an opening of the dorsal aspect of the joint. The volar lip at the base of the proximal phalanx jams against the adherent volar plate, and the

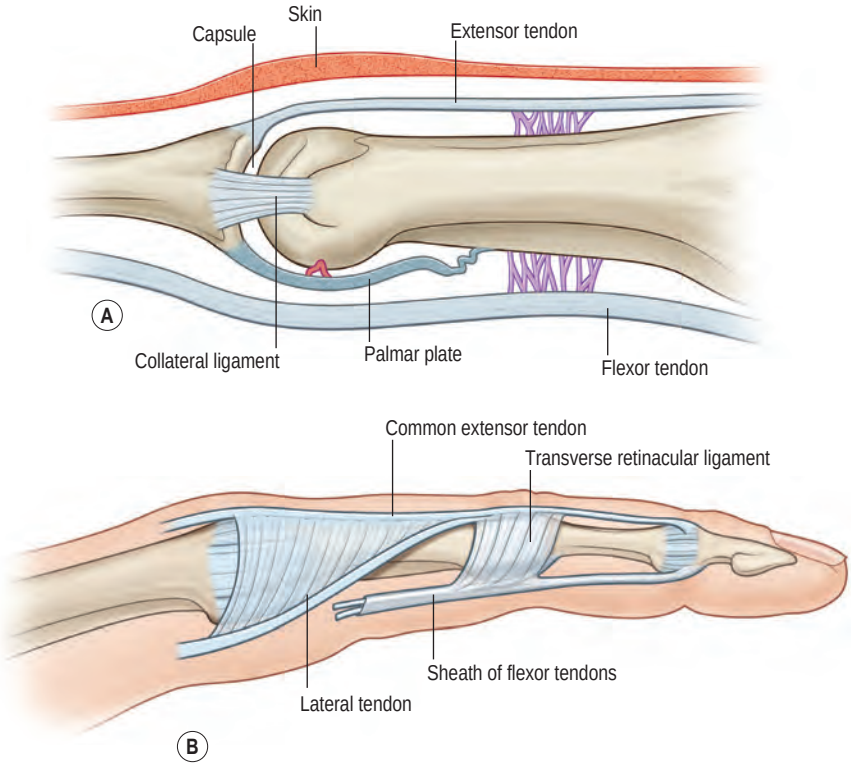

Fig. 21.2 (A) Extension contracture may result from tightness of dorsal structures, including skin, extensor tendons, collateral ligaments and joint capsule, as well as from a bone block. Volar structures may also impede the ability to flex the joint. **(B)** In addition, adhesions in the lumbrical canal and of the transverse retinacular ligament fibers may impede both flexion and joint extension.

unaffected (loose) collateral ligaments allow the flexion force to rock the dorsal lip away from the metacarpal head, felt as a subtle dorsal recess between head and base. This sign should always be sought intraoperatively as a residual impediment to passive flexion after tight collateral ligaments have been released.

Painful resistance to passive PIP joint flexion may indicate volar plate injury (volar plate test).[6] Pain results from synovial involvement, and the most common cause is volar plate avulsion with or without a small bone fragment torn from the base of the middle phalanx. Positive volar plate test at 6–9 months following injury indicates that volar plate repair of the middle phalanx may be necessary.

Transverse retinacular ligaments

Transverse retinacular ligaments may be adherent to the lateral capsular ligament at the PIP joint.

Flexor tendon adherence

Flexor tendon adherence within the sheath may be sufficiently bulky to block full flexion of the interphalangeal joint.

Bone

This may be a true block or result from intraarticular incongruity. Chondral fractures may not be radiographically apparent and so may present a diagnostic problem (Fig. 21.3). Persistent waxing and waning joint swelling with limited flexion may result from a chondral fracture, which is more likely at the MP joint. Questioning the patient may lead to recollection of an injury that could have caused the proximal phalangeal base to impinge on the metacarpal head. Surgical exploration may reveal the chondral fracture and consequent loose body in the joint. Computed tomography scanning may help in arriving at the correct diagnosis.

Seesaw effect

This results when a contractural element spans two joints. Presence of this sign helps in the diagnosis of structures that potentially contribute to a stiff joint.[7] If one joint in a contracted system is flexed, the other joint can then be extended, and vice versa. This is seen, for example, when a longitudinal volar skin scar crosses both proximal and distal interphalangeal joints. The distal interphalangeal (DIP) joint can be extended only if the PIP joint is flexed. A similar effect is seen with adherent extrinsic flexor or extensor tendons (Fig. 21.4). For example, flexion of MP joints in the presence of a flexor tendon adhesion over the proximal phalanx has no effect on the flexion contracture of the PIP joint. If the adhesion lies proximal to the MP joint, flexion of that joint results in correction of the contracture apparently present in the PIP joint. Furthermore, with flexor tendon adhesions, passive flexion of the affected joint exceeds active flexion, provided the extensor tendon is healthy. Similarly, in the presence of a Volkmann contracture of the flexors in the forearm, passive extension of the finger joints is reduced with the wrist extended and not if the wrist is flexed.

If the extrinsic extensor tendon is adherent to the metacarpal, the limitation of extensor tendon excursion distal to that joint prevents simultaneous flexion of MP and PIP joints. This is the test for extrinsic tightness (Fig. 21.5A).[8,9] The test of Bunnell for intrinsic tightness results from the seesaw phenomenon in which the band acts across two joints but is an extensor of one joint and a flexor of the adjacent joint.[10] If the intrinsic musculotendinous system is foreshortened,

Fig. 21.3 **(A)** This patient had an osteochondral fracture involving the metacarpal head after a finger "jam" and presented with inability to flex at the metacarpophalangeal joint and joint swelling. The fracture involved about one-third of the articular surface but was still attached by a single collateral ligament. **(B)** Bone fixation restored perfect joint function.

extension of the MP joint, either actively or passively, increases the tone in the system and restrains flexion of the PIP joint. This is tested by passively extending the MP joint and passively flexing the PIP joint (Fig. 21.5B). If flexion of the PIP joint is greater when the MP joint is flexed than when it is extended, intrinsic tightness is present. In the swan-neck deformity, not only is there an extension contracture of the PIP joint, but that joint hyperextends because of volar plate laxity. There is dorsal displacement of the lateral bands at the PIP joint. This slackens the distal tension on the extensor mechanism because of the fixed attachment of the central tendon at the PIP joint. Thus there is unopposed force of the flexor digitorum profundus at the distal joint, which then drops into flexion (Fig. 21.6A).[9]

A similar volar to dorsal seesaw effect occurs at the DIP joint secondary to action of the oblique retinacular ligament

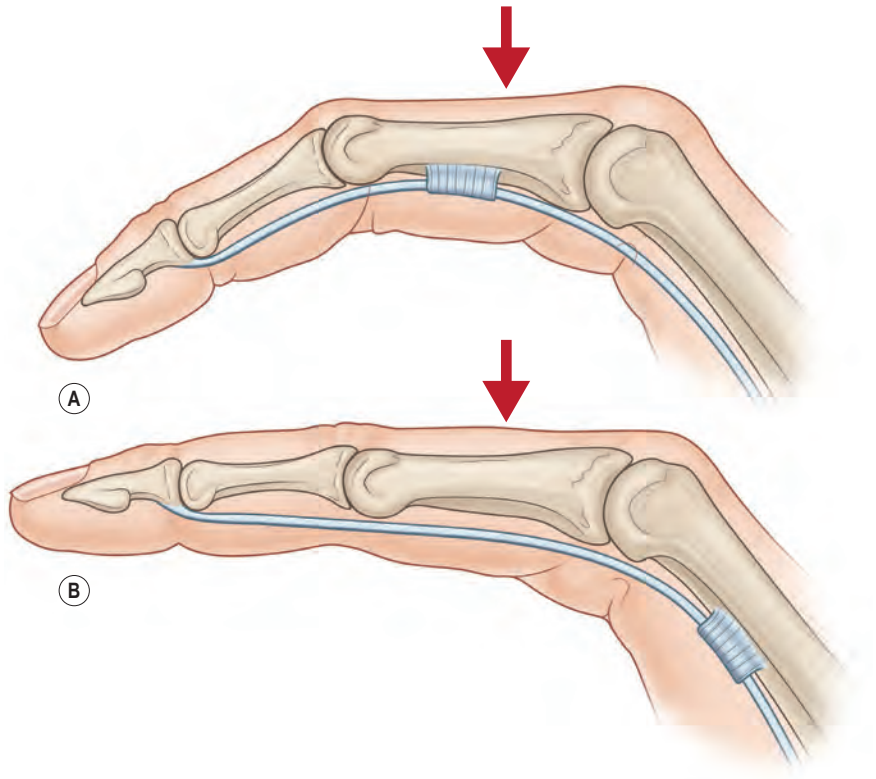

Fig. 21.4 By adjusting the joints proximal to the joint that appears to be the cause of the contracture, the primary problem may be revealed. **(A)** If a patient has a proximal interphalangeal (PIP) flexion contracture, flexion of the metacarpophalangeal (MP) joint in the presence of flexor tendon adhesion at the proximal phalanx has no effect on the PIP flexion contracture. **(B)** If the flexor tendon adhesion is proximal to the MP joint, flexion of that joint will result in correction of the PIP joint contracture.

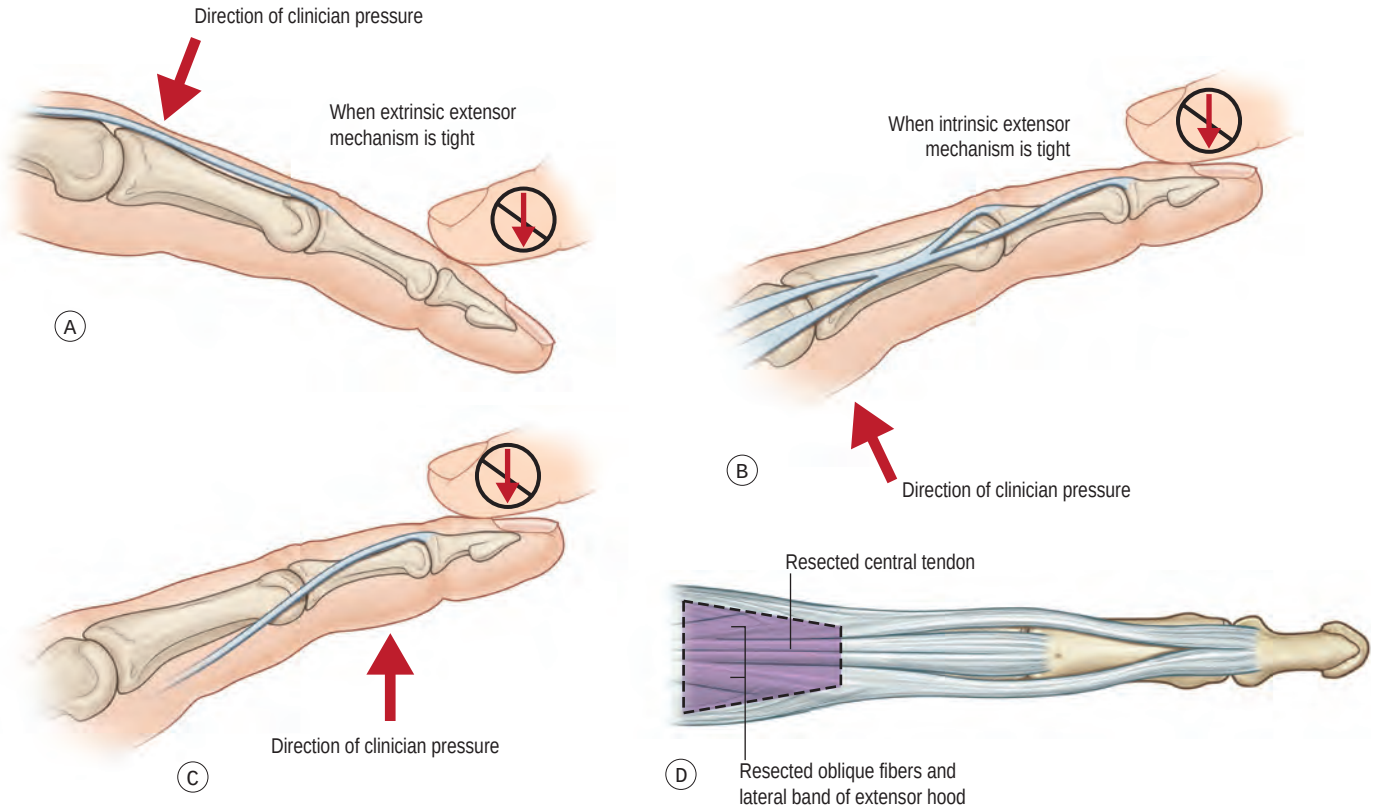

Fig. 21.5 **(A)** Test for extrinsic tightness. When the metacarpophalangeal (MP) joint is flexed (arrow), passive proximal interphalangeal (PIP) joint flexion is increasingly difficult. **(B)** Test for intrinsic tightness. When the MP joint is extended (arrow), passive PIP joint flexion is more difficult. **(C)** Boutonnière test. The oblique retinacular ligament is foreshortened so that when the PIP joint is extended (arrow), passive DIP joint flexion is difficult. **(D)** Central slip tendon excision is performed for extrinsic extensor tightness and wing tendon excision (oblique fibers and lateral bands) for intrinsic tightness – either of which might cause PIP hyperextension.

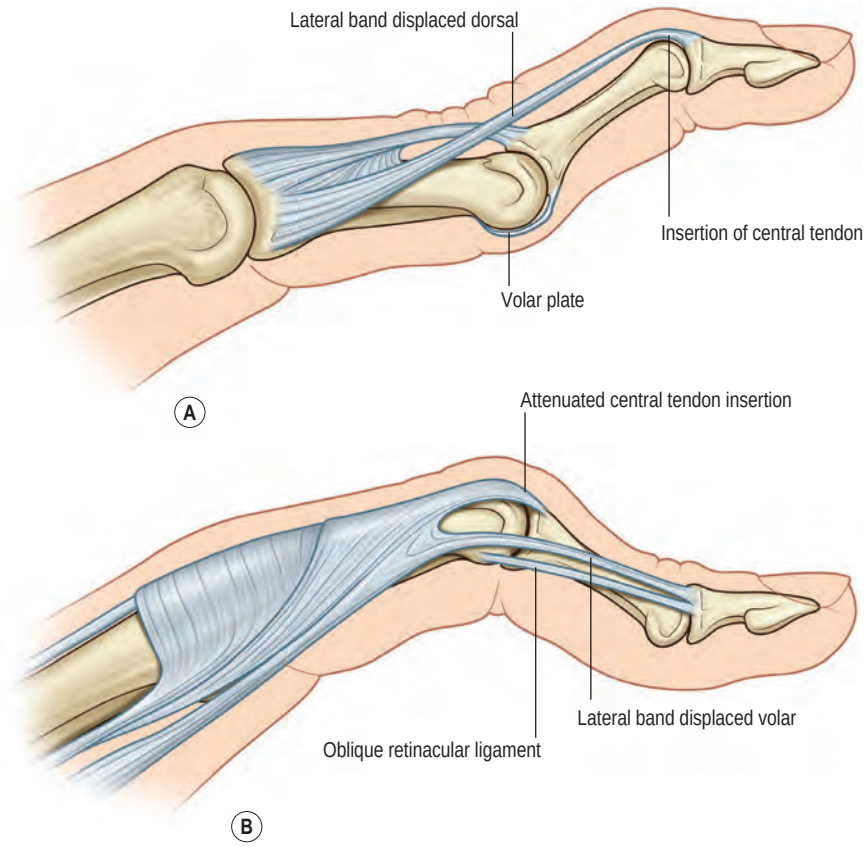

Fig. 21.6 **(A)** Swan-neck deformity with hyperextension at the proximal interphalangeal (PIP) joint. Dorsal displacement of the lateral bands slackens distal extensor tension, and so the unopposed flexor digitorum profundus draws the distal interphalangeal (DIP) joint into flexion. **(B)** Boutonnière deformity. The PIP joint drops into flexion because of central slip attenuation, and the lateral bands move volar. Excess extensor pull bypasses the PIP joint and hyperextends the DIP joint. The oblique retinacular ligament foreshortens.

and lateral bands, resulting in extension contracture at that joint. This occurs with the boutonnière deformity. When the central tendon insertion into the dorsal base of the middle phalanx ruptures or attenuates, the PIP joint drops into flexion and the lateral bands move volar to the axis of motion of that joint.[11] They will foreshorten and adhere in that position. Excess extensor pull that secondarily bypasses the PIP joint is imposed dorsally at the DIP joint with consequent recurvature at that joint (Fig. 21.6B). The oblique retinacular ligament is an extensor of the DIP joint and a flexor of the PIP joint.[11] It also foreshortens and this permits the DIP joint to be flexed as long as the PIP joint is maintained in flexion. Passively extending the PIP joint brings the DIP joint into extension, making passive flexion increasingly more difficult. This maneuver is the boutonnière test (Fig. 21.5C).

Volar plate and collateral ligament changes

Changes in the volar plate and collateral ligaments occur with flexion contractures. Flexion and extension contractures can occur at the PIP joint. In contrast, at the MP joints, extension contractures occur, but flexion contracture is rare due to volar plate and collateral ligament anatomy. The volar plate at MP joints is different anatomically from that of interphalangeal joints.

The protected position of MP joints is in flexion. The cam and volar flare shape of the metacarpal head places collateral ligaments in greatest tension during flexion (Fig. 21.7). The MP joint volar plate has crisscrossing bands of fibers that expand with joint extension and are collapsible with flexion.[6] Thus, the volar plate at the MP joint is considerably longer in extension than in flexion (Fig. 21.8A).

In contrast, the interphalangeal joint collateral ligaments do not change in tightness with joint flexion and extension. The volar plate is relatively uncollapsible. Rather, the volar plate slides proximally and distally with flexion and extension of the joint (Fig. 21.8B). The volar plate is not attached to the proximal phalanx as this would prevent full extension. The assembly lines are the two ridges on the volar lateral surfaces of the phalanx to which are attached the flexor sheath, Cleland ligaments, Grayson ligaments, oblique retinacular ligaments, and transverse retinacular ligaments, and the transverse metacarpal ligament and MP joint volar plate more proximally. Normally, there is no ligament structure between the volar plate of the PIP joint and the assembly line or extension of that joint would not be possible. Two bands (checkreins)[6,12,13] form between the lateral proximal volar plate and the assembly lines after injury. These are pathologic structures (Fig. 21.9). They are thicker at the base attached to the volar plate and have a thinner, longer proximal apex attached to the assembly line. The communicating artery of the vincula system passes deep to the checkreins. With interphalangeal joint contracture, it is the checkreins that mainly prevent extension. Division of these checkreins and accessory collateral ligaments enables extension at the interphalangeal joint to be achieved when surgery is required. It is virtually never necessary to divide collateral ligaments.

Clinical tips

Post-traumatic contractures

- Dorsal hand edema
- Negative hand position driven by hydraulic MP joint fluid accumulation
- Reciprocal tone in tendons
  - Wrist flexed, finger MP extended
  - Finger MP extended, PIP flexed
- Fixed extension at MP and fixed flexion at PIP with time
- MP collaterals and PIP volar plate tight

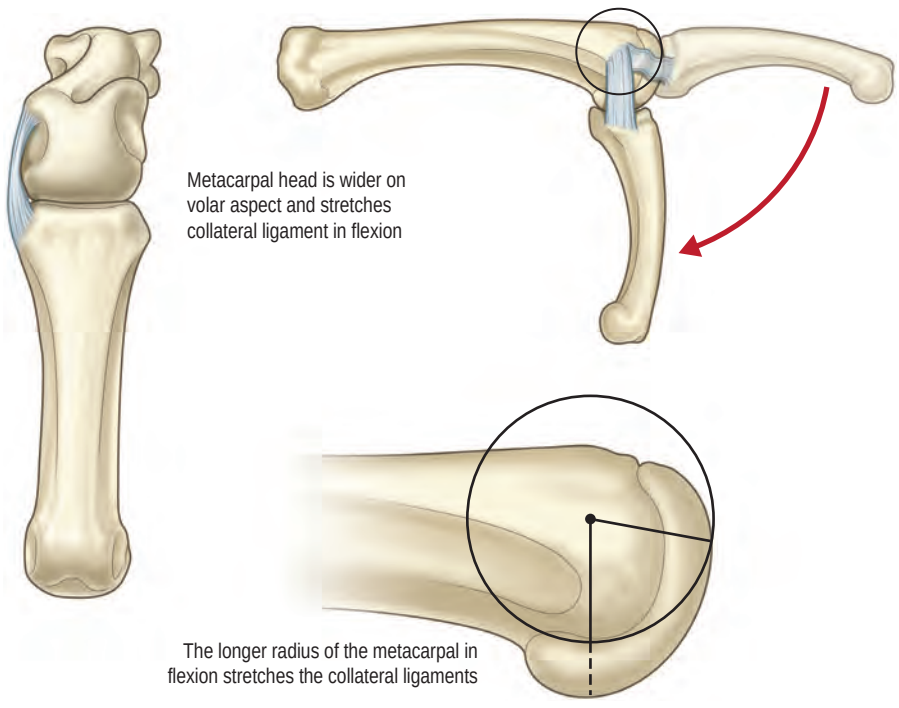

Fig. 21.7 Cam-like action of the collateral ligaments at the metacarpophalangeal (MP) joint. Collateral ligaments are in greatest tension during flexion because of the cam and volar flare shape of the metacarpal head.

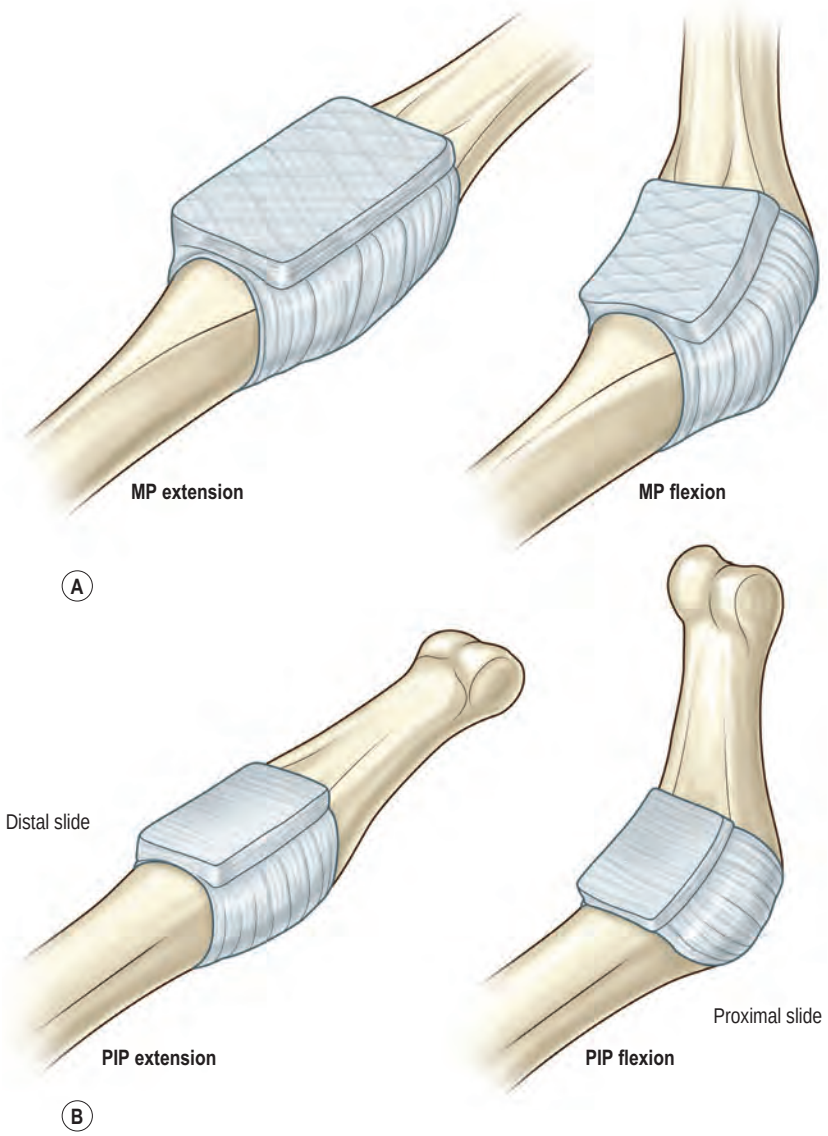

Fig. 21.8 (A) Crisscrossing bands of fibers make up the metacarpophalangeal (MP) joint volar plate, and these allow expansion with joint extension. **(B)** The volar plate at the proximal interphalangeal (PIP) joint is relatively uncollapsible. In contrast to the MP joint, the PIP volar plate slides proximally and distally with joint flexion and extension.

Basic science/disease process

Injury, infection, excessive immobilization, and inappropriate splinting of the hand all predispose to joint stiffness. The initial response to any insult of the hand is edema formation. Unless edema accumulation is prevented, joints assume the posture in which their ligaments are most relaxed.[1,14,15] Ligament contracture and fibrosis then cause joints to become immobile in this abnormal position (Fig. 21.10), which is:

- Wrist: flexion
- Thumb: adduction
- MP joint: extension
- PIP joint: flexion.

This is the negative or injured hand position; wrist position and MP joint posture are the keys to its development. When the wrist is allowed to flex, increased tone in the extrinsic extensor tendons causes MP joints to extend. When nearly fully extended, the MP joint has maximum capsule and collateral ligament laxity as well as intracapsular fluid capacity. When the MP joint is fully flexed, intracapsular fluid capacity is minimal and the ligaments are taut. After injury, edema fluid drives the MP joints hydraulically into extension. In this position, tension is increased in the flexors and decreased in the extensors. Thus, fingers flex at PIP and DIP joints. There is no hydraulic drive at PIP or DIP joints because there is only minimal change in collateral ligament tightness and fluid capacity of flexed versus extended interphalangeal joints. Positional changes in interphalangeal joints are thus secondary to changes in MP joints. Slight wrist flexion occurs in the neglected edematous hand because total power of flexors exceeds the extensors.[16] Post-burn claw contractures from dorsal hand burns similarly drive the MP joints into fixed extension and the PIP joints into flexion. Thus, the traumatized hand, susceptible to joint stiffness, must be appropriately immobilized by placing it in the intrinsic plus position with MP joints in flexion and interphalangeal joints in extension.

Patient selection

These measures may be more effective early on after the injury during the edema phase and subsequent collagen phase of

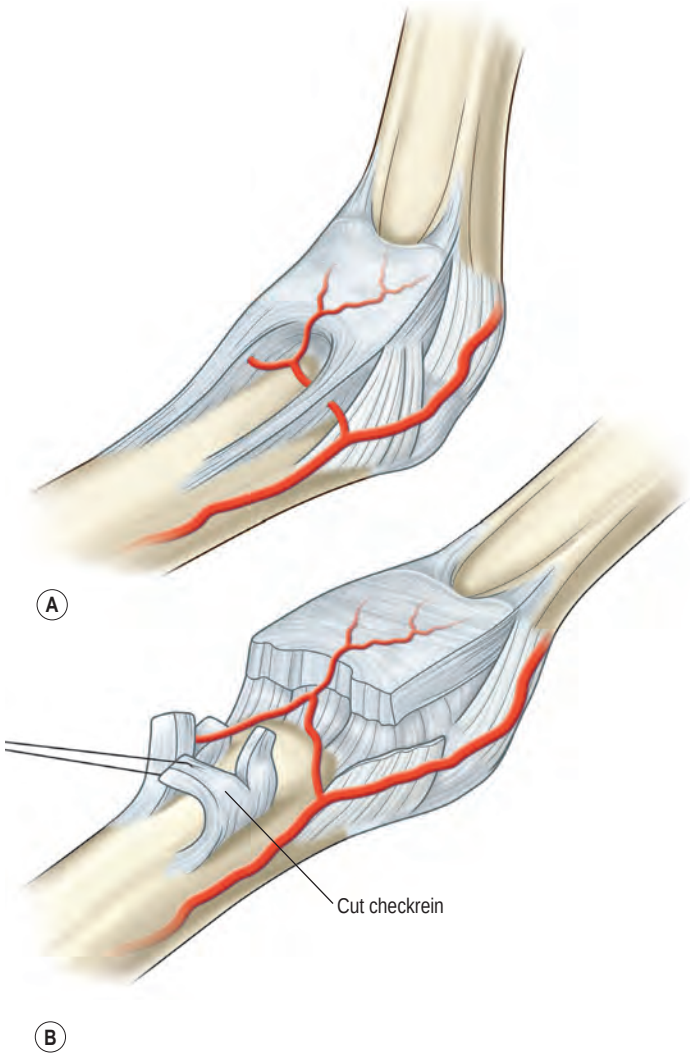

Fig. 21.9 **(A)** Checkreins are attached by a broad base to the volar plate, and a tapering apex is attached to the assembly line. **(B)** Release of the proximal interphalangeal (PIP) flexion contracture requires excision of the checkreins, with care taken not to injure the transverse communicating vessel between the two digital arteries.

wound healing, when fluid can be displaced and collagen remodeled. Once a scar and fibrosis have reached maturity, it is less likely to respond to non-operative measures. These measures include splinting. Other hand therapy endeavors such as edema reduction (by extremity elevation and compression gloves), moist heat, and ultrasound may enhance the beneficial response achieved by splinting.[17] Splinting involves the application of a non-elastic force in the direction of the desired correction. Initial splinting displaces tissue fluid during 5–12 min. This is the rapid gain phase of splinting. Only once this tissue edema has been displaced can the external forces of the splint result in collagen remodeling. Rapid deformity recurrence after a period of splinting should not discourage the patient because this is due to redistribution of tissue fluid originally displaced by exercise. Only if prolonged, will splinting eventually have the desired effect on collagen.[18] As weeks pass, patients notice that less time and force are necessary to achieve the desired result and that the finger returns to its contracted position more slowly and less severely after splint removal. Finally, active muscle contraction may be able to achieve complete joint range of motion, and the patient may then experience only morning stiffness that finally progressively resolves.

For PIP joint flexion contractures, the patient may wear a nighttime progressive static splint (Fig. 21.11). With a Joint Jack (Joint Jack Company, Glastonbury, CT), the patient tightens the screw every 2 or 3 min as tolerated, starting 1 h before bedtime. The screw can then be loosened half a turn at bedtime for comfort. A Joint-Jack may be difficult to keep in position on the little finger because its proximal base tends to rock off the ulnar border of the palm. In that case, a custom palm-based thermoplastic splint with Velcro straps that can be tightened over the PIP joint may be appropriate. High compression foam built into the brace supports the distal phalanx. For PIP joint flexion contractures of more than 60°, these splints may be inappropriate because they will place undue extension stress on the DIP joint. These splints must be fitted with care to avoid hyperextension stress at the DIP joint. The volar distal pressure should be on the volar plate of the DIP joint and not at the fingertip. Splints such as Wire-Foam finger extension splints (DeRoyal LMB Hand Rehab Products, San Luis Obispo, CA) are less bulky and may be more acceptable for daytime use by the active patient. Serial finger casting, with a new cast replaced every 3 days, may be helpful in a difficult, seemingly unresponsive case or when PIP joint flexion is >60°.

PIP joint extension contractures rarely occur as pure joint contractures. They nearly always involve structures other than joint capsule, such as extensor mechanism adhesions. A joint strap may be placed around the middle phalanx and the finger positioned in maximum passive flexion (Fig. 21.12). With time, the strap is tightened to increase flexion. Snug Coban wrapping about the palm and finger can accomplish the same objective.

A variety of flexion splints are available that place a static flexion force across MP joints when there are extension contractures at those joints. One such chronic progressive flexion splint is the Knuckle-Jack splint (Joint-Jack Company, East Hartford, CT).[7]

Treatment/surgical technique

PIP joint flexion contracture of more than 70° is unlikely to respond effectively to non-operative therapy alone. Furthermore, once a plateau in improvement has been reached with non-operative measures and there is still a functionally impairing residual deformity, surgery is indicated. Radiographic changes within a joint or an obstructing bone block may also persuade one to undertake surgery. Once swelling has resolved, and if the joint range of motion reaches an abrupt stop rather than having a gradual increase in resistance to passive motion, clinical judgment would make one believe that maximum benefit has been reached from splinting.

PIP joint flexion contracture

It is important to first evaluate whether there is shortage of skin. Prolonged joint contracture, even without soft-tissue scar, may result in longitudinal shortening of soft tissues. One may decide to make a mid-volar longitudinal incision that is broken up into multiple Z-plasties as the access incision. For

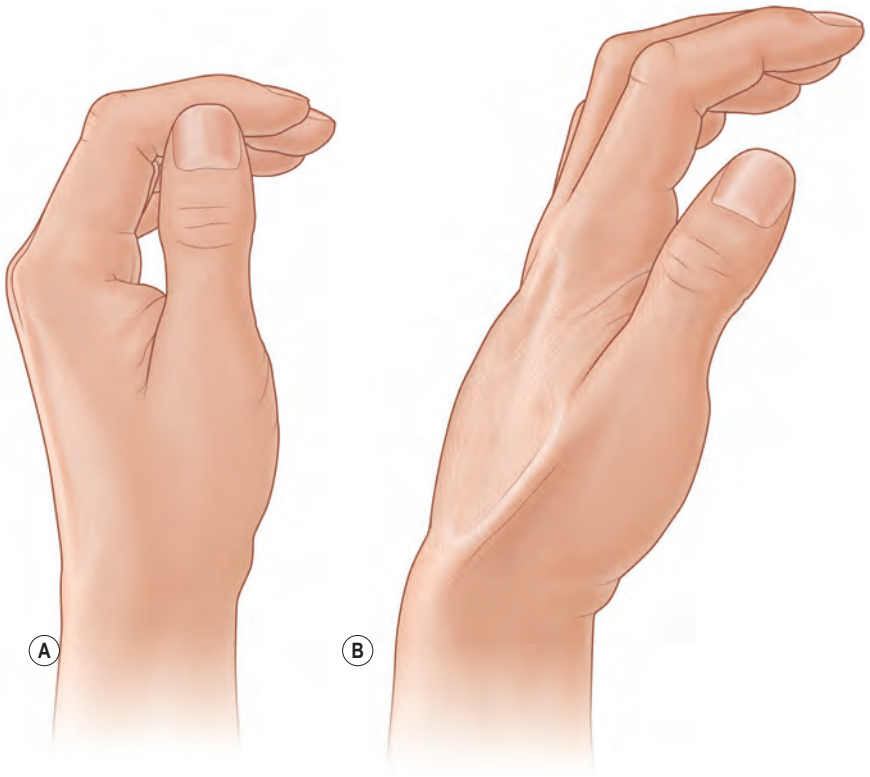

Fig. 21.10 **(A)** Posture of the relaxed uninjured hand. **(B)** Edema accumulates in the available space on the dorsum of the injured hand, drawing the wrist into flexion, the metacarpophalangeal joints into hyperextension, the proximal interphalangeal joints into flexion, and the thumb into adduction.

severe accompanying soft-tissue contracture, a transposition flap from the dorsolateral surface of the homolateral digit (Joshi flap)[19] (Fig. 21.13) or cross-finger flap from an adjacent finger, or homodigital island flap may be planned.[20] If there is no soft-tissue deficit, any conventional volar zigzag type surgical approach may be used.[21]

Shortened checkrein ligaments are the primary abnormality.[12,13] If a flexor tendon injury was the initiating event, a flexor tenolysis or secondary repair may be required. The flexor sheath just distal to the A2 pulley and the checkreins are cut free from their attachments to the proximal edge of the volar plate (see Fig. 21.9). Gentle passive extension may be required to break up other adhesions after checkrein resection to achieve full joint extension.

A "jumping" sensation is occasionally noted as the PIP joint is fully extended once checkrein release has been done. This is secondary to a cam effect of the collateral ligament and is relieved by cutting only the most dorsal fibers of both collateral ligaments.[6]

Tightness of the oblique retinacular ligaments may also contribute to the PIP joint flexion contracture, especially in association with DIP joint hyperextension in the boutonnière deformity. Transection of the oblique retinacular ligament is then indicated.

PIP joint extension contracture

A mid-dorsal longitudinal curvilinear surgical incision affords the luxury of not needing to close the entire incision proximally or distally, provided an adequate soft-tissue flap covers the extensor mechanism. In this way, soft-tissue closure will not limit the flexion achieved as a result of the joint release. A dorsolateral skin incision may also adequately expose the extensor hood.

The transverse retinacular ligament fibers are divided and the lateral band is elevated while the central slip insertion is preserved.[2,6] The dorsal joint capsule is incised and the joint passively flexed. Extensor tendon adhesions to the dorsum of the proximal phalanx are released. If the jump phenomenon occurs after dorsal capsulotomy, the most dorsal fibers of both collateral ligaments are cut until there is no residual jumping. In the presence of severe intra-articular fibrosis, both collateral ligaments may need to be divided and a small dissector used to free volar plate adhesions (without detaching the volar plate from its distal insertion).

Partial resection of the appropriate portion of the extensor mechanism in carefully selected cases is helpful in those patients who have intrinsic tightness or extrinsic extensor tendon tightness (see Fig. 21.5). In patients with extrinsic extensor tightness, the central tendon portion is resected. In those with intrinsic tightness, only the lateral bands and oblique fibers of the extensor hood are resected.[22] Sagittal band fibers are left intact because they are the prime method through which extension is transmitted to the MP joint from the extensor mechanism

Once the finger has been stiff in extension, the flexor tendons frequently become adherent in their bed. The operator should return and check function of these tendons by making a counterincision in the palm or forearm.[2,6] By placement of traction on the flexors, the fingers should fully flex. Failure for this to occur necessitates performance of a flexor tenolysis as well. An excellent method of anesthesia administration when performing a tenolysis, is to use the tumescent technique of local anesthesia infiltration using a mixture of

lidocaine with epinephrine added. This enables the so-called "wide-awake" method of local anesthetic infiltration, avoiding the paralytic effects of prolonged tourniquet ischemia or of a regional block, and ensuring full cooperation of the patient. The end-point of the tenolysis or joint release is achieved only when the patient can actively reproduce normal function on the operating table.[23]

MP joint extension contracture

A longitudinal dorsal skin incision is used. Sagittal band hood fibers are retracted distally and the dorsal capsule is transected.[2,6,24] As the joint is flexed passively, one may note that the tight collateral ligament cannot pass over the condyles on the volar aspect of the metacarpal head. In such circumstances, it is necessary to transect the collateral ligaments proximally at their attachments to the metacarpal head. It may be necessary, as with extension contractures of the PIP joint, to free volar plate adhesions by inserting a blunt dissector into the volar plate pocket dorsal to that structure. If the jump phenomenon is encountered, it is managed in a fashion similar to that of the PIP joints.

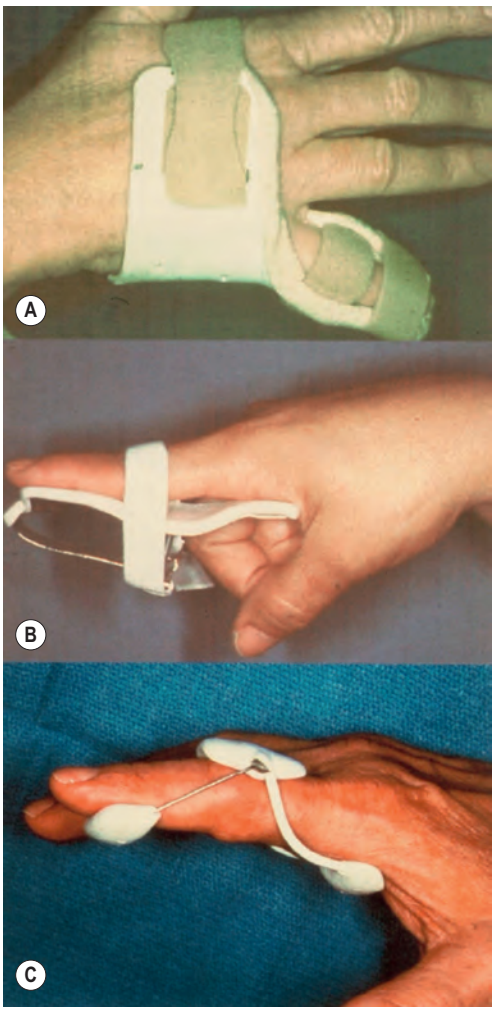

Fig. 21.11 **(A)** Custom palm-based night proximal interphalangeal (PIP) extension splint. **(B)** Joint Jack splint. **(C)** Wire-Foam PIP extension splint.

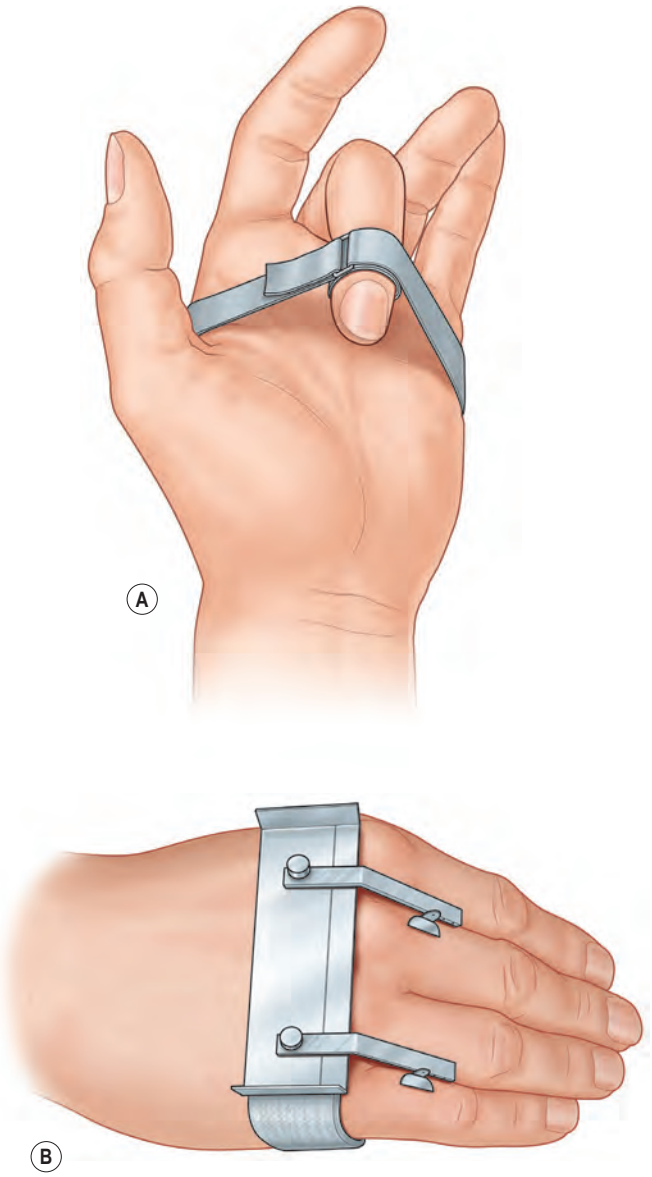

Fig. 21.12 A flexion strap can be progressively tightened around the hand and finger for treatment of a proximal interphalangeal joint extension contracture.

Postoperative care

Extremity elevation reduces postoperative edema. A postoperative splint applied during the first week maintains the restored joint position. Thereafter, active mobilization is begun. Daily application of splints as well as a continuous night splinting is sometimes necessary for several weeks to months postoperatively to help minimize the risk of contracture recurrence. Continuous passive motion (CPM) may be a useful modality to maintain joint motion but it is not a substitute for maintaining active motion and tendon gliding and excursion.

Outcomes, prognosis, and complications

Full extension of PIP joint flexion contractures after operative release occurs in 96% of cases.[12,13] There is frequently relapse,

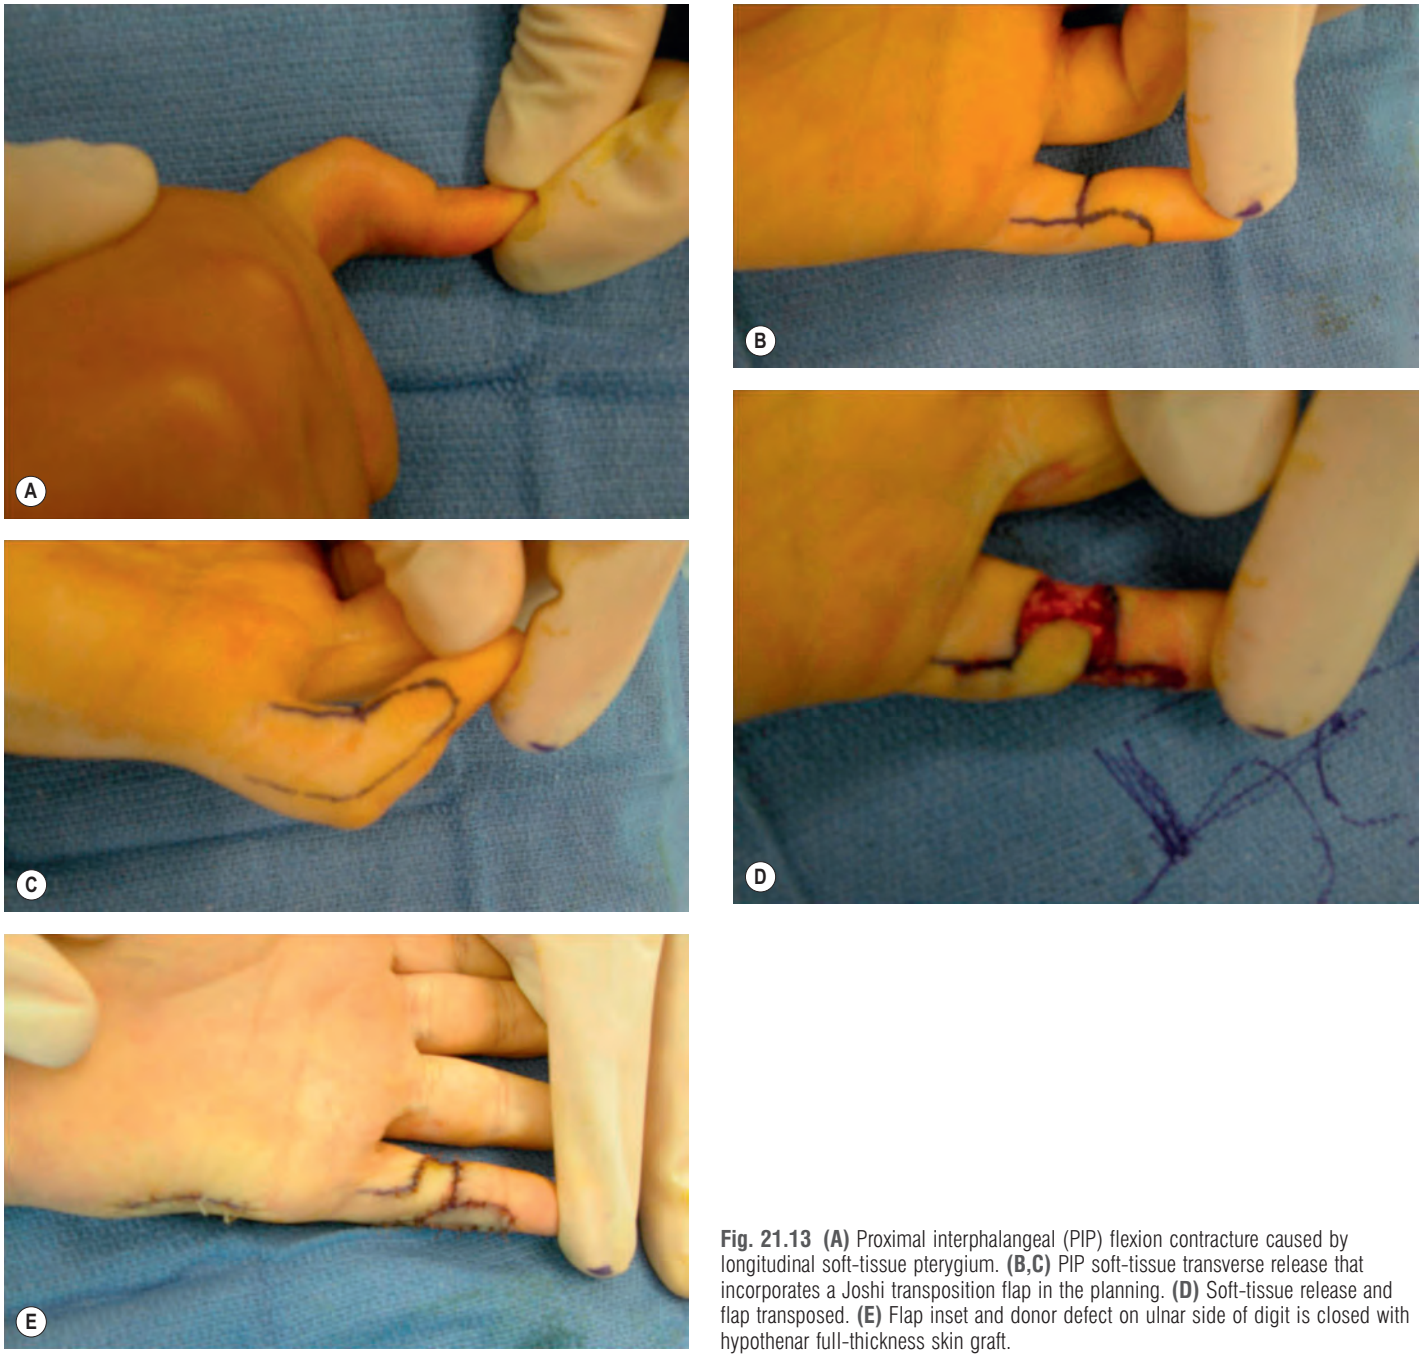

Fig. 21.13 **(A)** Proximal interphalangeal (PIP) flexion contracture caused by longitudinal soft-tissue pterygium. **(B,C)** PIP soft-tissue transverse release that incorporates a Joshi transposition flap in the planning. **(D)** Soft-tissue release and flap transposed. **(E)** Flap inset and donor defect on ulnar side of digit is closed with hypothenar full-thickness skin graft.

though not complete recurrence, of the deformity despite adequate release and good postoperative management. After PIP joint flexion contracture release in patients with Dupuytren contractures, there is reported relapse in those with severe contractures from a preoperative mean of 78° to a postoperative mean of 36°.[25] With severe PIP flexion contractures, one can seldom expect to regain normal extension, although the deformity can be improved.

Neurovascular injury may occur during surgical release. However, even if there has not been a sharp injury to the digital neurovascular structures, ischemia to the finger may result from neurovascular overstretch when the finger has been previously flexed for a long time. Skin flaps may be thin and ischemic and develop postoperative necrosis. Necrotic skin flaps may leave tendons and their sheaths exposed and in danger of desiccation, necessitating secondary soft-tissue reconstruction. Skin flap marginal necrosis may also lead to secondary wound healing and adverse scarring with relapse of contractures.

Excessive and unwarranted attempts at release of the volar plates, accessory collateral ligaments, and collateral ligaments, and use of excessive passive extending force in treatment of PIP joint flexion contracture may result in the joint subluxing into hyperextension. This results in a significant postoperative problem and the finger must then be held in a flexed position until adequate scarring heals the torn ligaments.

Cartilage necrosis may result at the distal end of the proximal phalanx when it is brought into full extension from a flexed position because of excessive pressure now applied on the fully extended joint surface.[26] Risk of overstretched neurovascular ischemia and cartilage necrosis may be heightened if a Kirschner wire has been used to temporarily fix the PIP joint in extension to maintain the contracture release.

A hyperextending force of the DIP joint by an improperly placed Joint Jack splint that applies excessive pressure on the fingertip may cause iatrogenic functional problems at the DIP joint. Dysesthesias to the fingertip, stiffness in both flexion and extension, and reflex sympathetic dystrophy are potential complications of contracture release.

Secondary procedures

A relapse of a functionally impairing PIP joint flexion contracture may necessitate disarticulation amputation at the PIP joint or bone shortening at the PIP joint arthrodesis site with fusion in a more favorable position. Either of these two options may be considered in the primary treatment of the patient who is too frail to undergo any other surgical management or the patient who lacks the motivation needed for successful postoperative management. The patient who is a heavy smoker and has a longstanding severe flexion contracture (more than 70°) of the PIP joint may also potentially be best served by PIP joint disarticulation amputation or perhaps fusion.

Table 21.1 House functional classification for cerebral palsy

Grade	Designation	Activity level
0	Does not use	Does not use
1	Poor passive assist	Uses as stabilizing weight only
2	Fair passive assist	Can hold onto object placed in hand
3	Good passive assist	Can hold onto object and stabilize it for use by other hand
4	Poor active assist	Can actively grasp object and hold it weakly
5	Fair active assist	Can actively grasp object and stabilize it well
6	Good active assist	Can actively grasp an object and then manipulate it against other hand
7	Spontaneous use, partial	Can perform bimanual activities easily and occasionally uses the hand spontaneously
8	Spontaneous use, complete	Uses hand completely independently without reference to the other hand

The spastic hand in cerebral palsy

Diagnosis/patient presentation

Treatment of cerebral palsy necessitates accurate assessment of the clinical problem, non-surgical modalities, as well as surgical treatment. Overall upper extremity function is classified by the nine-level House activity scale (Table 21.1).[27] Surgical intervention has been shown to improve limb function by 2.6 functional levels.

Patient selection

The age of the patient is important and the child should be at least 6 or 7 years old to cooperate with the preoperative assessment and postoperative therapy. The type of palsy is important and may be spastic, ataxic, or choreoathetotic. The last is a contraindication to tendon transfers. Surgery for athetoid patients usually will involve only joint stabilization through fusions such as at the MP joint of the thumb. The patients who derive the most benefit from surgery usually have spastic hemiparesis.[28] A hand with poor sensibility is less likely to be used after reconstructive surgery. Some believe that an intelligence quotient of >70 is desirable if surgery is contemplated, but others feel that intellect is less important.[29,30]

Non-surgical treatment

Non-surgical modalities include splinting, occupational therapy, and pharmacologic intervention. Splinting may help prevent joint contractures. This requires a high level of compliance from patients and caregivers. It may also be a necessary component of postoperative management. Many medications have been used, some of which have significant adverse drug reactions. The most commonly used are intramuscular injection of botulinum toxin A and intrathecal baclofen. Botulinum toxin injection relaxes muscles that may then be responsive to splinting and stretching in therapy.

Surgical technique

The typical spastic posture of the upper limb includes shoulder internal rotation, elbow flexion, forearm pronation, wrist flexion and ulnar deviation, thumb-in-palm, and clenched fist (Fig. 21.14). A thorough preoperative analysis of the pattern of spasticity is required and an assessment of joint contractures that may need to be released. Assessment of passive range of motion must be done slowly to overcome muscle spasticity. Joint contractures are assessed by evaluating particular muscles. Thus, positioning the wrist joint in flexion will allow passive finger extension if there is no joint contracture.

Spastic muscles need to be either released or weakened by lengthening to correct muscle imbalance around joints. At the wrist, there is usually poor volitional control of extensor carpi radialis longus, extensor carpi radialis brevis (ECRB), and extensor carpi ulnaris (ECU) and there is spastic overpull of flexor carpi radialis (FCR) and flexor carpi ulnaris (FCU). One next assesses which muscles are weak or have poor motor control. These flaccid muscles need to be augmented by tendon transfer. Finally, assess which muscles are available for transfer. Those under good voluntary control are the best for tendon transfer, though transfer of a spastic muscle may

Fig. 21.14 Typical spastic hemiplegic posture of the upper extremity shows shoulder internal rotation, elbow flexion, forearm pronation, wrist flexion and ulnar deviation, thumb-in-palm, and clenched fist deformities.

weaken the overpowered side and utilize it to strengthen the weaker side of the unbalanced joint. Severe joint contractures or joint instability may necessitate joint fusion.

Surgical treatment options by type of deformity

Shoulder

Shoulder surgery is rarely indicated. Occasionally, Z-lengthening of pectoralis major through a deltopectoral incision is done together with Z-lengthening of the subscapularis (or simple division by myotomy or recession from the scapula, which maintains subscapularis integrity) may be necessary. With a tight adduction contracture, there may be a soft-tissue deficit requiring flap reconstruction (although this is more frequently necessary with tight shoulder adduction contractures that may occur with spastic post-traumatic or stroke brain injury). Latissimus dorsi and teres major transfer to the posterolateral humerus at the greater tuberosity is seldom required, as is an external rotational humeral osteotomy.

Elbow

Mild flexion contractures may be improved simply by the necessary surgical procedures directed towards forearm pronation and wrist flexion (flexor–pronator muscle slide; or flexor aponeurotic release (FAR)) as these muscles cross the elbow. More significant flexion contractures (usually >40° or 50°) demand attention to biceps, brachialis, and possibly brachioradialis. Antecubital soft-tissue paucity may become apparent after the release, necessitating Z-plasty or even a flap (Fig. 21.15). If brachioradialis needs to be released, this can be done distally and the muscle turned up into the antecubital fossa for wound coverage and a skin graft placed over it.

Lacertus fibrosus is released and Z-lengthening of the biceps tendon done. If residual unacceptable contracture remains, then stepwise release of brachialis (which is weakened by intramuscular incision into the fibrous septae) and of the brachioradialis (either proximally or distally) is performed.[28,31] Less severe flexion contracture can be treated by fractional biceps tendon lengthening (a series of transverse step cuts in the tendon). This retains biceps strength better than Z-lengthening. Postoperative elbow extension splinting is done for 4 weeks, followed by progressive range of motion and intermittent extension splinting.

Forearm pronation

This deformity has been classified into four groups[28,32]:

- Group I: Active supination beyond neutral
- Group II: Active supination less than neutral
- Group III: No active supination; free passive supination, but with active pronator teres
- Group IV: No active supination; tight passive supination.

When treating the forearm pronation deformity in isolation, recommendations are: no surgery for group I; pronator quadratus release with or without FAR for group II; pronator teres release for group III, and pronator quadratus release and FAR for group IV. FAR consists of excision of a 2-cm transverse strip of fascia from the flexor–pronator mass as well as division of all fascial septae. This allows muscle fibers to be stretched, so releasing myostatic contracture without cutting tendons. Pronator teres re-routing involves taking down the distal insertion with a distal cuff of periosteum and then re-routing it through an interosseous membrane window and reattaching to the dorsoradial side of the radius with a suture anchor. Alternatively, a Z-tenotomy of pronator teres distal insertion is done, re-routing the distal segment around the radial side of the radius and reattaching the two ends.

However, often the forearm pronation deformity cannot be taken out of context with the wrist and finger flexion deformities. A flexor–pronator muscle slide used for the latter problems will often significantly improve forearm pronation, as will the Green FCU transfer for active wrist extension.[33]

Wrist flexion

It is important to note the amount of digital flexor tightness that is also present. Digital flexor tightness can be quantitated by measurement of the Volkmann angle (Fig. 21.16). The wrist is flexed with the digits held extended. Wrist is then passively extended as much as possible while keeping digits extended. Full wrist extension can be accomplished in the absence of flexor tendon tightness. With digital flexor contracture, the wrist cannot be extended to neutral. As digits are extended, with wrist extended, one can assess selective digital spasticity. When PIP joint extension is limited, flexor digitorum superficialis (FDS) spasticity is suspected (flexor digitorum

Fig. 21.15 **(A)** Release of an elbow flexion contracture often results in a soft-tissue antecubital defect. **(B,C)** A transposition fasciocutaneous flap will cover the exposed vital structures in the antecubital fossa and then the donor defect over the proximal forearm muscles can be replaced with a split-thickness skin graft. **(D)** Final elbow extension accomplished.

profundus (FDP) spasticity may also be present). If full PIP joint extension is possible, but DIP joints do not extend, FDP spasticity is present.

The Zancolli classification of active finger and wrist extension is helpful (Table 21.2).[34] In the patient with active wrist extension, spastic wrist flexion, and no significant digital flexor tightness, a FAR procedure along with fractional lengthening of the FCU, Z-lengthening of the FCR, and release of palmaris longus may be required. In contrast, the patient with flexed fingers, but relatively little spasticity of wrist flexors, may benefit from fractional lengthening of the involved finger flexors. If the fingers can be extended only with the wrist in moderate flexion, then one can perform wrist flexor releases and additional finger flexor fractional lengthening. However, a flexor–pronator muscle slide will address simultaneous wrist and finger flexion and the forearm pronation deformity (Fig. 21.17 and Video 21.1 ▶).

Clinical tips

Flexor–pronator slide

- Allows each muscle to slide distally differentially, with each finding its "new" place of attachment
- Identify and mobilize median and ulnar nerve first before commencing release.
- Anterior interosseous nerve and artery are "safely" reflected volarly.
- May need to divide origin of posterior interosseous artery for mobilization of the deepest fibers of FDS to middle and ring fingers
- Splint wrist and fingers for 5–6 weeks to allow muscles to attach at new sites of origin
- Continue night position splinting.
- Flexion strength may take some months to return.

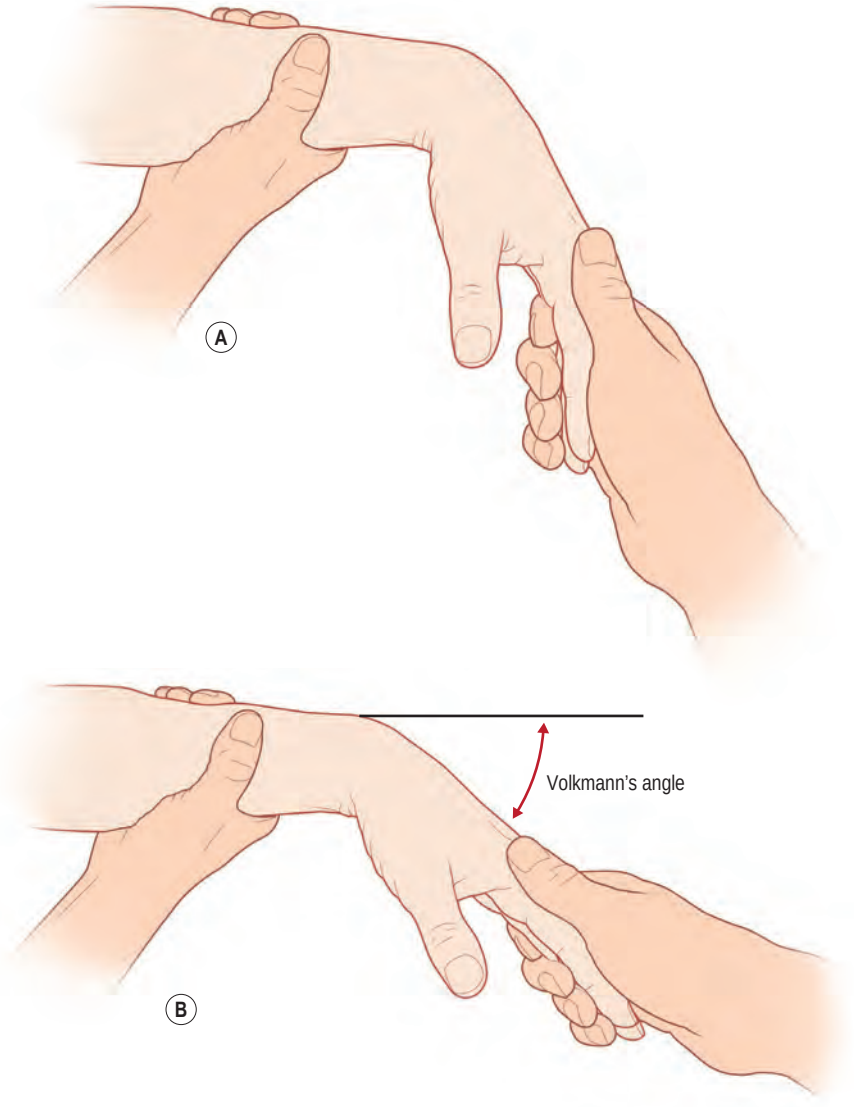

Fig. 21.16 Volkmann test for digital flexor tendon tightness. When wrist extension is less than neutral (Volkmann's angle), surgical intervention is indicated.

Table 21.2 **Zancolli classification of active finger and wrist extension**

Level	Designation	Description
1	Minimal flexion spasticity	Can completely extend the fingers with a neutral position of the wrist or with <20° of flexion
2	Moderate flexion spasticity	Fingers can be actively extended but only with >20° of flexion
2A		Can actively extend, partially or totally, the wrist with the fingers flexed
2B		Cannot actively extend the wrist with the fingers flexed because of flaccid paralysis of the wrist extensor muscles
3	Severe flexion spasticity	Cannot extend the fingers even with maximal flexion of the wrist

(Reproduced with permission from Zancolli EA, Zancolli ER Jr. Surgical management of the hemiplegia spastic hand in cerebral palsy. *Surg Clin North Am*. 1981;61:395–406.)

Only once the acute flexor spasm has been released is it possible to accurately assess if there is active wrist extension. This may be addressed by ECU transfer to ECRB or by brachioradialis transfer. Alternatively, the author has found that FCU can be transferred (and will have sufficient strength) several months after a flexor–pronator muscle slide has been performed. This may greatly improve grasp by removing the habitual grasp pattern of simultaneous wrist flexion. The fingers and wrist and elbow are splinted for 4 weeks postoperatively, with continued wrist splinting for another 6 weeks, and night positional splinting of the fingers.

Wrist fusion by proximal row carpectomy (PRC) and using those removed carpal bones for graft is reserved for very severe wrist flexion contractures (often with a non-functional hand). Shortening accomplished by PRC may reduce the need to shorten finger flexors.

Correction of wrist and finger flexion deformities may unmask intrinsic hand tightness. A simultaneous thenar release can be done through a curvilinear thenar incision (avoiding the median motor nerve branch), but the author prefers to address finger swan-neck deformities at a later date.

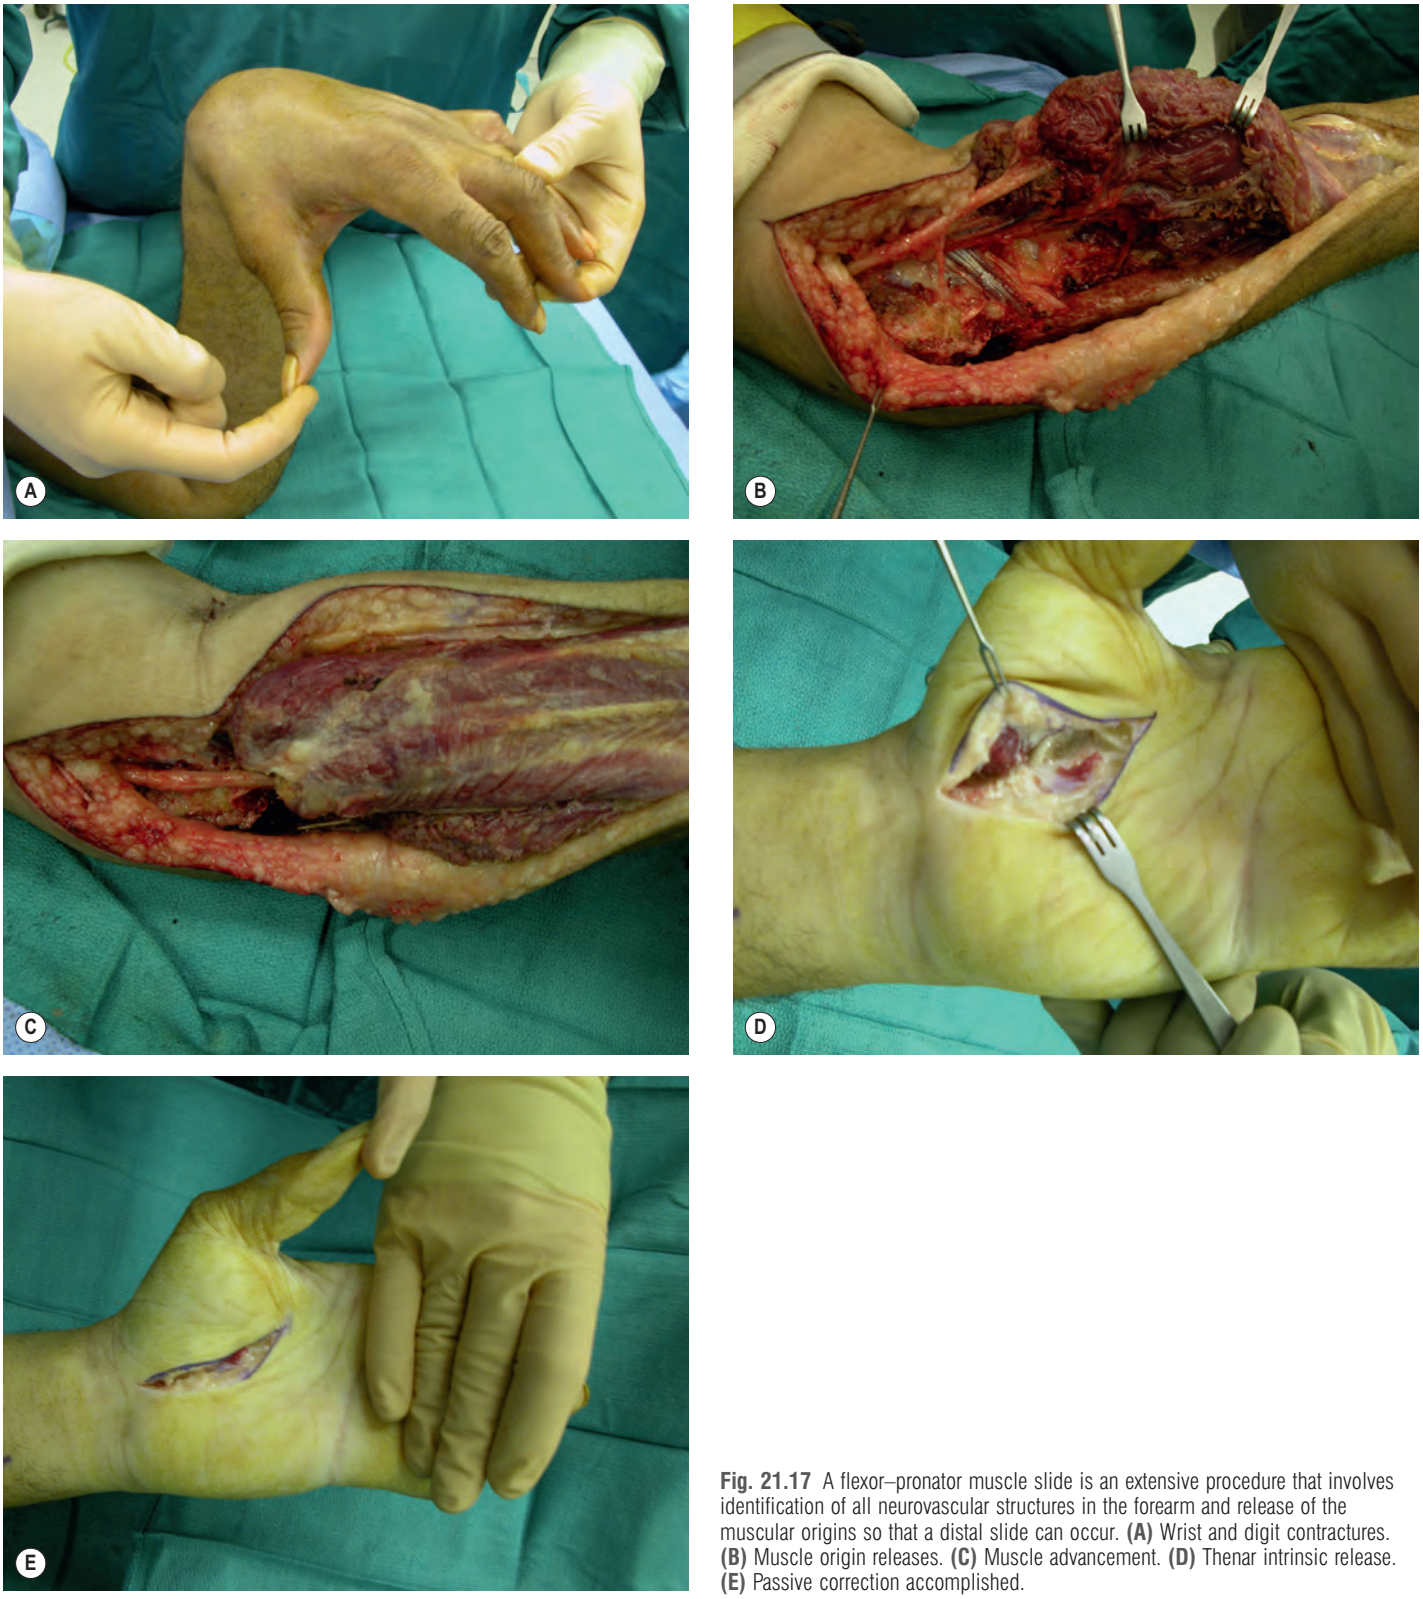

Fig. 21.17 A flexor–pronator muscle slide is an extensive procedure that involves identification of all neurovascular structures in the forearm and release of the muscular origins so that a distal slide can occur. **(A)** Wrist and digit contractures. **(B)** Muscle origin releases. **(C)** Muscle advancement. **(D)** Thenar intrinsic release. **(E)** Passive correction accomplished.

Thumb

Deformity as described by House and modified by Tonkin *et al*.[35] is a useful classification (Table 21.3). If the deformity is adduction without MP or IP joint deformity, then release of adductor pollicis is performed in conjunction with first webspace Z-plasty. Release of the dorsal fascia or even first dorsal interosseous release may also be required. If there is tight thumb adduction with MP joint flexion (without significant IP joint deformity), then also release the flexor pollicis brevis though the same incision.[36] If both MP and IP joints are flexed together with thumb adduction, then add flexor pollicis

Table 21.3 Modified House classification of thumb deformity

Type	Deforming forces	Thumb position
1. Intrinsic	Adductor pollicis 1st dorsal interosseous Flexor pollicis brevis	Metacarpal adduction MCP joint flexion IP joint extension
2. Extrinsic	Flexor pollicis longus	MCP joint flexion IP joint flexion Metacarpal adduction less marked
3. Combined	Adductor pollicis 1st dorsal interosseous Flexor pollicis brevis Flexor pollicis longus	Metacarpal adduction MCP joint flexion IP joint flexion (True "thumb-in-palm" deformity)

MCP, Metacarpophalangeal; IP, interphalangeal.
(Reproduced with permission from Tonkin MA, Hagrick NC, Eckersley JR, et al. Surgery for cerebral palsy part III: classification and operative procedures for thumb deformity. *J Hand Surg Br*. 2001;26:465–470.)

longus (FPL) lengthening through a separate incision, performing either fractional lengthening or Z-lengthening (for more severe IP joint flexion).

In a patient who does not have sufficient antagonistic strength, tendon transfers will be needed to augment these previously described releases. One must assess extrinsic thumb extensor function. If there is a functioning extensor pollicis longus (EPL) and weak abduction, re-routing EPL is helpful. EPL is transected proximal to the IP joint, the extensor mechanism is repaired, and the proximal end is re-routed through the first dorsal compartment and reattached to the radial side of the extensor mechanism, so changing its vector direction[30] or into the proximal phalanx. If there is MP joint hyperextension, then the re-routed EPL is inserted into the radial side of the distal metacarpal.[37] If there is no EPL function, brachioradialis to abductor pollicis longus transfer can be performed.

With MP joint hyperextension instability, then either a volar tenodesis or capsulodesis of the joint must be done or MP joint fusion performed.

Finger swan-neck deformity

If there is mild deformity, secondary to intrinsic spasticity, extrinsic silver ring splints may be used, or intrinsic muscle slide performed (Fig. 21.18). With a concomitant thumb adductor spasticity, and if a temporary ulnar nerve block favorably affects both the thumb-in-palm deformity and intrinsic finger spasticity, then one may, on occasion, consider ulnar motor neurectomy in Guyon's canal. With more severe PIP joint instability, an FDS distal slip tenodesis secured to the proximal phalanx works well (Fig. 21.19).[38]

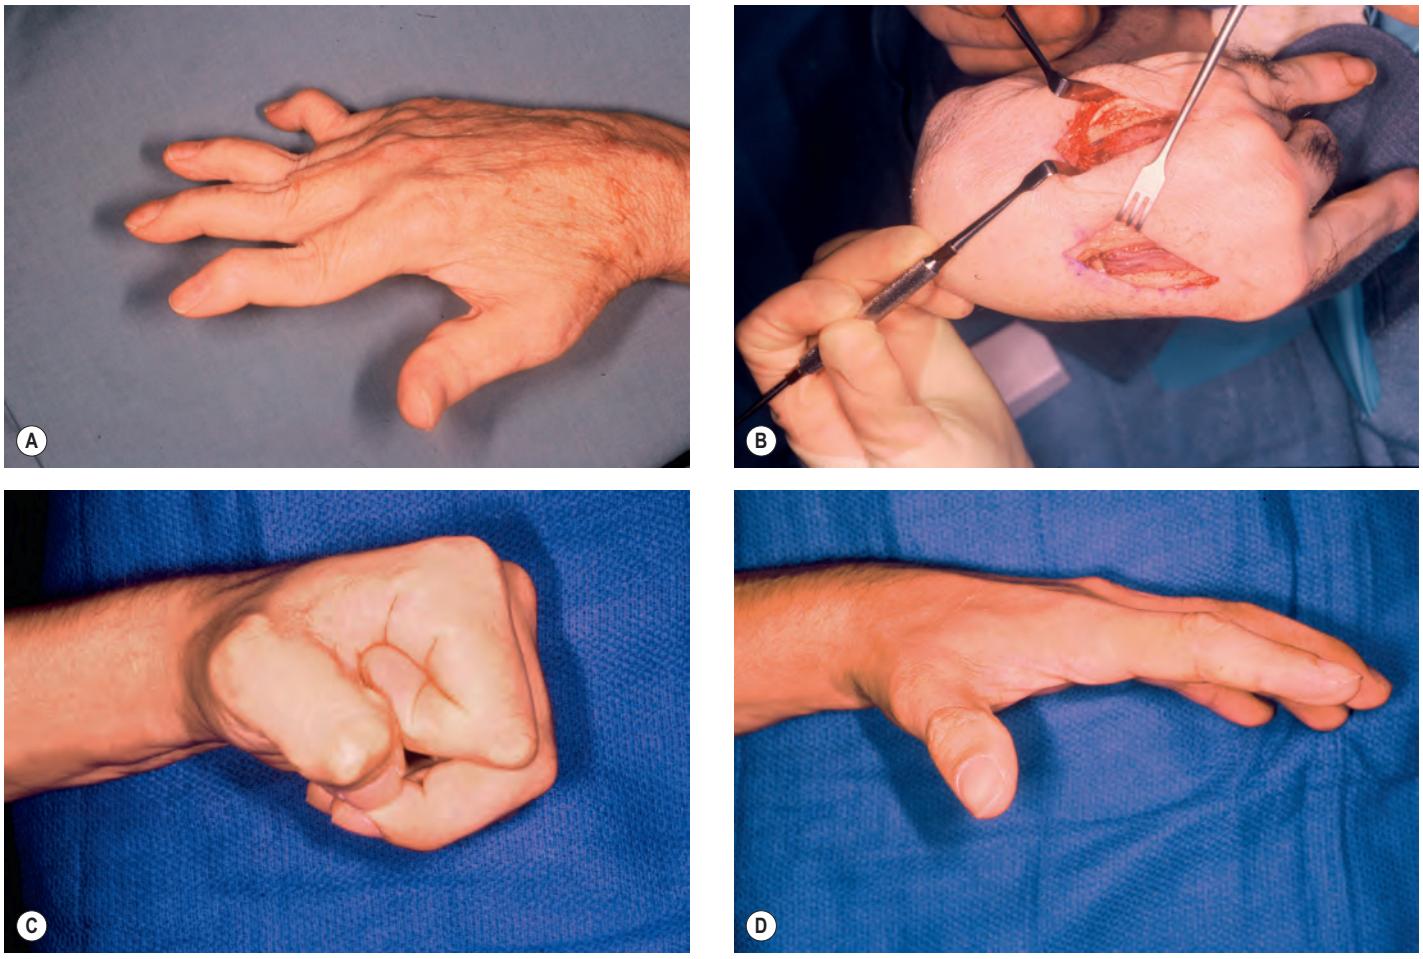

Fig. 21.18 **(A)** Patient with residual swan-neck deformities and intrinsic muscle contractures following more proximal release. **(B)** Interosseous muscle slide. **(C,D)** Final ability to flex and extend the fingers.

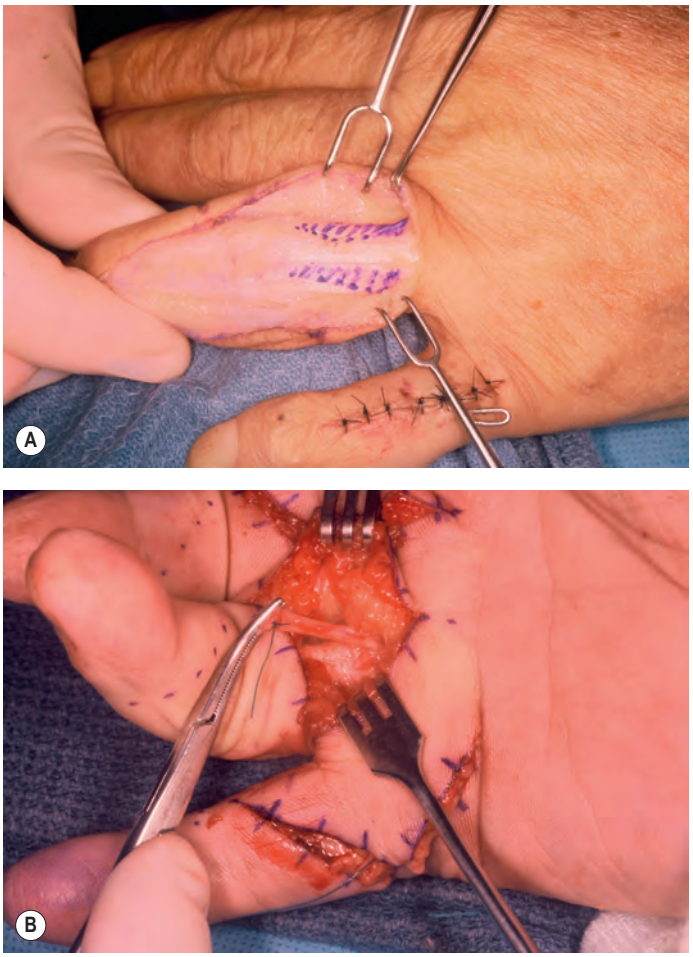

Fig. 21.19 A residual hyperextension swan-neck deformity at the PIP joint may be treated by **(A)** a proximal intrinsic release and **(B)** tenodesis using a distally based slip of, flexor digitorum superficialis that is re-routed back around the origin of the flexor tendon sheath or anchored into bone of the proximal phalanx.

Hints and tips

Spastic swan-neck deformity

- Differentiate between intrinsic "tightness" and "tightness" of extrinsic extensors.
- The former is treated by intrinsic release (dorsally) or volar fractional lengthening.
- The latter is treated surgically by central slip ("Fowler") tenotomy.
- "Mild" swan-neck may be treated by figure-of-eight splinting.

Swan-neck deformity may result from either intrinsic spasticity or overpull of digital extensors. Each will cause overstretch of the PIP volar plate, resulting in hyperextension at that joint. Accurate diagnosis is essential, therefore, for proper surgical treatment.[39]

These two variants of swan-neck deformity are distinguished by observing the MP joint position during active digital extension. Patients with intrinsic muscle spasticity have MP joint flexion and PIP joint hyperextension. The Bunnell test will further confirm intrinsic spasticity. Patients who present with swan-neck deformity and full MP joint extension upon active digital extension have this deformity from overpull of the long digital extensors. Surgical treatment of the former is done through a transverse incision in the palm and fractional lengthening of lumbricals and volar and dorsal interossei,[40] avoiding the first dorsal interosseous if possible to reduce the risk of weakened pinch strength. Extensor digitorum communis overpull, on the other hand, is treated by central slip tenotomy about 1 cm proximal to the PIP joint.

PIP joint volar tenodesis may be required as a concomitant procedure if the volar plate is very lax or has been described as the sole treatment of swan-neck deformity. This is done by either using a slip of FDS tendon[41] or using lateral bond translocation.[42]

The spastic hand following stroke and traumatic brain injury

Patient selection

The principles of assessment and treatment are very similar to cerebral palsy. Procedures for flexed fingers are divided into functional procedures or those that are hygiene procedures.[43] The results of surgery are better when deformities are corrected early, before fixed joint contractures have developed. Surgery should not be considered as a treatment of last resort. "Non-functional" surgical procedures may actually help overall bodily function. For example, in spite of not having active function in the upper extremity after spastic releases, dressing may be facilitated or positioning the hand on a walker may improve ambulation.

Fingernails may dig into the palm and palm skin may be macerated. Clenched fist is often accompanied by a flexed wrist. Assess for active finger flexion. If the PIP joints flex while DIP joints remain extended, there is spasticity in the FDS rather than FDP.

Surgical technique

If there is skin maceration and no volitional flexion, then significant lengthening of flexor tendons is required and superficialis-to-profundus (STP) transfer is performed. At best, a mass action grasp pattern is achieved with the STP transfer and, at worst, passive restraint to extension is accomplished rather than a "floppy hand" with joint instability if simple tenotomies were to be performed. Associated procedures may be required such as thenar release and Z-lengthening of wrist flexors.

If there is volitional control of extrinsic finger flexors, and if the degree of flexion contracture is less severe, then fractional lengthening of FDS, FDP, and even FPL is done by sharply incising the intramuscular tendon fibers. A short volar splint may be used for postoperative comfort, but active exercises are begun immediately. A flexor–pronator muscle slide may sometimes be used for a more global correction of flexed elbow, forearm pronation, wrist and finger flexion.

Conclusions

Contractures in the upper extremity result not only from joint pathology but also from disorders of periarticular structures as well as tendon adhesions and muscle imbalance. The correct treatment is predicated on making the appropriate diagnosis. A variety of specific disorders are known to lead to contractures, but the most common conditions that the hand surgeon will have to treat are the consequences of trauma. Meticulous postoperative therapy and splinting are essential to optimize best functional outcome.

Future directions

With regard to joint contractures and stiff joints, wide-awake local anesthesia technique has added an extra dimension to surgical treatment. With this approach, one can assess functional outcome in the operating room. The patient can immediately see the outcome while pain-free. This technique also serves as a bridge to ongoing postoperative hand therapy.

Biochemical and mechanical scar modification are ongoing directions for research. The introduction of corrective surgery will bring about all the phases of wound healing once again with inflammation, edema, collagen deposition, and scar remodeling. The postoperative problem of new scar formation following joint releases and tenolyses remain an issue.

In the area of spasticity, gait analysis has been pivotal in evaluating the lower extremity. We are now gaining insights from motion analysis laboratories for the upper extremity. This will not only help in the preoperative analysis of spastic problems but will also help in assessing postoperative functional outcomes.

Ischemia of the hand

Hee Chang Ahn and Neil F. Jones

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Upper extremity ischemia is caused by many etiologies and may be classified into acute and chronic cases.
- A precise understanding of arterial anatomy is pertinent to preoperative diagnosis, patient selection, and operative procedure.
- A history of cold intolerance, Raynaud's phenomenon, and frequency of ischemic pain is important. Color changes, ulcerations, and infections are evaluated.
- Non-invasive vascular examination includes measurement of fingertip temperatures, Doppler ultrasound, segmental arterial pressures, and capillaroscopy.
- Various pharmacologic agents can be used to counteract the sympathetic effect on the muscular layers of the arterial wall in a conservative medical approach.
- Surgical intervention is directed at interrupting the sympathetic innervation of the muscle layer, by physical dilatation of the obstructed lumen, or by microsurgical reconstruction of the occluded lumen.

Access the Historical perspective section online at http://www.expertconsult.com

Introduction

Hand ischemia occurs when the vascular system is no longer able to transport blood efficiently because of trauma, constriction, obstruction, or vasospasm. It is the critical vascular event that results in eventual tissue necrosis and even amputation without proper management. Compared with the lower extremity, the symptomatology and presentation is varied in the upper limb and it is frequently underdiagnosed. Upper extremity ischemia is caused by many etiologies[3] and may be classified into acute and chronic cases (Box 22.1). Any microvascular injury that diminishes the vascular flow induces the acute ischemic conditions of the hand. Systemic, congenital, and genetic problems also cause chronic ischemic conditions. Raynaud's phenomenon is a well-known vasospastic condition that affects 5–10% of the general population.[4,5] Primary Raynaud's disease occurs in the absence of any underlying condition whereas secondary Raynaud's syndrome is associated with other vasospastic conditions.

Fuchs classified arterial disease according to the three arterial layers: the intima, media, and adventitia. Several of the most frequent pathologic processes (atherosclerosis, intimal hyperplasia) originate in the intimal layer. Endothelial disruption produces thrombotic occlusion and embolization.[6] The media consists of smooth muscle cells, fibroblasts, and elastic tissue. Atherosclerosis also influences the loss of tissue integrity. The media can become chronically dilated in a diffuse (ectasia) or localized (aneurysm) pattern. The adventitia is involved in diffuse pathologic entities (arteritis, Buerger's disease). Jones categorized hand ischemia into subgroups of acute and chronic disease. There are multiple causes of upper extremity ischemia (see Box 22.1),[3] but a classification system based on the underlying pathophysiologic mechanism responsible for producing the ischemia would seem to be most appropriate as a rationale for suitable treatment. Jones described five main pathophysiological mechanisms of hand ischemia: emboli, thrombosis, occlusive disease, vasospasm, and low-flow states.[7]

Regardless of its causes, ischemia of the hand is manifested by color and temperature changes, pale fingers, cold intolerance, numbness, digital ulcerations, and gangrenous changes. Despite appropriate treatments, such as smoking cessation, cold avoidance, biofeedback techniques, and pharmacological therapy, ischemia commonly progresses to the eventual consequence of amputation.[8–13] This chapter provides an insight to accurate diagnosis and appropriate treatment to avoid devastating tissue losses.

Raynaud's phenomenon

Raynaud's disease is a rare disorder but it is an important cause of upper limb ischemia. This entity is often confused with Raynaud syndrome. Raynaud's phenomenon in patients

Historical perspective

Maurice Raynaud described Raynaud's phenomenon in 1862 and attributed the condition that bears his name to overactivity of the sympathetic nervous system, but a review of his cases reveals that most of his patients probably had small-vessel occlusive disease. He hypothesized that "local asphyxia of the extremities" was a result of "increased irritability of the central parts of cord presiding over vascular innervations."[1]

Lewis first postulated a peripheral rather than central mechanism for Raynaud's disease caused by a "spasm of digital arteries". He stated that "the abnormal element in the reaction to cold is a direct reaction and due to a peculiar condition of the vessel wall locally: it is not the result of a reflex through the vasomotor nerves." However, the pathophysiology remained poorly understood.[2]

BOX 22.1 **Etiology of acute and chronic ischemia of the hand**

- Atherosclerosis: proximal (more common) or distal
- Buerger's disease
- Cervical rib compression
- Connective tissue disease
  - Scleroderma
  - Mixed connective tissue disease
  - Systemic lupus erythematous
  - Rheumatoid arthritis
  - Wegener's granulomatous
- Emboli
  - Atrial fibrillation
  - Myocardial infarction
  - Poststenotic dilatation of subclavian artery
- Iatrogenic
  - Brachial artery: cardiac catheterization
  - Radial artery: arterial pressure cannulation
  - Hemodialysis access: shunts and fistulas
- Intra-arterial drug injection
- Myeloproliferative and immunologic disorder
  - Polycythemia
  - Leukemia
  - Myeloma
  - Cryoglobulinemia
- Renal vascular disease
- Post-irradiation
- Septicemia
- Trauma
  - Shoulder dislocation
  - Supracondylar fracture of the humerus
  - Posterior dislocation of the elbow
  - Hypothenar hammer syndrome
- Toxins
  - Heavy metals
  - Vinyl chloride
  - Others
- Vibratory tool disease

with upper extremity ischemia is common and classically consists of an orderly progression of color changes (white, blue, and then red) and symptoms in the affected hand secondary to vasospasm. Pallor is followed by a cyanotic appearance, and culminates with reactive hyperemia and burning pain or dysesthesias. This classic pattern occurs in about two-thirds of affected patients. In 1932, Allen and Brown proposed that Raynaud syndrome/phenomenon be differentiated from Raynaud's disease in that no underlying organic cause can be found in Raynaud's disease.[14] They listed the following criteria as necessary for the diagnosis of Raynaud's disease:

1. Bilateral symptoms
2. Absence of gangrene
3. No evidence of underlying organic disease
4. Symptoms present for at least 2 years.

Merritt,[15] and Blunt and Porter[16] argued that these criteria are confusing and perhaps obsolete, considering that Raynaud's phenomenon can be present for an average of 11.5 years prior to diagnosis of an underlying connective tissue disease.[17] Furthermore, in one study using sensitive laboratory testing of patients with Raynaud's disease, more than one-half of patients were found to have some evidence of an underlying systemic disease.[18]

The relationship between vasospasm in Raynaud's phenomenon and occlusive disease continues to be controversial. Some researchers have suggested that occlusive disease may initiate vasospasm via humoral and/or sympathetic mediators. This concept is supported by the fact that excision of the occluded arterial segment in patients with traumatic ulnar artery thrombosis (hypothenar hammer syndrome) will improve the digital vasospasm often seen in this disorder.[19] Vasospastic symptoms in patients with connective tissue disorders may also be related to an underlying abnormality of the vessel wall. Intimal hyperplasia, thrombosis, fibrosis, embolism, adventitial thickening, aneurysm formation, and calcification have all been found in patients with Raynaud's phenomenon.[20,21] The question remains whether these changes are responsible for the vasospastic symptoms or merely potentiate vasospasm initiated at another site. Therefore, bypass of distal arterial occlusions may not only provide oxygen delivery via increased blood flow to the hand but also may remove a potential source of vasospasm.

Basic science

Anatomy

Embryology

The limb buds appear at 4 weeks of embryonic life as lateral swellings and the forearm vasculature evolves through several stages between 4 and 8 weeks (see Chapter 25). A median artery, ulnar artery, and radial artery arise in order from the brachial artery at the elbow, but the median artery involutes as the radial and ulnar arteries provide the majority of blood flow to the hand.

Arterial system in the forearm, hand, and digits

Variations in the vascular pattern of the deep and superficial palmar arches and the common digital arteries are frequent. Therefore, a precise understanding of arterial anatomy is pertinent to preoperative diagnosis, patient selection, and operative procedure.

Superficial palmar arch

The superficial palmar arch may be classified as either "complete" or "incomplete". This classification provides the simplest understanding of the anatomy of the arches.[22] Gellman *et al.* defined an arch to be complete if there was an anastomosis between the vessels constituting it and an incomplete arch as having an absence of communication or anastomosis between the vessels constituting the arch.[23] Coleman and Anson also described an incomplete superficial arch as one

"in which the contributing arteries do not anastomose, or when the ulnar artery fails to reach the thumb and index finger."[22] Koman *et al.*[24] also reported a complete arch in 78.5% of extremities. Gellman *et al.* reported a complete arch in 38 of 45 specimens studied (84.4%). In contrast to these studies, Fazan[25] reported that only 43% of right hands and 52% of left hands had complete arches.

Multiple variations of the superficial palmar arch have been classified into subgroups. According to Gellman's study, complete arches have been divided into five subgroups:

- Type A: The radioulnar arch is formed by anastomosis between the superficial volar branch of the radial artery and the continuation of the ulnar artery.
- Type B: The superficial arch is formed by a continuation of the ulnar artery and even provides common digital vessels to the thumb and index webspace.
- Type C: The median and ulnar arteries combine to form the superficial arch without a contribution from the radial artery.
- Type D: This is characterized by all three vessels (radial, median, ulnar) contributing to the arches.
- Type E: A branch from the deep palmar arch communicates with an ulnar artery-initiated superficial arch.

The main branches from the superficial palmar arch are the three common digital arteries to the index–middle, middle–ring, and ring–small finger webspaces[22,26] and the proper digital artery to the ulnar border of the small finger.[23,27,28] When the princeps pollicis artery and a vessel to the radial side of the index finger (index radial digital artery) originate from the superficial palmar arch, this should be named as the first common digital artery.[27,29]

Deep palmar arch

The deep palmar arch is less variable than the superficial arch. The radial artery forms the deep arch when it passes from dorsal to palmar by piercing the two heads of the first dorsal interosseous muscle. The arch then curves along the bases of the metacarpal bones. The deep arch may anastomose with one or both volar branches of the ulnar artery.[23,30] At least one of the deep volar branches was present in all individuals in a recent study. The deep palmar arterial arch travels across the palm, deep to the flexor tendons, at the level of the carpometacarpal joints to connect with a deep arterial branch from the ulnar artery.[22,31] The deep palmar arch gives rise to as many as five palmar metacarpal arteries that pass distally to the level of the metacarpal heads, where they branch dorsally to join the dorsal metacarpal arteries and also connect to the common digital artery through a small palmar arterial branch. Nystrom *et al.* described three palmar and three dorsal arches that connect the four forearm arteries (ulnar, median, radial, and interosseous arteries). Dorsal metacarpal arteries that originate from the dorsal carpal arches pass to their respective webspaces distally, where they join perforating vessels from the palmar circulation.[32]

The most consistent of the dorsal vessels supplying the dorsal carpal rete, which consists of numerous small, thin vessels (0.3–0.5 mm), is the radial dorsal carpal branch. It branches off the radial artery 10–15 mm distally to the radial styloid.[23]

When the superficial arch is well developed, the deep palmar arch is correspondingly less developed and vice versa. A reciprocal inverse relationship was also found between the common palmar digital arteries and the palmar metacarpal arteries.[22,30,33,34]

Digital arteries

The ulnar digital arteries of the thumb and index finger are larger than the radial digital arteries. The radial digital artery is larger in the ring and small fingers. The difference between the radial and ulnar digital arteries is statistically significant only in the border digits. The anatomy of the thumb digital arteries is unique. The blood supply of the thumb comes mainly from the princeps pollicis artery, the terminal branch of the superficial palmar arch, and the first dorsal metacarpal artery. There are numerous sources of blood supply from the radial and ulnar arteries, including the palmar ulnar, palmar radial, dorsal ulnar and dorsal radial arteries. The first palmar metacarpal artery is absent in about 2% of patients.[22,31] This accounts for the tolerance to ischemia by the thumb due to numerous collateral blood vessels.

According to the Hagan–Poiseuille's law, the blood viscosity, diameter, length and the pressure gradient influence flow through the digital arteries, and larger digital arteries can carry more blood. Strauch and de Moura described the numerous interconnections between the digital arteries beyond the metacarpophalangeal joints. These connections play an important role in hand ischemia if segmental arterial obstruction develops.[34]

Micro-arterial system

Microvascular vessels are defined as having a diameter of <100 μm. Their role is to deliver oxygen and nutrients at a cellular level. They consist of nutritional capillary and thermoregulatory vessels.[33] In the digits, 80–90% of the total flow passes through thermoregulatory beds and 10–20% are involved in capillary nutrition.[35] In pathologic states, cellular hypoperfusion leads to ischemic symptoms and imbalance in the distribution of thermoregulatory and nutritional flow, resulting in cell death or damage.

Physiology of blood flow

Hemodynamics

Koman *et al.*[24] described macrovascular structures that are defined as vessels >100 μm. Their function is to deliver nutrients to the microvascular beds, provide adequate capacity for arteriovenous thermoregulatory flow, and drain nutritional and thermoregulatory beds.

Cellular control mechanisms

Blood flow does not only follow principles of fluid dynamics. There is compensation between arterial dilatation, collateral vessels, and resistance in the peripheral circulation. In a normal extremity, blood flow in the hand depends on sympathetic tone, metabolic demands, environmental events, local factors, and circulating humoral mediators. Alpha-adrenergic control is the dominant control arm of vasoconstriction; however, vasodilatation is initiated by endothelium-derived relaxing factor. Active vasoconstriction and vasodilatation may

be initiated by a central control process mediated through peripheral neural structures or circulatory factors or by local autoregulation, which is metabolic or myogenic. Metabolic autoregulation occurs in response to local metabolic needs and is mediated by decreased oxygen and build up of adenosine and potassium.[36] Myogenic autoregulation is mediated via transmural pressure and stretch-operated calcium channels.[37] The microcirculation is also affected by endothelial factors within blood vessels. The endothelium plays a major role in control of vasomotor tone and blood fluidity, lipid metabolism, and finally angiogenesis. The endothelium has been recognized as an active tissue responsible for elaborating both vasodilatory and vasoconstrictor substances. Endothelial cells respond to differences in intravascular pressure due to variations in the size of the lumen by releasing endothelium-derived relaxing factor.[38] Endothelium-derived relaxing factor produces active vasodilatation, and endothelin is a potent vasoconstrictor. Both compounds are released from the endothelial cells to regulate vascular flow. Endothelial cells can also release thromboxane A2, prostacyclin, and molecules of thrombomodulin and heparan sulfate.

Pathophysiology

As described previously, Fuchs classified arterial disease according to the three arterial layers: intima, media, and adventitia. Several pathologic processes (atherosclerosis, intimal hyperplasia) originate from this intimal layer. Endothelial disruption produces thrombotic occlusion and embolization.[4] The media consists of smooth muscle cells, fibroblasts, and elastic tissue. Atherosclerosis leads to loss of tissue integrity, and the media becomes chronic dilated in a diffuse (ectasia) or localized (aneurysm) pattern. The adventitia is involved in diffuse pathologic conditions (arteritis, Buerger's disease).

A classification system based on the underlying pathophysiological mechanism responsible for producing the ischemia would seem to be most appropriate as a rationale for determining treatment. The pathological processes that produce ischemia in any end organ (and the hand can be considered such an end organ) are emboli, "sludging" of blood in low-flow states, thrombosis, external compression, intimal proliferation progressing to occlusion (arteriosclerosis), and vasospasm.[5]

Emboli

Large emboli from the heart due to atrial fibrillation or myocardial infarction lodging at the bifurcation of the brachial artery are best managed by embolectomy by a vascular surgeon. However, smaller emboli or "micro-emboli" dislodged from an ulcerated atherosclerotic plaque in a large artery may lodge in the distal radial and ulnar arteries and digital arteries, and result in digital ulcerations or gangrene.

Trauma

Traumatic causes of ischemia can be occupational, iatrogenic, or secondary to an injury. Hypothenar hammer syndrome (HHS) first described by Van Rosen in 1934 is an uncommon cause of secondary Raynaud's phenomenon, and occurs mainly in patients who use the hypothenar part of their hand as a hammer.[39]

Because of its anatomic configuration within Guyon's canal, the ulnar artery is particularly vulnerable to mechanical injury. The hook of the hamate bone presses against the superficial palmar branch of the ulnar artery in Guyon's canal, leading to the development of progressive periadventitial scarring, damage to the media, disruption of the internal elastic lamina, intimal damage, and subintimal hematoma of the ulnar artery. These events are postulated to be the pathophysiological mechanism whereby repetitive trauma causes thrombosis in competitive athletes (volleyball, karate, handball, and baseball).[40–42]

"Vibration white finger" or vibration-induced Raynaud's phenomenon is also related to repetitive trauma in workers who frequently use drills, jackhammers, and chainsaws. High-frequency vibration is assumed to affect the response of the sympathetic vasoconstrictor nerves and receptors, not only to mechanical- but also to thermal-induced pain.[43,44]

Radial artery catheterization frequently results in radial artery thrombosis, although it is frequently asymptomatic because of communication between the radial and ulnar arterial systems. However, if the patient has an incomplete superficial palmar arch, distal ischemia may occur.[23] Cardiac catheterization via the brachial artery may result in thrombosis and distal emboli, with an incidence of approximately 0.6%.[45]

Arteriovenous shunt operations in renal failure patients may also result in hand ischemia. The arteriovenous shunt may redirect a critical volume of blood flow away from the hand, resulting in a "steal" phenomenon producing severe motor and sensory deficits.[46,47]

Systemic disease

Systemic disease may produce distal hand ischemia and/or Raynaud's symptoms, including connective tissue disease, vasculitis, malignancy, septicemia, arteriosclerosis, Buerger's disease, polycythemia, cryoglobulinemia, and chemical toxicity.[15]

Diagnosis/patient presentation

Evaluation

Evaluation of vascular competency should define the patient's vascular anatomy and function under stressed and unstressed conditions. Therefore, a combination of studies is needed. Most importantly, a complete history and physical examination is essential in establishing a diagnosis. Investigations including non-invasive or invasive vascular studies may be required for exact evaluation of the patient's status. The patient's symptoms and studies are carefully reviewed to identify those patients who require surgical intervention.

History and physical examination

A history of cold intolerance, Raynaud's phenomenon (Fig. 22.1), and frequency of ischemic pain is important, as is smoking history; occupation involving repetitive injury or vibration trauma, and systemic disease including diabetes, cardiac disease, arrhythmias, drug use, blood dyscrasias, and peripheral neurological abnormalities. Unilateral Raynaud's

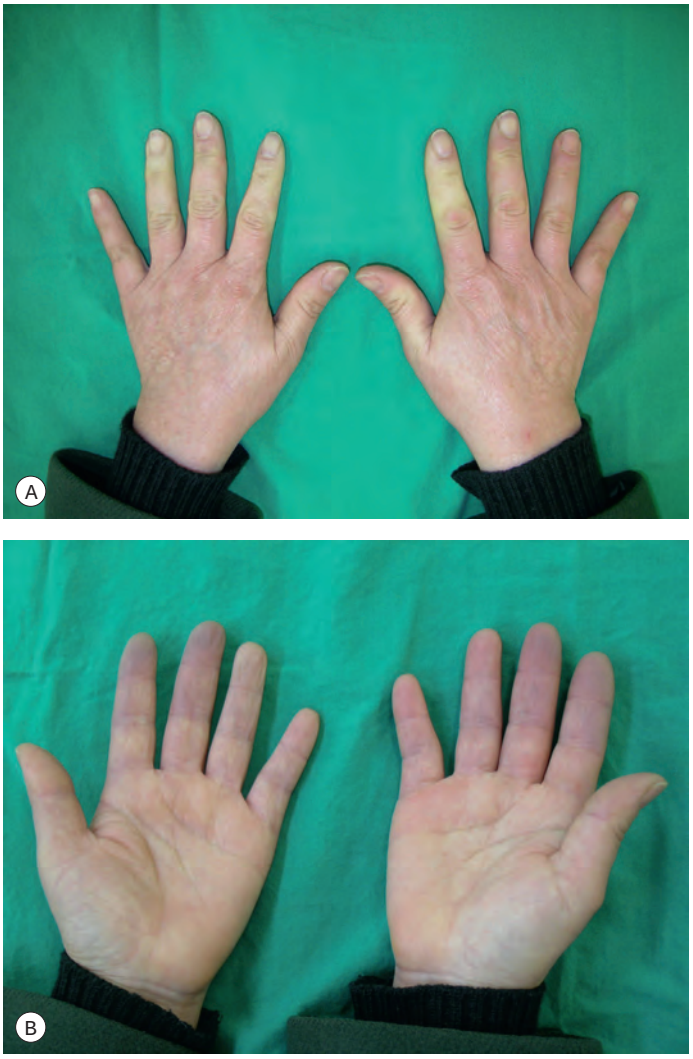

Fig. 22.1 Triphasic color changes. **(A)** Fingers turn white. **(B)** Fingers turn purple.

symptoms are especially suspicious and are usually indicative of occlusive disease on the affected side.

McCabe *et al.* and Troum *et al.* developed a questionnaire that can be used to assess the severity of cold sensitivity and quantify the magnitude, duration, and frequency of vasospastic symptoms and their effect on function.[48,49]

A thorough examination of the upper extremity for previous trauma, old scars or operative incisions, skin color, temperature, presence of digital ulcers, and motor and sensory evaluation of the three peripheral nerves should be routine. Observation of blood flow in the fingernails may help to diagnose ischemia due to connective tissue disease.[25,50]

Palpation may detect an abnormal mass or thrill. The brachial, radial, and ulnar arterial pulses are also palpated. The Allen test allows rapid evaluation of the patency of radial and ulnar arterial inflow into the hand. A digital Allen test can occasionally be performed either by forcing blood out of the finger or by sequential compression of the digital arteries.[51,52]

Color changes, ulcerations, and infections are evaluated. Non-healing ulcerations and/or impending gangrene associated with unilateral Raynaud's symptoms are presumptive evidence of thrombosis or embolism.[25,53]

Diagnostic investigations

Non-invasive vascular examination includes measurement of fingertip temperatures, Doppler ultrasound, segmental arterial pressures, and capillaroscopy.

Capillaroscopy

The capillaries of the nail fold can be examined directly by specialized dynamic videophotometric capillaroscopy, which provides measurements of capillary diameter, red blood cell velocity, and total flow. It can be difficult to perform in 10–12% of individuals due to anomalous vessel orientation, varying length of capillary loops, hyperkeratotic skin, or dense pigmentation. Dynamic capillary videomicroscopy allows direct assessment of nutritional perfusion and arteriovenous shunting, and provides objective evidence of the effects of systemic disease on the microcirculation and objective confirmation of any improvement with medical intervention.[25]

Ultrasound

The pencil Doppler probe can also be used to assess the patency of the distal radial and ulnar arteries at the wrist and the dorsal branch of the radial artery as it passes through the webspace, the superficial palmar arch, the common digital arteries, and each proper digital artery on the radial and ulnar aspects of each digit. Jones found the pencil Doppler probe to be the simplest, most informative technique providing precise determination of the patency of the arterial structures. Doppler evidence of occlusion of either the distal radial or ulnar arteries is one of the primary criteria for proceeding to invasive arteriography.[1,5]

Segmental arterial pressures of the brachial artery at the elbow and the distal radial and ulnar arteries at the wrist may be measured with a pencil Doppler probe. A radial-brachial index (RBI) and a digital-brachial index (DBI) can be calculated with a value of ≤0.7 indicating that arterial outflow to the hand is decreased.[54]

Duplex ultrasonography

A duplex ultrasonogram is non-invasive, repeatable, and can be used for follow-up investigation. Its most important advantage is presenting real-time blood flow information (Fig. 22.2).[55,56]

Isolated cold stress testing

Cold stress testing was developed to provide an evaluation of the digital response to physiologic stress. Digital temperatures or digital plethysmography (pulse volume recordings) are measured before, during, and after application of a cold stress-immersion in cold water or a cold chamber at 4°C.[57] If the fall in digital temperature or drop in pulse volume recording can be partially ameliorated by a prior injection of local anesthetic, this implies that vasospasm is a likely mechanism for the ischemia.

Infrared thermography

Infrared thermography (IRT) provides a measure of the decreased skin temperature of patients with hand ischemia due to decreased superficial skin blood flow.[44] The advantage

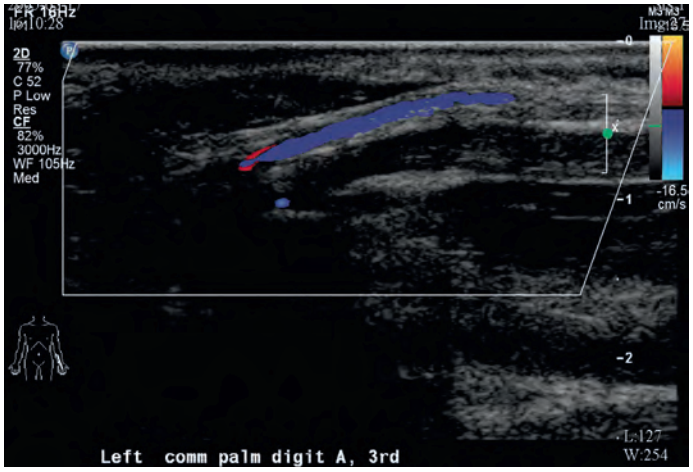

Fig. 22.2 Duplex ultrasonogram.

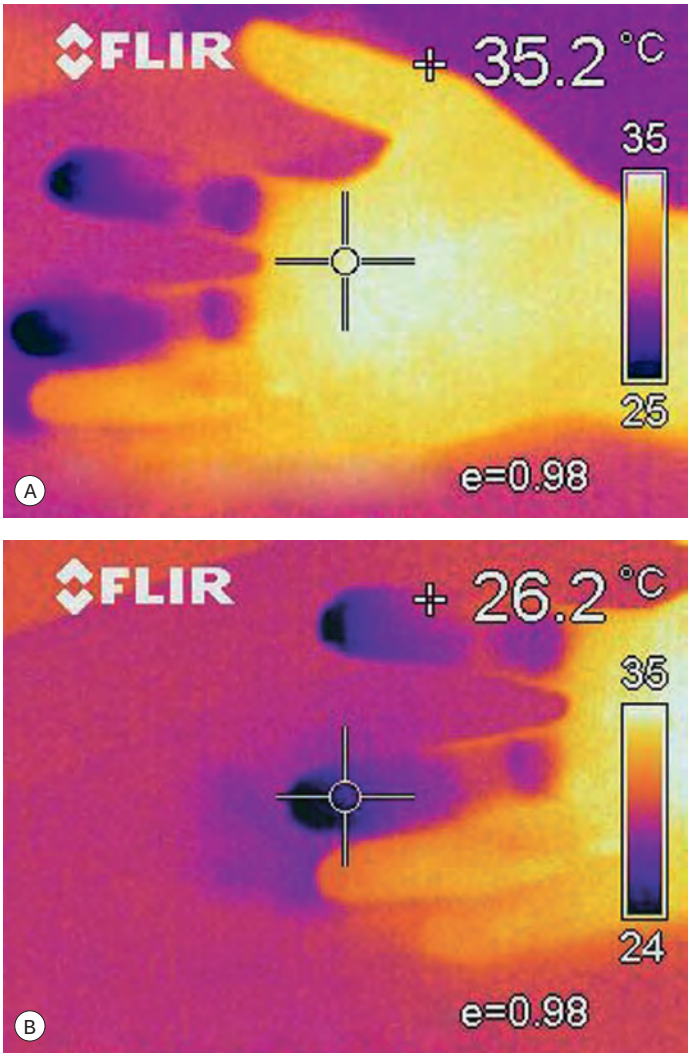

Fig. 22.3 Infrared thermography. **(A)** Normal temperature in the palm. **(B)** Ischemic fingers.

of IRT is that it is non-invasive, easy to use and inexpensive (Fig. 22.3). However, it is influenced by the ambient temperature, and skin temperature itself does not reveal the condition of a blood vessel and cannot visualize the site of stenosis.

Angiography

Potential disadvantages of conventional angiography include bleeding, allergic response to the contrast media, and X-ray exposure. A major problem with invasive angiography is the vessel spasm induced by the contrast media (Fig. 22.4).[23,56,58] This can be circumvented by performing angiography under a brachial plexus block or by preventing vasoconstriction by intra-arterial injection of 4 mg phentolamine.[59]

Angiography defines the site and extent of thrombosis or occlusion of the distal radial and ulnar arteries and even the common digital and proper digital arteries.[23,58,60] Jones[5] has suggested some criteria for angiographic investigation of upper extremity ischemia as follows: (1) unilateral Raynaud's phenomenon; (2) progressive digital ulceration or gangrene despite good medical management; (3) recurrent digital ulceration; (4) Doppler evidence of occlusion of a major inflow artery; and (5) acute onset of ischemic symptoms.

Magnetic resonance and computed tomography angiography

More recently, high-resolution contrast-enhanced magnetic resonance (MR) angiography and computed tomography (CT) angiography continue to be refined to compete with conventional angiography.[61] Even though enhanced MR angiography and CT angiography are non-invasive, the resolution still does not allow the same visualization of the digital arteries compared with conventional angiography. Currently, if the surgeon requires accurate visualization of the digital arteries, conventional angiography is still preferred (Fig. 22.5).

Hints and tips

Diagnostic approach

1. A history of Raynaud's phenomena is usually very diagnostic. Patients can bring digital photos of the color changes in their hands.
2. Thermal scan is a very easy tool for checking the temperature of various parts of the hand.
3. Even though arteriography is invasive, it is the most valuable investigation for detecting arterial abnormalities of the hand – obstruction, stenosis, ectasia, coiling, aneurysm, velocity of flow.
4. Occupational history is important for "vibration white finger".

Patient selection

Acute ischemia

Acute arterial injury

Acute ischemia of the hand may occur following laceration of the brachial, radial, and ulnar arteries. Closed vascular injuries are often caused by high-energy trauma with accompanying fractures.[62] High-energy trauma may cause hemorrhage, thrombosis, incomplete vessel injury with development of an aneurysm, compartment syndrome, or progressive thrombosis and distal embolization.[63] Specific injuries of the upper extremity that may result in ischemia of the hand include shoulder dislocation, posterior dislocation of the elbow, and supracondylar fracture of the humerus. Diagnosis is usually not difficult in patients with significant hemorrhage and distal ischemia. Undetected injury to non-critical vessels may result in a false aneurysm or formation of an arteriovenous fistula.[64] Thal described the indications for operative exploration.[65]

Physical findings of a pulsatile hematoma, a thrill, an audible bruit, decreased peripheral pulses, or associated neurologic deficits are very important, but the presence of a distal pulse is not reliable in the evaluation of vascular integrity (Box 22.2). Immediate diagnosis is crucial in patients with acute ischemia of the hand, and this has been accomplished most expeditiously with Doppler examination and angiography.

Arterial emboli

The heart is the most common origin for arterial emboli. Acute onset of pallor, pain, coolness, paresthesias, and pulselessness should lead to strong suspicion for embolism. Ischemia will produce muscle paralysis after an embolus proximal to the forearm muscles, but paralysis is not present in distal emboli. Segmental arterial pressures are helpful, and arteriography of the entire upper extremity will determine if there is a more proximal arterial source of emboli and also will help differentiate embolism from acute arterial thrombosis.[66]

Iatrogenic injuries

- Cannulation of the radial artery
- Catheterization through the brachial artery
- Harvest of radial artery for coronary artery bypass
- Harvest of the radial forearm flap
- Drug injection injury
- Acquired arteriovenous fistula – for dialysis in renal failure.

Cannulation injury

Radial artery cannulation injuries have increased because of the increased frequency of arterial blood pressure monitoring. Repeated injury to the radial artery can cause acute thrombosis with distal embolization, pseudoaneurysm, and arteriovenous fistula. Because of concomitant endothelial injury in cannulation injuries of the radial artery, immediate resection of the involved segment and reconstruction with an arterial or vein graft is more effective than thrombectomy with small Fogarty catheters.

BOX 22.2 **Signs of arterial injury**

Hard signs

- Distal circulatory deficit
  - Ischemia
  - Absent or diminished pulses
- Bruit
- Expanding or pulsatile hematoma
- Arterial bleeding

Soft signs

- Small or moderate-sized hematoma
- Adjacent nerve injury
- Shock unexplained by other injuries
- Penetrating wound overlying course of major artery

(Reproduced with permission from Thal ER, Synder WH, Perry MO. Vascular injuries of the extremities. In: Rutherford RB (ed.). *Vascular surgery*, 4th edn. Philadelphia, PA: WB Saunders; 1995:713–735.)

Arterial injection injuries

Self-inflicted or inadvertent drug injection arterial injuries result in severe acute ischemia due to chemical endarteritis, arterial blockage by acid crystals, activation of the clotting cascade, and secondary vasospasm, which causes severe vasoconstriction and widespread thrombosis. Diagnostic modalities are the same as in other vascular injuries.[67]

Acquired arteriovenous fistula

Arteriovenous fistulas may occur following trauma or infection but are usually created surgically to provide vascular access for patients undergoing hemodialysis.[68] End-to-end radial artery to cephalic vein anastomosis may result in both ischemic and neurological complications related to a "steal" phenomenon.[69] Side-to-side anastomosis (radiocephalic arteriovenous fistula) also may reduce digital blood flow to the thumb because of proximal shunting.[70] Dialysis access-associated "steal" syndrome occurs in 2–4% of surgically created arteriovenous fistulas.[71] Diagnosis is usually obvious. For traumatic or post-injection fistulas, duplex sonogram imaging, technetium scanning, or MR angiography are diagnostic. Arteriography is usually not necessary unless embolization is selected as a treatment option.

Chronic ischemia

Arterial thrombosis

The ulnar artery is the most common site for thrombosis in the upper extremity. The anatomy of Guyon's canal leaves the ulnar artery vulnerable at the hook of the hamate.[54]

Repetitive trauma may damage the intima and cause hypothenar hammer syndrome. Ischemic pain or paresthesias in the ulnar two digits, color changes, and tenderness are the usual signs at presentation. Allen's test will show poor inflow through the ulnar artery. Digital plethysmography (pulse volume recordings) quantifies the degree of compromised perfusion. Duplex sonogram or MR angiography will reveal occlusion of the ulnar artery. Arteriography may show the diagnostic "corkscrew" sign of hypothenar hammer syndrome due to alternating segmental stenoses.[72]

Radial artery thrombosis occurs much less frequently compared to ulnar artery thrombosis. Ischemic pain and cold intolerance are confined to the thumb and index finger. Diagnostic modalities are similar to those described for ulnar artery thrombosis.

Vibration-induced "white finger syndrome" represents thrombosis of the digital arteries, and occurs most frequently in the index finger. A digital Allen test is helpful, but an ultrasonogram and angiography is diagnostic.[44]

Aneurysm

Upper extremity aneurysms may be divided into two types. True aneurysms contain three layers of the arterial wall whereas a false aneurysm or pseudoaneurysm lacks endothelial cells. A true aneurysm occurs most frequently in areas of repetitive trauma or is related to atherosclerosis. A pseudoaneurysm is usually the result of a penetrating injury.

A painless, palpable mass is highly suspicious of an aneurysm but signs and symptoms of ischemia are very uncommon. Rarely nerve compression may cause pain or sensory abnormalities. An aneurysm is readily identified by a Doppler duplex ultrasonogram. Arteriography defines the extent of involvement and allows for evaluation of collateral flow for preoperative planning.[73]

Arteritis

Buerger's disease

Buerger's disease or thromboangiitis obliterans is an inflammatory disease of the small and medium-sized vessels of the upper and lower extremities.[74] Diagnosis is dependent on five criteria: (1) smoking history; (2) onset before 50 years of age; (3) arterial lesions below the knee; (4) upper limb involvement or migratory phlebitis; and (5) absence of atherosclerotic risk factors other than smoking. Surgical treatment by interposition or bypass vein grafting has been ineffective because the process occurs in the very distal vessels.

Connective tissue disorders

- Systemic sclerosis (scleroderma)
- Mixed connective tissue disease
- Systemic lupus erythematosus
- Wegner's granulomatosis.

Ischemic symptoms in connective tissue disorders should be investigated with non-invasive modalities first, such as segmental arterial pressure measurements, pulse volume recordings, and cold stress testing. Angiography is necessary if surgery is contemplated.

Vasospastic disease

1. Primary Raynaud's disease
2. Secondary Raynaud's syndrome.

As described previously, the medical literature relevant to vasospastic disease or Raynaud's syndrome is confusing and at times misleading. Koman[24] described the criteria of Raynaud's disease and Raynaud's phenomenon (Box 22.3, Table 22.1).

Vasospastic conditions are either defined as primary with absence of an identifiable etiology or secondary associated

BOX 22.3 Criteria defining Raynaud's disease

- Characteristic triphasic digital color changes
- Bilateral hand movement
- Absence of occlusive disease
- Absence of gangrene or trophic changes (fingertip trophic findings permissible)
- Absence of identifiable systemic disease (e.g., collagen vascular disorder)
- Symptoms at least 2 year's duration
- Female predominance

(Data from Dabich L, Bookstein JJ, Zweifler A, et al. Digital arteries in patients with scleroderma. Arteriographic and plethysmographic study. *Arch Intern Med*. 1972;130:708–714.)

Table 22.1 Raynaud's disease versus Raynaud syndrome

Characteristics	Disease	Syndrome
History		
Triphasic color change	Yes	Yes
Age >40	No	Yes
Progression rapid	No	Yes
Underlying disease	No	Yes
Female predominance	Frequent	Occasional
Physical examination		
Trophic findings (ulcer, gangrene)	Infrequent	Frequent
Abnormal Allen test	No	Common
Asymmetric findings	Infrequent	Frequent
Laboratory testing		
Blood chemistry	Normal	Frequently abnormal
Microangiography	Normal	Frequently abnormal
Angiography	Normal	Frequently abnormal

with an underlying cause. Based on this terminology, Raynaud's disease is primary and all other conditions are secondary.[25] The vessels in primary Raynaud's disease are not diseased, hence the prognosis is benign. Because the structure of the artery is normal, arterial reconstruction is not necessary, but occasionally patients who are refractory to medical treatment may be candidates for cervical sympathectomy or digital sympathectomy.

In comparison to primary Raynaud's disease, secondary Raynaud's syndrome has a more severe prognosis, which is primarily related to the severity of the underlying disease.[15] Surgical treatment of the ischemia in secondary Raynaud's syndrome includes digital sympathectomy and arterial reconstruction.

Treatment

A detailed history, physical examination, and differential diagnosis are the first steps in the management of ischemia of the hand. An arteriogram is essential to evaluate the arterial system of the entire upper extremity from the aortic arch to the digital arteries. The aims of treatment are to restore blood flow to an ischemic limb, prevent thromboembolic complications, and preserve hand function by avoiding secondary muscle ischemia and necrosis through compartment syndrome.

Treatments are selected according to the cause of ischemia,[25] with options ranging from environmental modification to surgical intervention. Various pharmacologic agents can be used to counteract the effect of humoral factors on the muscular layers of the arterial wall in a conservative medical approach, whereas surgical intervention is directed at interrupting the sympathetic innervation of the muscle layer or by physical dilatation of the obstructed lumen or by microsurgical reconstruction of the occluded lumen.

Non-surgical treatment

Environmental modification

Cessation of smoking, avoidance of cold exposure, and limitation of activities that precipitate symptoms are fundamental. Cigarette smoking increases vasoconstrictor tone and alters blood coagulability; both are detrimental to a patient with ischemic disease. Nicotine patches may be used because they do not impair nutritional blood flow.[25] It is important that patients are aware of the relationship between cold and emotional stress and the reflex vasospasm in their hands.[57] Most patients intuitively avoid these circumstances but should also be instructed in protective techniques.

Medical management

Pharmacological agents

Drug therapy is aimed at mitigating the sympathetic hyperactivity in vasospastic and occluded arteries. Topical nitroglycerine is a simple first-line treatment in an attempt to relieve the pain associated with digital ulcerations. Currently, calcium channel blockers are the optimal choice for vasospastic symptoms,[75] by preventing calcium influx in vascular smooth muscle cells, which, in turn, ameliorates sympathetically driven vasoconstriction. Nifedipine, 10–30 mg orally three times a day, or in a long-acting form (30–60 mg/day) sustained-release capsules once or twice a day is most commonly used.[11]

Both tricyclic antidepressants and selective serotonin reuptake inhibitors have also proved efficacious in the treatment of chronic pain due to ischemia. However, some drugs that directly affect sympathetic tone (α-adrenergic antagonists) are often difficult for patients to tolerate due to their side effects.[76,77] Local anesthetic blockade and intra-arterial vasodilators such as reserpine and guanethidine have been used systemically and by local injection, but long-term benefit has not been achieved.[78]

For treatment of obstructive Raynaud's syndrome, vasodilator drugs that alter prostaglandin metabolism (prostaglandin E1, prostacyclin and its analogues), and rheologic agents (aspirin, pentoxifylline, piracetam) have been advocated.[15] Some success has been reported with intra-arterial administration of prostaglandin E1, a potent vasodilator and inhibitor of platelet aggregation.[74]

Recently, Van Beek *et al*. described a novel use for Botox (botulinum toxin A) in the management of vasospastic disorders.[75] Injection of botulinum toxin A into the hand appears to have a beneficial effect on intractable digital ulcerations and rest pain in patients with severe vasospastic disorders.[79]

Thrombolytic therapy

Thrombolytic agents may be helpful for an embolic occlusion of a small vessel, especially if the agent is administered shortly after the acute embolic event. They can also be used preoperatively as an adjunct to vessel repair by lysing clot that is obscuring an underlying vascular abnormality (e.g.,

aneurysm), permitting the surgeon to plan reconstruction of the vessel abnormality.[80] Successful salvage of hand ischemia events has also been described with a combination of PGE1 and local fibrinolytic therapy with tissue plasminogen activator (rt-PA).[81] Although some authors[82] have doubted the benefit of fibrinolytic agents for treatment of a preformed thrombus in a small (0.82–1.5 mm) vessel, low-dose streptokinase has been shown to be clinically effective for a thrombus in the hand if the drug is administered locally as a continuous infusion within 36 h after the onset of symptoms.[83] Anticoagulation using intravenous heparin to prevent the propagation of thromboemboli and permit early lysis of thrombotic arterial occlusions should be instituted intraoperatively.[84–86] The role of low-molecular weight heparin in contrast to intravenous heparin has not been addressed thus far. McClinton made the following suggestions to increase the likelihood of success: initiate the infusion as soon as possible, be alert to the effect of systemic anticoagulation, and proceed with surgical exploration if no lysis occurs after the initial 2-h high-dose treatment. Steroids and iloprost (a prostacyclin analogue with potent vasodilating and anti-aggregant properties) have anecdotal results.[84,86] The role of phosphodiesterase inhibitors such as sildenafil has yet to be determined.

Biofeedback

Biofeedback training to develop central nervous system control over peripheral autonomic functions involves instruction in techniques that allow the conscious regulation of autonomic body processes. This entails consciously increasing digital blood flow or temperature.[87]

Biofeedback improves symptoms most effectively in patients with Raynaud's disease, vasospasm from non-neural or non-vascular etiology, and Raynaud's phenomenon with adequate collateral circulation. However, it tends not to be helpful in secondary vasospastic disease.

Thermal biofeedback is effective in primary vasospastic disease increasing digital flow, raising digital temperatures, and reducing cold-induced symptoms 2–3 years after treatment.[15,25,88]

Surgical treatment

Surgical intervention should be considered in patients who are refractory to medical treatment. Surgical options include reconstruction or bypass of occluded vessels by microvascular reconstruction with or without vein grafts and/or modification of sympathetic tone.[49,89–91] Sympathetic tone may be reduced by (1) proximal cervicothoracic sympathectomy, (2) Leriche sympathectomy (resection and ligation of a thrombosed or occluded arterial segment), (3) peripheral periarterial sympathectomy, and (4) new techniques in balloon angioplasty with periarterial sympathectomy.

Embolectomy

Emboli can be removed through a brachial arteriotomy and passage of catheters both proximally and distally. Number 2 or 3 Fr Fogarty catheters can usually be threaded all the way into the hand. If distal pulses do not return following restoration of flow, completion angiography is mandatory.

In high-flow arteriovenous malformations when emboli diminished the blood flow, initial attempts to preserve the fistula and relieve the vascular steal were aimed at reducing flow across the fistula by narrowing the fistula with bands. Even with precise intraoperative monitoring, this technique failed because of a high rate of fistula thrombosis.[92] Berman *et al.*[93,94] reported successful distal revascularization–interval ligation in more than 90% of patients.

Sympathectomy

When medical management has failed to control rest pain, or there is impending infarction of digits, or non-healing of ischemic ulcerations, digital artery sympathectomy is indicated.

Most of the sympathetic nerves in the upper extremity emerge from the spinal cord with the ventral roots of the second and third thoracic nerves[95] and are widely dispersed in the brachial plexus to the forearm and hand.[90,96] Cervical sympathectomy has a long history in the treatment of secondary vasospasm, but has currently lost favor because it has a high relapse rate and is essentially of no benefit in connective tissue disease.[15,95] Pick[96] first noted in his dissections of the sympathetic nervous system that some of the sympathetic nerves bypass the sympathetic trunk and pass first with proximal somatic nerves and then in the periarterial adventitia to the digits. Failure of cervical sympathectomy for upper extremity vasospastic disease may be due to branches that bypass the cervicothoracic sympathetic trunk and are not interrupted during the operative procedure of cervical sympathectomy.[90,91]

Sympathetic nerve branches pass from the peripheral nerves to adjacent arteries at intervals along the extremity and travel in the perivascular tissue including the large and easily identifiable nerve of Henle. This nerve accompanies the ulnar artery along its course from forearm to the hand, supplying several large segments to the ulnar artery.[97] Pick[96] identified individual sympathetic nerve branches to the arterial structures from the wrist to the digits, providing a basis for the current approach to surgical sympathectomy of the hand and digits.[98] This anatomic concept has provided the basis for two types of peripheral sympathectomy.

Leriche sympathectomy (arteriectomy)

Leriche advocated excision and ligation of the thrombosed or diseased arterial segment to improve collateral circulation and interrupt the vasomotor disturbance. If there is adequate collateral flow, excision of a thrombosed arterial segment without reconstruction interrupts sympathetic control over the distal vessels and reduces vasospasm. Several surgeons determine intraoperatively whether adequate collateral flow exists (e.g., after excision of a segment of ulnar artery) by measuring digital arterial pressures.[54,88,99] Zook *et al.*[100] have applied the Leriche sympathectomy concept to the digits by excising segments of occluded digital arteries when digital artery bypass was not possible.

Periarterial sympathectomy

Flatt[90] first introduced the concept of a sympathectomy at the digital level to apply its effect more distally in the extremity. Surgical stripping of the adventitia from arteries to interrupt the sympathetic innervation to the smooth muscle in the vessel media has been tried in situations of acute vasospasm following trauma or during microsurgery. However, this

technique may be ineffective because of the vasoconstrictive effect on the smooth muscle by humoral factors, including catecholamines encountered in ischemic conditions.

By directly removing the sympathetic nerve input from the arteries, it is possible to block alternative sympathetic pathways or receptor upregulation. Flatt divided connections carrying sympathetic nerve fibers between the digital nerve and digital artery by stripping a 3–4 mm long segment of adventitia from the common digital artery; eight patients had variable relief of their symptoms. Wilgis[10,91] extended this surgical dissection to include a 2 cm segment of the common and proper digital arteries and used preoperative anesthetic blockade to predict which patients would benefit from the procedure. Both Flatt and Wilgis noted symptomatic relief in patients with primary vasospastic disease but did not achieve consistently good results in patients with connective tissue diseases.

Jones[101] introduced a more radical digital sympathectomy, with an extended digital sympathectomy for patients with connective tissue disease both to interrupt the sympathetic fibers and to remove fibrous tissue that encircles and compresses the arteries. Both the radial and ulnar arteries at the wrist are exposed and stripped over a 3 cm distance. The incision for the ulnar artery is extended into the palm in an inverted J-shaped fashion so that the entire ulnar artery and superficial palmar arch can be stripped of adventitia and sympathetic nerve fibers. The common and proper digital arteries are stripped from their origin to the base of the fingers, but not as far as the proximal interphalangeal joint, under the operating microscope. If the thumb and index finger are involved, the dorsal branch of the radial artery[102] is stripped from the anatomic snuffbox to the origin of the deep palmar arch. The high incidence of ulnar artery occlusion has been previously mentioned in connective tissue disorders. In such patients, if there is sufficient distal arterial run-off, microsurgical bypass grafting from the proximal ulnar artery to the superficial palmar arch or common digital arteries can be performed.[15,101,103] Koman *et al*.[104] demonstrated that sympathectomy can increase the percentage of nutritional blood flow with resultant healing of ulcers and gangrene.

The authors suggest that two different sympathectomy procedures should be considered depending on the severity of the disease: In a limited digital sympathectomy, adventitia is stripped from the radial and ulnar digital arteries and common digital arteries (Video 22.1 ▶). In an extended, radical digital sympathectomy, adventitia is stripped from the radial and ulnar arteries, the common digital arteries and the proper digital arteries (Figs. 22.6 & 22.7).[105] Long-term follow up of peripheral sympathectomy was reported recently.[106]

Because of the myogenic nature of the spasm, treatment may not just be directed towards the autonomic nervous system. The principle of mechanical dilatation is based on the observation of Bard,[107] who noticed that a vessel in a state of tonic contraction may respond by reflex dilatation when mechanical dilatation is applied. Vessel constriction should not be treated by physical dilatation until the nature of the lesion has been determined, intimal damage with or without thrombosis has been excluded, and if pharmacologic treatment has been ineffective. A closed technique may be tried initially in which heparinized saline solution is injected under pressure between occluding vascular clamps. An arteriotomy may be required and the vessel dilated with a small Fogarty catheter.

Clinical tips

Periarterial sympathectomy

1. A palmar incision along a skin crease will result in a less prominent scar and less contracture postoperatively.
2. Two step incisions along the horizontal palmar crease are sufficient to expose the common digital arteries.
3. The entire superficial palmar arch can be exposed through a longitudinal palmar crease incision.
4. The vena comitantes may also be removed with the periarterial adventitia, but it may result in postoperative edema of the hand.
5. Periarterial sympathectomy is routinely performed on both the radial and ulnar arteries at the wrist level and the second, third, and fourth common digital arteries in primary Raynaud's disease. However, sympathectomy of the proper digital arteries may also be necessary for "vibration white finger" disease and systemic sclerosis.

Arterial reconstruction

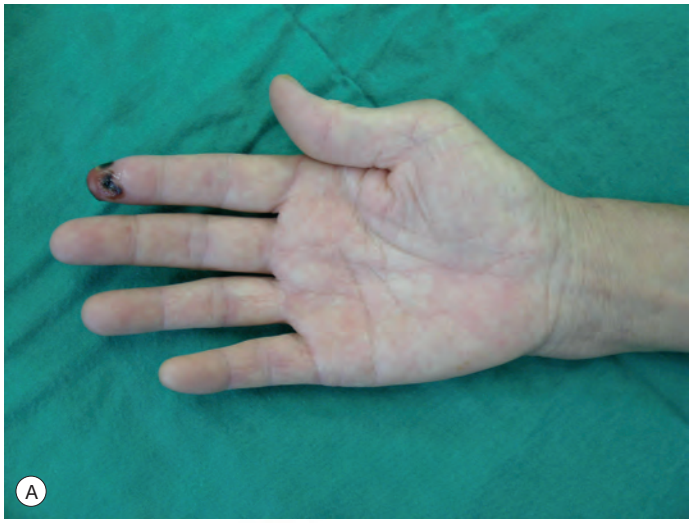
For small partial arterial injuries, closure in a transverse direction prevents narrowing of the lumen. Even with significant (up to 60%) arterial narrowing after transverse closure, flow is not affected.[108] A vein patch can be used to close a more extensive partial injury.[65,88] Sharp arterial transections can often be repaired end-to-end if the vessel ends are mobilized sufficiently. More extensive untidy arterial injuries commonly require a reversed vein graft interposed between the proximal and distal arterial ends. The cephalic, basilic, distal greater saphenous, and distal lesser saphenous veins are used most frequently. Some 10–30% more length of vein than is estimated, is harvested and then the vein graft is reversed or the valves incised. For axillary and brachial arterial injuries, the greater saphenous vein is preferred.[64,65] A local forearm vein can be used for distal brachial, radial, and ulnar artery repairs when the extremity has not sustained significant additional soft-tissue trauma. If forearm trauma precludes use of a local vein graft, leg or dorsal foot veins are used.[64]

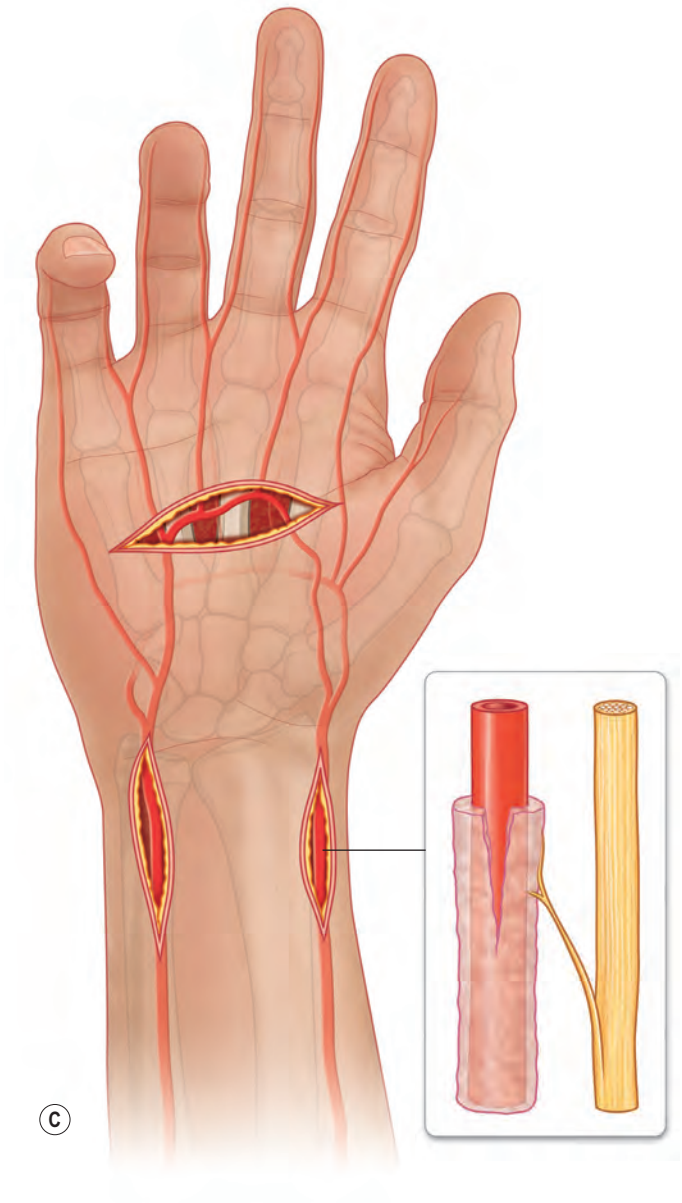
Arterial reconstruction for symptomatic thrombosis or occlusion can be managed by ligation alone, excision with end-to-end repair, or excision and interposition grafting. Surgical indications include (1) absence of an alternative arterial inflow, (2) two or more levels of occlusion that compromise potential collateral flow, (3) thrombosis extending beyond the origins of the common digital vessels, and (4) incomplete deep and superficial arches. The major indication for arterial reconstruction is inadequate perfusion with a DBI of <0.7; if an appropriate risk–benefit ratio exists, arterial reconstruction should be performed.[25]

Surgical techniques include:

1. *In situ* and non-reversed vein grafts
2. Interposition reversed vein grafts
3. Interposition arterial grafts (Video 22.2 ▶)
4. Arterialization of venous flow
5. Free omental transfer.

The goal of arterial reconstruction is to increase digital blood flow and restore nutritional flow. Successful arterial





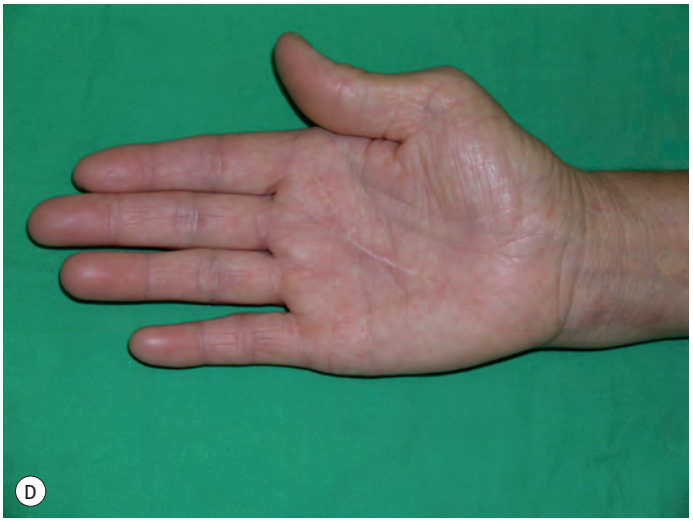


Fig. 22.6 Limited digital sympathectomy: **(A)** Preoperative. **(B)** Operative view. **(C)** Schematic drawing. **(D)** Postoperative view.

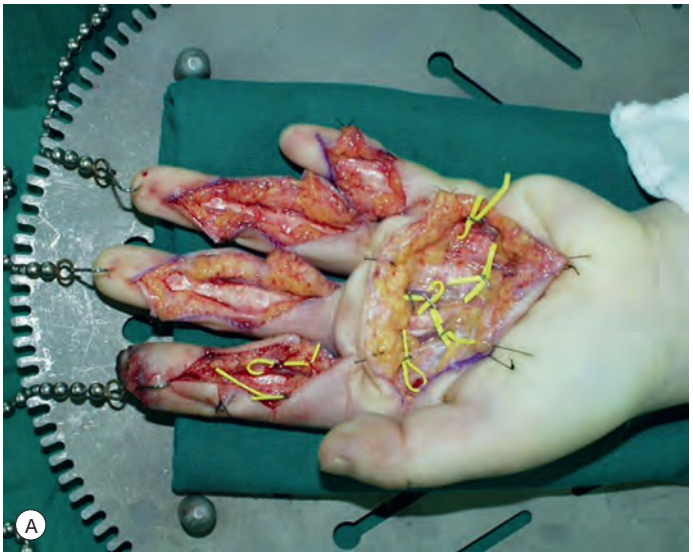

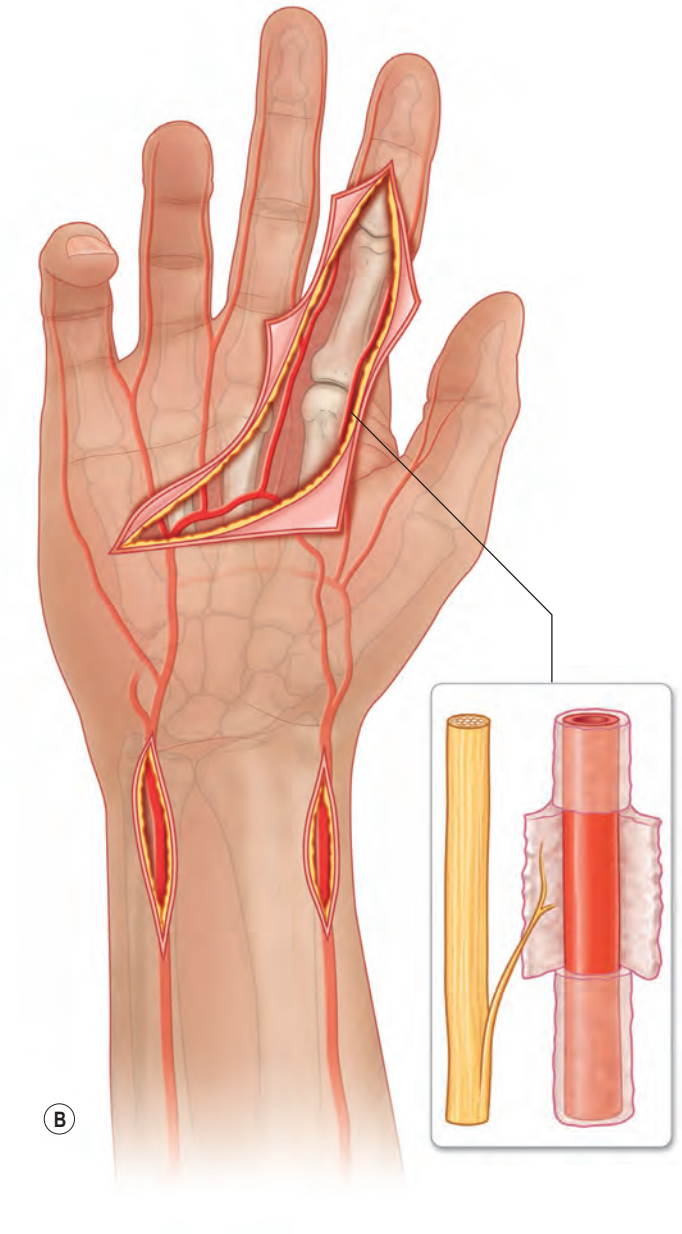

Fig. 22.7 Radical digital sympathectomy: **(A)** Radical sympathectomy of common and proper digital arteries in the palm and digits. **(B)** Schematic drawing of radical digital sympathectomy.

reconstruction in patients with underlying collagen vascular disease increases total digital blood flow and nutritional flow, diminishes symptoms, and promotes healing of ulcers.[109] Regardless of the etiology, the level and extent of occlusion, the adequacy of collateral flow, and any component of sympathetic overactivity obviously influence the results of reconstruction for arterial thrombosis and occlusion.

Jones advocated that if by stringent clinical and angiographic criteria, segmental thrombosis or occlusions are identified in the distal radial and/or ulnar arteries and the superficial palmar arch, and if adequate distal "run-off" can be demonstrated in the common digital arteries, microsurgical revascularization should be considered in patients with symptomatic hand ischemia unresponsive to medical management.[5] Jones described four basic vein graft configurations that have evolved for revascularization of the hand, and this classification may be helpful in planning surgery.[1]

For short segmental occlusions or thrombosis of the ulnar artery in Guyon's canal, end-to-end anastomosis of a vein graft or arterial graft from the ulnar artery in the distal forearm to the distal ulnar artery just proximal to the superficial palmar arch is classified as a type I configuration.

Occlusion of the distal radial artery is much rarer in comparison to ulnar artery occlusion. End-to-end anastomosis of a vein graft or arterial graft from the distal radial artery in the forearm to the deep palmar arch or princeps pollicis artery in the thumb–index webspace is classified as a type II configuration.

If the superficial palmar arch is involved but the common digital arteries are spared, reconstruction of the superficial palmar arch may become necessary with end-to-end anastomosis of the vein or arterial graft to the ulnar artery in the distal forearm and end-to-side anastomoses of the common digital arteries to the interposition vein graft. This type III configuration is commonly required in systemic disease manifest by secondary Raynaud's disease. In this situation, a deep inferior epigastric arterial graft may be more useful than a vein graft. The deep inferior epigastric artery has numerous

branches that can be used to reconstruct a new palmar arch with end-to-end anastomoses to the common digital arteries. End-to-end anastomoses are easier to perform compared with end-to-side anastomoses if an interposition vein graft is used which may also cause turbulent flow.

There are other technical advantages to using an autologous deep inferior epigastric artery graft. The size match between the inflow ulnar artery and the proximal epigastric artery is excellent.[110] The deep inferior epigastric artery tapers as it gives off branches and the size of these distal branches is a close match for anastomoses to the common digital arteries (Fig. 22.8).

In a type IV configuration, two interposition vein grafts or two deep inferior epigastric artery grafts are used to revascularize the superficial palmar arch or common digital arteries from the distal ulnar artery and the deep palmar arch or princeps pollicis artery from the distal radial artery.[111]

In the Wake Forest classification of occlusive/vasospastic/vaso-occlusive disease (Table 22.2), Koman *et al.* recommended that arterial reconstruction is indicated in patients with refractory symptoms and inadequate collateral circulation (groups IIB and IIIB), and should be individualized in groups IIA and IIIA.[24]

Table 22.2 Wake Forest classification of occlusive/vasospastic/vaso-occlusive disease

Group	Etiology	Comments
I	Raynaud's disease	Idiopathic
II	Raynaud's syndrome	Collagen vascular disease
A	Adequate circulation	
B	Inadequate circulation	
III	Secondary vasospasm/ occlusive disease	Vascular injury
A	Adequate circulation	Occlusion/embolus
B	Inadequate circulation	
IV	Secondary vasospasm	Non-vascular injury Nerve/bone/soft tissue damage

Clinical tips

Interposition vessel grafts

1. Volar wrist veins are very useful for interposition grafts for the proper digital arteries.
2. The deep inferior epigastric artery (DIEA) is a good source for superficial palmar arch and ulnar artery obstruction. The vessel diameters of the DIEA are a good match for the proximal ulnar artery and distal palmar arch. Branches of the DIEA are also a good match for the common digital arteries.
3. The cephalic vein is a useful donor vein for radial artery obstruction. It can be harvested through the same incision. The radial artery graft is placed superficial to the abductor pollicis longus (APL), extensor pollicis brevis (EPB), and extensor pollicis longus (EPL) tendons to prevent the compression of the graft by these tendons.
4. Distal anastomoses into the digital arteries are very challenging in the ischemic hand because of the obliterated artery. The intima of the artery is markedly thickened in secondary Raynaud's syndrome.
5. Graft anastomoses should be performed into healthy recipient vessels with good inflow and a normal appearing intima.
6. The hand and wrist should be immobilized in a short arm splint for at least 1 week.

Aneurysms

Treatment options include: (1) resection and ligation[112]; (2) excision of the damaged wall and "patch" grafting; (3) resection with end-to-end repair; and (4) resection with an interposition graft, depending on collateral flow and vasomotor tone.[113]

Early excision of true or false aneurysms of the radial or ulnar arteries is strongly advocated to prevent distal embolization. An intraoperative Digital/Brachial Artery Index less than 0.7 after aneurysm excision indicates the need for arterial reconstruction.[54] Postoperative care and surgical outcomes are similar to those after reconstruction of ulnar artery thrombosis (Fig. 22.9).

Mycotic aneurysms are secondary to hematogenous or local bacterial infection that weakens the vessel wall and virtually all are now due to intravenous drug abuse.[73] Infection producing a soft-tissue swelling overlying an artery should be evaluated for the possibility of a false aneurysm to avoid an ill-advised incision and drainage procedure. If clinical examination is not conclusive, duplex scanning should be diagnostic. Excision and ligation of the artery are preferred if the feeding vessel is not critical to limb survival, otherwise excision and vein bypass around the infected area will restore arterial inflow.

Balloon angioplasty for stenotic lesions

Ahn applied the technique of balloon angioplasty to treating patients with secondary Raynaud's syndrome who had an arterial stenosis of their radial and ulnar arteries diagnosed by arteriography.[114] After adventitial stripping of the affected radial and ulnar arteries, palmar arch, and common digital arteries, vessel dilatation was performed using a percutaneous transluminal coronary angioplasty balloon catheter. The balloon was inserted through a branch of the ulnar artery and advanced from the main artery through Guyon's canal, into the palmar arch and common digital arteries. Sequential dilatation of any stenotic segment was performed by inflation of the balloon to 6 atmospheres for 40 seconds.

Balloon catheter dilatation is a useful adjunct procedure and may potentiate the effects of digital sympathectomy. The technique can also be used for incomplete arterial occlusions up to 15 cm in length and may eliminate the need for interposition vein grafts (Fig. 22.10).

Other surgical options

Surgeons have investigated alternative options to salvage severely ischemic limbs when standard arterial bypass procedures are not possible. Two salvage procedures for impending digital loss are reversal of blood flow through the upper extremity veins and vascularized omental transfer to the dorsum of the hand.

King *et al.*[115] reported arterialization of the venous system of the upper limb based on *in situ* vein bypass. *In situ* vein bypass is a standard vascular surgery technique that involves complete exposure of the chosen vein and ligation of all its branches. A small valvulotome is used to divide each half of the bicuspid valves in the vein all the way to the metacarpal heads distally. The vein is then anastomosed to a proximal artery (usually end-to-end to the brachial artery), shunting arterial blood through the vein into the hand. Patients are heparinized after this procedure. Pederson has used the concept of reverse venous flow to improve vascularity in severe hand ischemia. He anastomosed the distal portion of either the radial or ulnar artery to suitable hand veins, thereby creating a reverse-flow situation in an attempt to improve capillary perfusion. He reported his personal experience in over 20 cases, and showed significant improvement in pain and ulceration after the procedure.[116,117]

The recipient vein is prepared by removing the valves at the level of the metacarpal necks. The cephalic vein is well suited for this procedure because it has great interconnections with the dorsal venous system of the hand, which potentially allows for a single proximal anastomosis. Arterial branches are then ligated and the proximal end-to-side anastomosis is performed. Postoperative thrombosis and swelling of the limb may result.

A new blood supply can be supplied indirectly to the hand, by a second technique. A free omental flap is harvested and placed beneath the dorsal skin of the forearm and hand, and the superior gastro-epiploic artery and vein anastomosed to the brachial artery and cephalic vein at the elbow.[116,117]

Treatment algorithm

All patients with chronic ischemia of the hand should obviously be treated pharmacologically with topical nitroglycerin, calcium channel blockers, vasodilators, and possibly botulinum toxin.[75] Patients with ischemic pain often follow an intractable course and surgical intervention is frequently

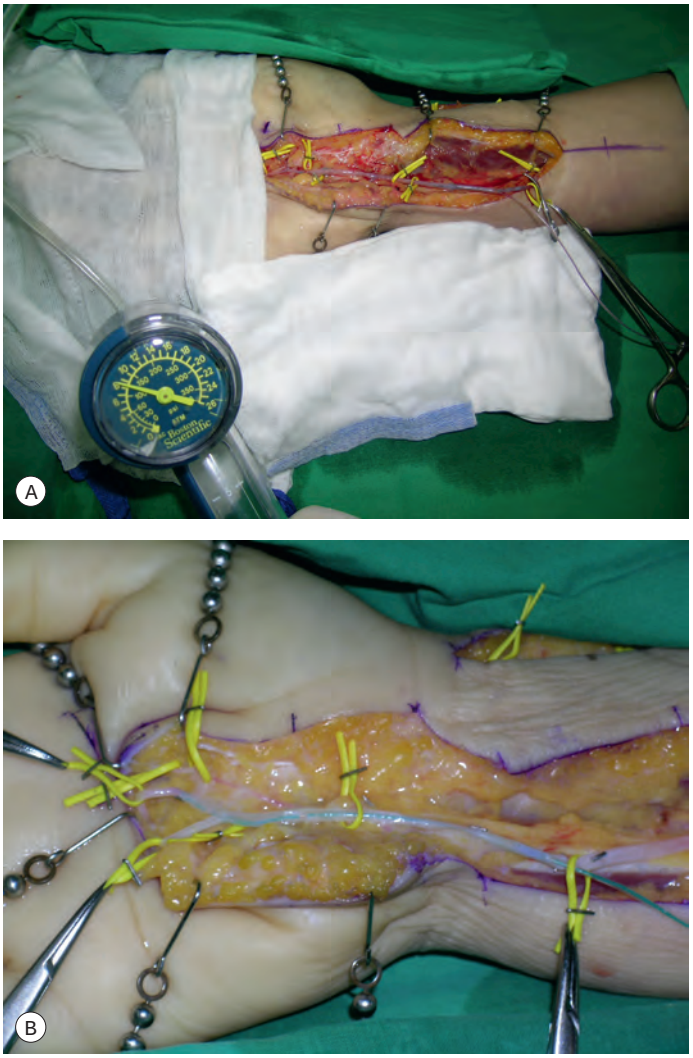

Fig. 22.10 Balloon angioplasty. **(A)** Ballooning of stenotic ulnar artery. **(B)** Ballooning of the palmar arch.

inevitable. Established gangrene, osteomyelitis, and septic arthritis usually require a digital amputation. Amputations are effective in relieving patients' pain, for which they are very grateful.

Arteriography, MR angiography or duplex ultrasound will allow delineation of the exact site and extent of any stenosis or complete occlusion, and assist in surgical planning. Indications for arteriography with the intent of surgical revascularization include the following:

- unilateral Raynaud's phenomenon;
- progressive digital ulceration or gangrene despite good medical management;
- recurrent digital ulceration; and
- Doppler evidence of occlusion of a major artery.[5]

Specific indications for surgical intervention in patients with chronic ischemia of the hand have been suggested.[5,101] Options for surgical intervention include digital sympathectomy, balloon angioplasty, and microsurgical revascularization using interposition vein grafts or arterial grafts. In some patients these procedures can be combined.

In a patient with Raynaud's phenomenon unresponsive to pharmacological treatment, if angiography reveals no evidence of occlusion of the main inflow radial and ulnar arteries and satisfactory visualization of the three common digital arteries, digital sympathectomy should be considered.[101,106]

If angiography reveals stenosis or occlusion of the radial or ulnar arteries over a distance of <3 cm, balloon angioplasty may be considered so that expansion of the vessel lumen may increase digital blood flow. Balloon angioplasty can also be combined with radical sympathectomy.

If angiography demonstrates segmental occlusions of the main inflow radial and/or ulnar arteries but there is satisfactory "run-off" in the common digital arteries, microsurgical revascularization of the superficial palmar arch from the ulnar artery and much less frequently microsurgical revascularization of the deep palmar arch from the radial artery can be considered.

Despite more complicated harvesting, a deep inferior epigastric artery graft may allow end-to-end anastomoses of the branches of the arterial graft to the common digital arteries, whereas an interposition vein graft requires end-to-side anastomoses. However, the more extensive the involvement of the ulnar or radial arteries, the more likely that an interposition vein graft rather than an interposition arterial graft is required.[114]

If the symptoms of chronic ischemia are localized to a single finger and angiography reveals a discrete segment of occlusion of a proper digital artery, resection of the segment of proper digital artery and reconstruction with an interposition vein graft or arterial graft may occasionally be considered (Fig. 22.11).[118] Balloon angioplasty of a stenotic common digital artery or proper digital artery is very difficult and may result in vessel rupture.[114]

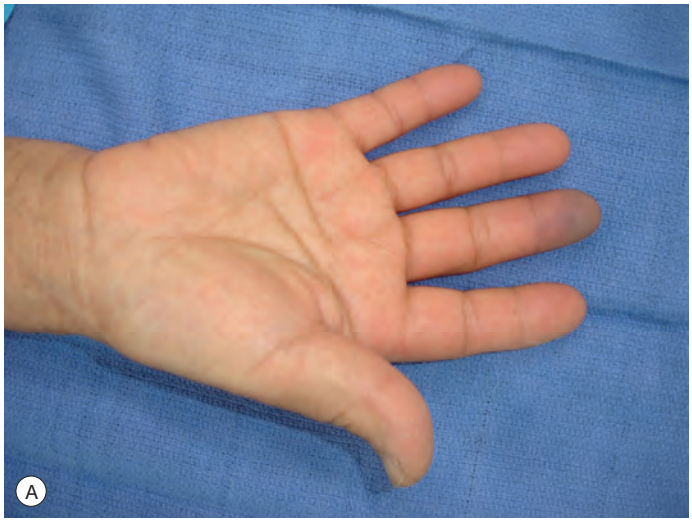
Clinical tips

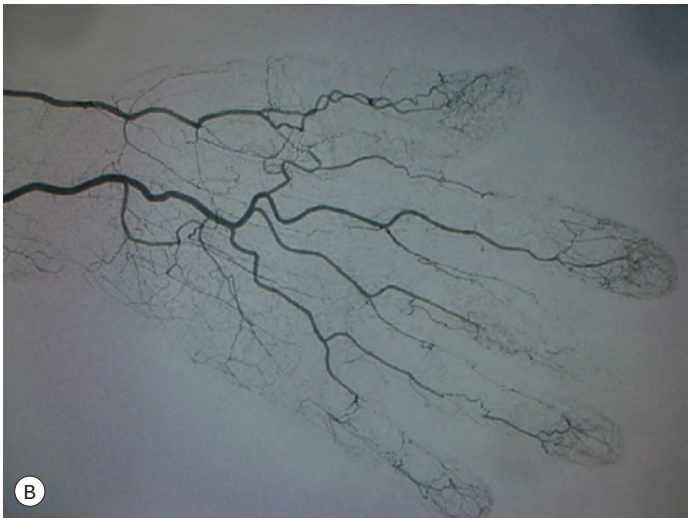
Management strategy

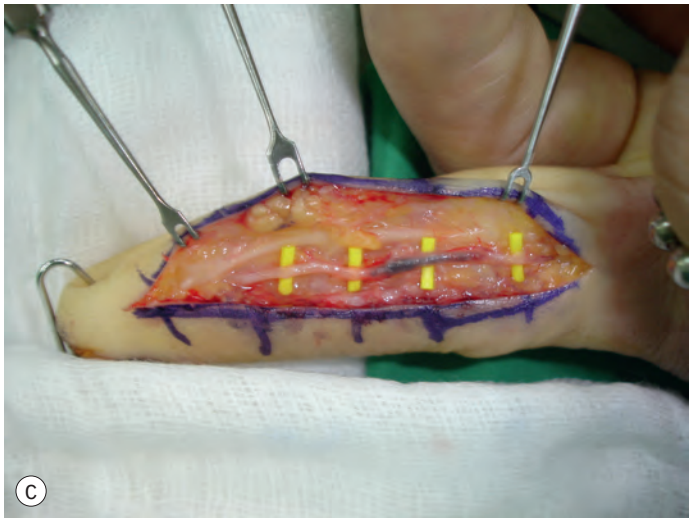
1. Medication with calcium channel blockers is acceptable in both primary Raynaud's disease and secondary Raynaud's syndrome. However, patients with secondary Raynaud's syndrome usually need periarterial sympathectomy or vascular reconstruction.
2. Balloon angioplasty is useful in selected cases of stenosis and short occluded segments.
3. Arterial reconstruction with interposition grafts in Raynaud's syndrome may be performed earlier than before the appearance of gangrene of the fingers.
4. Amputation of gangrenous fingertips should be conservative to preserve the length and shape of fingers in women. Small ulcers may heal spontaneously after improvement in vascular inflow.
5. Ischemic pain usually improves after appropriate surgery to increase blood flow.

Postoperative care

After microsurgical revascularization procedures, a single bolus of heparan (1000–2400 IU, intravenous push) is administered immediately before the microsurgical clamps







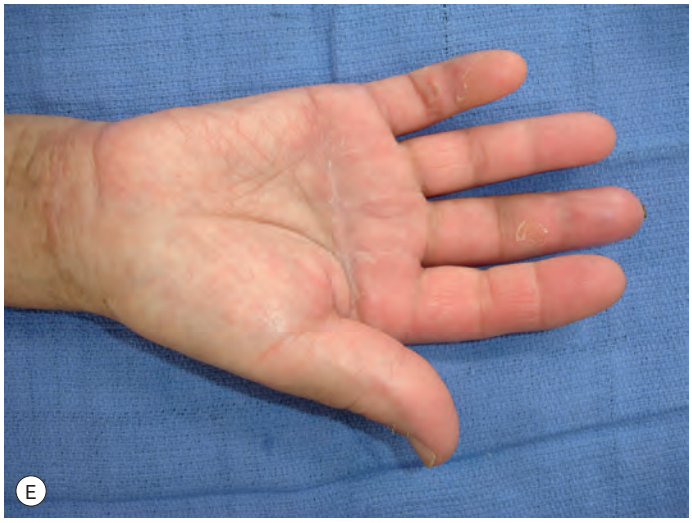


Fig. 22.11 Proper digital artery reconstruction with reverse vein graft. **(A)** Preoperative. **(B)** Angiogram showing occlusion of the proper digital arteries to the middle finger. **(C)** Occlusion of the ulnar digital artery. **(D)** Resection and interposition vein graft. **(E)** Postoperative.

are removed and either heparin is maintained for 7 days, or dextran 40 is administered intravenously at 25 cc/h for 5 days. If there is extensive intimal damage or vascular compromise, full heparinization and conversion to Coumadin is advisable.

A bulky hand and forearm dressing with a dorsal plaster of Paris splint is applied with the hand in a functional position. A drain is left in place for 12–36 h. Circulation to the fingertips is assessed every hour for 6 h and then every 4 h for 24 h. Critical arterial reconstructions are monitored in the same way as replantations. Changes in color and capillary refill; temperature monitoring (loss of >2°C in 1 h); pencil Doppler monitoring or pulse oximetry can be used. If sedation is required, chlorpromazine (25 mg orally three times daily) is prescribed. The patient obviously discontinues smoking and avoids caffeine consumption. The patient is discharged home on aspirin 81 mg daily and continued for up to 3 months.

Sutures are removed at 10–14 days postoperatively. The hand is protected for 2–6 weeks in a lightweight splint and the patient is instructed to avoid any trauma to the surgical site. Some residual cold sensitivity, soreness, pillar-type palm pain, and ulnar nerve irritability are expected. Return to work is based on job type after 6–12 weeks, no athletic or work restrictions are necessary if the patient is asymptomatic.

Outcomes, prognosis, and complications

Complications after surgical intervention for ischemia of the hand include impaired healing of the incision, dehiscence, infection, stiffness of the fingers, and specifically after microsurgical revascularization, thrombosis of the anastomoses.

After digital sympathectomy, patients usually report improvement in their symptoms of pain and cold tolerance, reduction in the frequency and severity of Raynaud's episodes, and healing of digital ulcers.[101]

Microsurgical revascularization increases distal arterial perfusion, reduces symptoms of ischemic pain, promotes healing of ulcers, and prevents progression to gangrene in hands without adequate collateral circulation.[101] Koman *et al.* have demonstrated that this is due to an increase in the ratio of nutritional to total flow without increasing total microvascular perfusion within digits.[104] Patency rates of 80–90% can be expected of interposition vein grafts for hypothenar hammer syndrome, but thrombosis of the grafts can occur and symptoms return in longer follow-up. Of 106 interposition vein graft reconstructions of the ulnar artery, 87 (82%) remained patent.[40,99,119–122]

The prognosis for patients with chronic ischemia of their hands depends on the etiology, the severity, the response to treatment, and progression of the underlying condition.[101,123] Prognosis seems to be worse in patients with diabetes and renal vascular disease. Hartzell *et al.* reported that long-term follow-up of 27 patients revealed that while digital sympathectomy healed digital ulcers and decreased the number of ulcers in vasospastic disease in autoimmune patients, the efficacy was much lower in patients with vasospasm secondary to atherosclerosis. This might explain why the prognosis is worse in patients with underlying diabetes. Patients with chronic ischemia of their hands due to scleroderma show improvement after digital sympathectomy and microsurgical revascularization, but because of progression of the underlying disease, there is a significant recurrence of digital ulcers 2 years after surgery.[21] Therefore, these procedures should be considered palliative rather than curative. Since digital sympathectomy and microsurgical revascularization cannot usually be repeated, recurrence of digital ulcerations may ultimately require amputations. Jones[101] has suggested that the hand be considered an "end organ" just like the heart, brain, and kidneys and therefore hand ischemia may reflect similar pathology in these other organs.

Secondary procedures

Secondary procedures after digital sympathectomy or microsurgical revascularization are rare because of the postoperative scarring from the original operation. Revision surgeries at the same location are usually not advised. Digital amputation or even ray amputation would be a last option should the ischemia progress.

Future directions

Occlusive/thrombotic disease of the inflow ulnar and radial arteries to the hand will still be managed by excision of the occluded or thrombosed segment and interposition vein or arterial grafting. Technically proficient hand surgeons may be inclined to utilize the same excision and grafting of an occluded segment of the proper digital arteries in affected fingers. However, the newer technique of balloon angioplasty may eliminate the necessity for interposition vein or arterial grafting within the fingers themselves.

Even though there are anecdotal reports of the successful use of botulinum toxin and fat grafting for vasospastic conditions causing ischemia of the hand, more rigorous randomized trials will be necessary in the future. Finally, newer pharmacologic agents may be developed to treat Raynaud's phenomenon, but digital sympathectomy may still be indicated for those patients with increasing frequency and increasing severity of their Raynaud's symptoms. The results of digital sympathectomy in patients with connective tissue disorders will only be palliative and dependent on the progression of the underlying disease.

Interposition vein graft configurations for microsurgical revascularization of the ischemic hand. *Tech Hand Up Extrem Surg*. 1999;3:121–130. *Despite the various causes of upper extremity ischemia, the presenting symptoms are usually predictable. These symptoms constitute acute ischemia, digital ulcers, and gangrene, Raynaud's phenomena, or claudication with exercise. For segmental arterial occlusive diseases in selected patients, microsurgical revascularization with bypass vein grafts may be effective. This study reviews such cases that are bypassable with vein grafts, and proposes a classification system for distal upper extremity bypass vein grafts.*

7. Jones NF. Acute and chronic ischemia of the hand: pathophysiology, treatment, and prognosis. *J Hand Surg Am*. 1991;16:1074–1083. *Fifty patients with acute and chronic ischemia of the hand were investigated using various methods over 4 years. For many causes of the ischemia, medical management with emergent intra-arterial streptokinase, heparin, or dextran was used, along with nifedipine and pentoxifylline in chronic cases. Surgical treatment such as stellate ganglion blocks, microsurgical revascularization, and digital sympathectomy was used. Eighteen patients underwent amputation due to end-stage gangrene, and long-term follow-up revealed 20% incidence of recurrent digital ulcerations.*

12. Wilgis EF. Evaluation and treatment of chronic digital ischemia. *Ann Surg*. 1981;193:693–698. *Forty-two patients were evaluated and treated for chronic digital ischemia. Manifestations of pain, severe cold intolerance and occasional tip ulceration were seen despite conservative treatment of vasodilators, tobacco abstinence, and beta-blockers. Direct microvascular reconstruction, thermal biofeedback, and digital sympathectomy were performed with improvement in 70% of patients.*

21. Jones NF, Imbriglia JE, Steen VD, et al. Surgery for scleroderma of the hand. *J Hand Surg Am*. 1987;12:391–400. *Out of 813 consecutive patients with scleroderma, 31 underwent one or more surgical procedures. Raynaud's phenomenon and digital tip ulcerations were controlled with vasodilators and meticulous local wound care. Frank gangrene was usually managed conservatively until autoamputation, but 23 digital amputations had to be performed. Digital sympathectomy and micro-revascularization were performed in selected patients. Arthrodesis was performed in patients with severe digital contractures.*

25. Fazan VP, Borges CT, Da Silva JH, et al. Superficial palmar arch: an arterial diameter study. *J Anat*. 2004;204:307–311. *Symptomatic vascular disorders of the upper extremity interfere with health-related quality of life, diminish function, and have a negative impact on patients and society. Although less prevalent than ischemic lesions of the lower extremity, heart, or brain, upper extremity vascular morbidity is a significant social burden. Aberrant microvascular flow secondary to acute or chronic trauma, congenital deformity, systemic processes, or genetic influences affect over 10% of the general population and 20–30% of premenopausal women. Pain, cold intolerance, numbness, ulceration, or gangrene can result from these vascular insufficiencies or incompetencies. Abnormal perfusion may occur secondary to congenital or acquired events that affect vascular structures, vascular function, or both. Vascular insufficiency occurs due to blood flow compromise with decreased cellular perfusion and resultant cell damage, cellular injury, and pain. Various approaches to diagnosis and management of vascular disorders based on physiologic factors are covered.*

60. Kim YH, Ng SW, Seo HS, et al. Classification of Raynaud's disease based on angiographic features. *J Plast Reconstr Aesthet Surg*. 2011;64:1503–1511. *We analyzed the angiographic features of the arterial supply of the hand at three levels: (1) radial or ulnar, (2) palmar arch and common digital, and (3) digital vessels. Subsequent surgical interventions were tailored according to disease types, and these included combinations of: digital sympathectomy, balloon angioplasty, and end-to-end interposition venous or arterial grafting. We classified Raynaud's disease into six types: type I and II involve the radial or ulnar arteries. Type I (27.3%) showed complete occlusion, while type II (26.2%) involved partial occlusion. Type IIIa (27.1%) showed tortuous, narrowed or stenosed common digital and digital vessels. Type IIIb (1.4%) is a subset which involved the digital vessel of the index finger related to exposure to prolonged vibration. Type IV and V showed global involvement from the main to digital vessels. Type IV (13.7%) showed diffused tortuosity, narrowing, and stenosis. Type V (4.3%) is the most severe, with paucity of vessels and very scant flow. Nearly half (47%) of the patients had associated systemic disease. This new classification provides objective and valuable information for decision-making regarding choice of surgical procedures for the treatment of patients with Raynaud's disease that had failed conservative therapy.*

79. Neumeister MW. Botulinum toxin type A in the treatment of Raynaud's phenomenon. *J Hand Surg Am*. 2010;35:2085–2092. *Raynaud's patients were injected with 50 to 100 units of onabotulinumtoxin A to improve perfusion of the digits. An institutional review board-approved retrospective review was undertaken to analyze outcomes. Laser Doppler scans were performed before and after injection to quantitatively measure perfusion. A total of 14 men and 19 women with Raynaud's phenomenon were injected with onabotulinumtoxin. Botulinum toxin appears to improve perfusion of the hand after direct injection around the neurovascular bundles. Further investigations are warranted to identify the exact mode of action in relieving vasospasm and alleviating pain.*

106. Murata K, Omokawa S, Kobata Y, et al. Long-term follow-up of peripheral sympathectomy for chronic digital ischemia. *J Hand Surg Eur Vol*. 2012;37:788–793. *This study investigates long-term clinical results (>10 years) of periarterial sympathectomy in chronic ischemic digits compared with intermediate-term results (3 years). Periarterial sympathectomy via the palm and volar wrist was carried out on 11 hands of seven patients with digital ischemia but no gangrene or severe ulceration. The periarterial sympathectomy via the palm and wrist could prevent long-term aggravation of symptoms of chronic digital ischemia when combined with adequate postoperative drug therapy.*

109. Savvidou C, Tsai TM. Long-term results of arterial sympathectomy and artery reconstruction with vein bypass technique as a salvage procedure for severe digital ischemia. *Ann Plast Surg*. 2013;70:168–171. *The aim of this study is to present a combined treatment of arterial sympathectomy and artery reconstruction with vein bypass technique in patients with severe digital ischemia. In all, 22 patients representing 53 digits received treatment during a 15-year period. Skin color and trophic changes including ulcers, necrosis, and amputation; pain level according to the visual analog scale; and functional assessment based on the disabilities of the arm, shoulder, and hand questionnaire were recorded. Based on the results of this study, vascular reconstruction combined with sympathectomy may be indicated on an individualized basis for patients with digital ischemia. This procedure can lead to healing of skin trophic changes, diminution of pain, avoidance of amputation, and long-term improvement in life quality.*

111. Masden DL, Seruya M, Higgins JP. A systematic review of the outcomes of distal upper extremity bypass surgery with arterial and venous conduits. *J Hand Surg Am*. 2012;37:2362–2367. *The aim of the authors was to conduct a systematic review of literature evaluating efficacy of venous and arterial grafts for distal upper extremity bypass surgery. Manual review produced 42 studies based on inclusion criteria of reported distal upper extremity bypass surgery, complete information on graft type used, examined patency of reconstruction, and described method for determining patency. In 145 patients, 152 grafts were performed for upper extremity revascularization, including 120 grafts for revascularization of distal ulnar artery circulation, 31 for distal radial artery circulation, and one for both distal ulnar and radial artery occlusions. Overall patency rate was 87% at an average follow-up of 34 months. This review showed a high patency rate and clinical efficacy of distal upper extremity bypass surgery with a mean follow-up of almost 3 years. There may be a benefit of using arterial versus venous conduits, although further examination is needed given the small number of arterial reconstructions reported.*

Type IV and V showed global involvement from the main to digital vessels. Type IV (13.7%) showed diffused tortuosity, narrowing, and stenosis. Type V (4.3%) is the most severe, with paucity of vessels and very scant flow. Nearly half (47%) of the patients had associated systemic disease. This new classification provides objective and valuable information for decision-making regarding choice of surgical procedures for the treatment of patients with Raynaud's disease that had failed conservative therapy.*

A systematic review of the outcomes of distal upper extremity bypass surgery with arterial and venous conduits. *J Hand Surg Am*. 2012;37:2362–2367. *The aim of the authors was to conduct a systematic review of literature evaluating efficacy of venous and arterial grafts for distal upper extremity bypass surgery. Manual review produced 42 studies based on inclusion criteria of reported distal upper extremity bypass surgery, complete information on graft type used, examined patency of reconstruction, and described method for determining patency. In 145 patients, 152 grafts were performed for upper extremity revascularization, including 120 grafts for revascularization of distal ulnar artery circulation, 31 for distal radial artery circulation, and one for both distal ulnar and radial artery occlusions. Overall patency rate was 87% at an average follow-up of 34 months. This review showed a high patency rate and clinical efficacy of distal upper extremity bypass surgery with a mean follow-up of almost 3 years. There may be a benefit of using arterial versus venous conduits, although further examination is needed given the small number of arterial reconstructions reported.*

Neuropathic pain in the upper extremity

Catherine Curtin

SYNOPSIS

- Pain is a common issue for those who care for people with disorders of the upper limb, ranging from mild musculoskeletal pain to complex regional pain syndrome.
- Neuropathic pain is often the cause of persistent surgical pain.
- Neuropathic pain is defined by the International Association for the Study of Pain (IASP) as pain caused by a lesion or disease of the somatosensory nervous system.

Introduction

Pain is a common issue for those who care for people with disorders of the upper limb, ranging from mild musculoskeletal pain to complex regional pain syndrome.[1] There is the "healthy pain" that protects the injured limb while the tissue heals. Then there is the persistent pain after surgery or trauma that continues long after the tissue has healed. This persistent pain becomes a pathologic process and is most commonly neuropathic in origin. Post-traumatic and post-surgical neuropathic pain will be the focus of this chapter.[2]

Neuropathic pain is defined by the International Association for the Study of Pain (IASP) as "pain caused by a lesion or disease of the somatosensory nervous system."[3] Neuropathic pain is seen in many clinical settings such as nerve compression and nerve injury. Perhaps the most frustrating presentation of neuropathic pain is the pain that occurs after a technically perfect surgery. Every surgeon wants better outcomes. Early recognition and treatment of neuropathic pain will improve outcomes in these challenging cases.

Pain and surgery have always been intertwined. From before the advent of anesthesia, surgeons strove to increase their speed to reduce their patients' suffering. Dr. Mitchell described neuropathic pain in a book explaining his experience with nerve injuries treated during the Civil War.[4] Throughout the treatise, he noted intense pain associated with these nerve injuries and uses the term causalgia to explain this "burning pain". Surgeons have continued to try and improve the treatment of nerve pain. We have changed techniques, medications, and added other treatments. The knowledge of neuropathic pain and its mechanisms has greatly expanded since Dr. Mitchell's time, but to this day, neuropathic pain remains a challenging problem. This chapter will provide the reader with information on the diagnosis and treatments available for the common complaint of neuropathic pain.

Terminology

Before progressing too far into this topic, it is first important to understand some basic definitions of terminology used within the pain field. Below are the IASP definitions for common pain vocabulary.

1. Allodynia: pain due to a stimulus that does not normally provoke pain. Example: "It hurts when the wind blows on my arm."
2. Dysesthesia: an unpleasant abnormal sensation. Example: "My arm feels like it is rubbed raw by sand paper when my shirt touches it."
3. Hyperalgesia: increased pain from a stimulus that normally provokes pain. Example: "Even a small bump feels like a sledge hammer hit me."

Another term to be clarified is complex regional pain syndrome (CRPS). CRPS represents a severe subset of patients who have neuropathic pain as well as other symptoms impacting the skin and tissues of the injured area. This term CRPS is often used inappropriately, resulting in confusion and fear associated with the diagnosis of CRPS. This confusion is likely due to two factors. First is that the terminology for CRPS has changed with increased understanding of the pathophysiology. Mitchell first named it "causalgia", where he described patients with nerve injuries, burning pain, glossy skin, and changes in hair and nails. In 1946, this process was

renamed reflex sympathetic dystrophy.[5] But as all cases did not seem to be sympathetically mediated, so a group of pain researchers again changed the taxonomy to complex regional pain syndrome in 1995.[6] CRPS has been subdivided this into two groups – type 1 (no known nerve injury) and type 2 (known nerve injury). There remains controversy whether this subdivision of CRPS is useful, as some believe all CRPS is mediated by some type of nerve injury, whether it can be identified or not.[7]

The second issue with CRPS is that there is no test to confirm the diagnosis; CRPS is a diagnosis based on history and physical exam. All patients with CRPS must have pain disproportionate to the trauma. The patients must also have a constellation of other sudomotor symptoms to receive a diagnosis of CRPS. What symptoms make a diagnosis of CRPS has been debated in the pain field, further adding to the confusion.[8] Table 23.1[9] presents the list of physical exam findings required for a diagnosis for CRPS based upon a consensus meeting of pain researchers in Budapest. Fig. 23.1A,B shows two hands with typical physical exam findings seen in the setting of CRPS. One thing about CPRS is clear: this complication has a great negative impact on the patient's quality of life.[10]

Table 23.1 **Diagnostic criteria for complex regional pain syndrome (CRPS)**

Must report at least one symptom in three of the following categories:	Must display at least one sign* at time of evaluation in at least two of the following categories:
1. Sensory: Reports of hyperalgesia and/or allodynia	1. Sensory: Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement)
2. Vasomotor: Reports of temperature asymmetry and/or skin color changes and/or skin asymmetry	2. Vasomotor: Evidence of temperature asymmetry and/or skin color changes and/or asymmetry
3. Sudomotor/edema: Reports of edema and/or sweating changes and/or sweating asymmetry	3. Sudomotor/edema: Evidence of edema and/or sweating changes and/or sweating asymmetry
4. Motor/trophic: Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)	4. Motor/trophic: Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)

*A sign is counted only if it is observed at time of diagnosis.

Fig. 23.1 **(A)** Hand in patient with complex regional pain syndrome (CRPS): note the shiny skin and edema. **(B)** Hand in CRPS: note the subtle color changes.

Epidemiology

There are several anatomic reasons that the limbs are at particular risk for the development of neuropathic pain. Chronic pain after extremity injury occurs in up to 79% of patients having surgery for traumatic injury to the feet and hands.[11–12] First, the upper limb is richly innervated, putting more nerves at risk of injury after trauma. Second, the nerves of the upper limb travel long distances crossing multiple joints with wide arcs of motion, so the nerves need to glide. Thus, trauma and scarring can tether a nerve resulting in repeated traction of the nerve. Finally, there are several tight areas along the course of the nerves, so an injured swollen nerve is at risk for secondary entrapments. All these anatomic characteristics of the

upper limb mean that injury can result in irritated painful nerves.[13]

Surgical trauma can be the inciting factor for chronic pain. The literature has noted that persistent pain occurs in 20–50% of surgical patients.[14] Carpal tunnel has a 20% rate of persistent pain. The most common complication after trigger finger release and distal radius fractures is pain.[15–16] The mechanism of post-surgical chronic pain is thought to be persistent firing of nerves injured at the time of surgery.[2] Every surgical incision cuts cutaneous nerves and for a subset of patients this injury results in chronic pain. The mystery is: Why do many patients develop peri-incisional numbness after surgery but a subset of patients develops neuropathic pain? Later in the chapter we will discuss risk factors associated with persistent post-surgical pain.

Although neuropathic pain is not uncommon after surgery, the incidence of post-surgical CRPS is fortunately rare. Post-surgical CRPS is a devastating complication, preventing return of function and often causing prolonged disability. A few upper limb surgeries are particularly at risk for CRPS. CRPS after distal radius fracture care is well described, occurring in 1–30% of patients[17–19] CRPS has also been described after palmar fasciectomy with rates reported as high as 17%.[20] Occasionally the patient with the seemingly smallest of traumas will develop CRPS.

Early recognition and treatment of the patient with CRPS is critical, as anecdotal evidence suggests that early intervention improves outcomes.

Risk factors

Much effort has been devoted assessing the risk factors associated with developing neuropathic pain, with the goal of identifying those at risk prior to surgery. Pain is clearly a complex multifactorial process but some patient characteristics have repeatedly been associated with post-surgical pain development. In 2017, there is no definitive risk assessment for postoperative pain. Listed below are some of the factors that have data suggesting an association with pain after surgery.

Gender

The available evidence clearly shows that women and men have different pain experiences. Women are more at risk for developing chronic pain and CRPS.[21] An overall epidemiologic study found CRPS incidence 4:1 women to men.[22] Jellead looked prospectively at distal radius fractures treated with a cast and found 32% developed CRPS and that women had a 5.77 greater odds of being in the CRPS group.[17] Sennwald found that 40% of women who had Dupuytren's release developed CRPS.[20] Overall, the data suggests women are at higher risk for pathologic pain processes and that surgeons should be aware of this heightened risk.[23–24]

High preoperative pain

Multiple studies have found that the patients with high preoperative pain values are more at risk of severe acute postoperative pain, which puts them at risk for chronic pain.[21,25–26]

Psychological factors

There are many studies looking to associate pre-existing psychological conditions with the development of neuropathic pain. These studies often have significant limitations and results have been mixed. The overall theory is that patients with increased psychological distress have higher concentrations of circulating catecholamines, which makes them more sensitized to pain. Two psychological factors commonly discussed in relation to development of pain after trauma/surgery are depression and pain catastrophizing.

Depression

Depression has long been thought to be associated with pain, and studies have shown correlations between depression and pain after surgery.[27,28] However, for much of the literature, it is difficult to assess the directionality of this relationship – does the depression cause the pain or is the pain causing the depression? The literature is mixed on this question, but a pooling of the available data found enough evidence to support depression as a risk factor for chronic post-surgical pain. [29] There are short forms to assess for depression in the clinic. One example is the Patient Health Questionnaire (PHQ-9), which has only nine questions.[30]

Pain catastrophizing (PC)

There is increasing evidence that PC may be one of the most important psychological factors associated with prolonged pain after surgery. PC is a cognitive style in which patients have a "set of exaggerated and ruminating negative cognitions and emotions during actual or perceived painful stimulation."[31] These patients feel helpless and say things like "this is the worst pain in the world." The Pain Catastrophizing Scale has 13 questions and was developed to capture the PC traits.[32] PC has been found to be associated with poorer outcomes after distal radius fracture.[33] PC has been shown in meta-analysis to be one of the strongest predictors of prolonged pain after knee arthroplasty.[34] PC can be addressed with cognitive–behavioral therapy and there is increased interest in this psychological trait as a potential target for "pre-habilitation" before surgery.

Immobilization

Immobilization is often required to protect healing tissue. However, immobilization is not a benign intervention, and there is increasing evidence that immobilization can contribute to neuropathic pain.[35] It makes intuitive sense that immobilization, which prevents nerve gliding in an inflamed tissue bed, is not ideal. A study putting healthy volunteers in a cast for a month found that the subjects developed some of the changes associated with CRPS.[36] Another study also found that those immobilized after surgery had increased inflammatory factors as well as trophic factors similar to CRPS.[37]

Diagnosis

Localizing the pain generator can be challenging to providers, as the patient's perception of neuropathic pain often is not dermatomal. It is difficult to target interventions when the

patient reports, "the whole arm hurts." Strategies to diagnose neuropathic pain and to localize pain generator(s) are presented below.

Patient history

There are several clues in the patient history to suggest a neuropathic component to the pain. The first is the pain quality. Neuropathic pain is often described as burning or shooting. However, neuropathic pain can also be described as dull or sore.[38–40] Thus, pain quality can help diagnose but should not rule out neuropathic pain. Pain severity can also provide a clue. Severe pain without a clear cause can point to activation of the somatosensory nervous system. If the pain is out of proportion to the injury, a neuropathic component is suspected. Pain duration beyond the time that tissue has healed points to a pathologic pain process, often of neuropathic origin.[2]

Physical examination

Physical examination can help differentiate neuropathic from musculoskeletal pain. The examination can also help localize area(s) of nerve irritation that are contributing to the pain. First, the examination should begin with inspection. If the patient is uncomfortable, apprehensive, and distressed before the examination begins, this can suggest that the pain has become a pathologic process (Fig. 23.2). Next, the provider should assess for the physical signs associated with CRPS such as edema, shiny skin, and temperature changes (see Table 23.1). These same physical exam findings can be found in patients with neuropathic pain who do not meet the criteria for a diagnosis of CPRS. The presence of these trophic signs does suggest a neuropathic pain component.

After the patient has been inspected, the provider should begin with gentle palpation. Allodynia or pain to light tough suggests a neuropathic pain process. If light touch of the skin is painful or unpleasant, then the pain is not generated from a deeper musculoskeletal problem.

After surgery, patients can have persistent pain from a "scar neuroma". These patients will have tenderness to light touch or manipulation localized over the scar. Often the scar will be tethered or depressed at the area of maximal tenderness (Fig. 23.3).

Fig. 23.2 Woman with complex regional pain syndrome (CRPS): note the posture with which she holds her arm.

Fig. 23.3 Patient with a scar neuroma: note the tethered area was site of maximal tenderness.

The provider should then perform a standard full upper extremity examination looking for other potential causes of the pain. There are several specific tests that will help with identifying areas of symptomatic nerve entrapments.

Clinical diagnostics

Specific tests in the physical examination

Motor examination If the patient can tolerate it, a focused motor examination can provide useful information. Nerve entrapment can result in subtle changes in strength. The maneuvers proposed by Hagert are useful for assessing nerve entrapments.[41] This examination technique assesses bilateral muscle strength simultaneously. By testing bilateral muscle groups at the same time, the examiner can see subtle differences between the two sides, suggesting areas of nerve pathology.

Cold perception Patients with nerve injuries or entrapments will often have changes in perception of temperature and these changes can localize injured nerves. In clinic, a quick inexpensive way to assess cold perception is to place a piece of ice in the finger of an exam glove and test the patient's cold perception on various nerve distributions.

Tinel's sign The Tinel's sign has long been used to assess nerve pathology. It is easy and quick and can help localize areas of nerve compression. However, this test has low sensitivity/specificity and wide variability between providers.[42,43] Thus Tinel's sign provides information but should be used as one small piece of a full physical exam.

Clinical tips

Scratch collapse test This is a newer test that is a useful addition to the physical exam.[44,45] For this technique, the patient is seated with upper arms at their sides and elbows at 90° of flexion. The patient is asked to resist as the examiner pushes medially on forearm (loading shoulder external rotation). The examiner then lightly scratches the skin *directly* over the area of the suspected nerve entrapment. Then the examiner immediately repeats the loading of the shoulder external rotation. If the patient's external rotation is weaker, i.e., "collapses", this is a positive test. This test is particularly useful for less common proximal nerve entrapments such as radial tunnel, pronator syndrome, and thoracic outlet. The scratch collapse test is one more tool to help localize an area of nerve pathology.

Diagnostic testing

Neuro-diagnostic testing Neuro-diagnostic studies are key diagnostic tests for assessing peripheral nerve pathology. These studies can assess for neuropathy, localize nerve compression, and exclude more proximal spinal pathology. After trauma, patients have swelling, which can result in painful nerve entrapments, such as carpal tunnel syndrome. Treating the nerve entrapment is a key part to treating the pain. However, it is important to understand the limitations of these studies. There are patients with symptomatic nerve entrapments with normal neuro-diagnostic tests.[46] This is particularly true for proximal nerve entrapments such as radial tunnel or thoracic outlet. Remember, a negative nerve study does *not* rule out entrapment. These tests, like many of the others, provide one more piece of information for consideration.

Ultrasound Ultrasound is being increasingly utilized in evaluating nerve pathology.[47,48] Ultrasound is attractive as it is not painful, dynamic, and does not expose the patient to radiation. Ultrasound can identify swelling and changes in nerve architecture. As the nerves become smaller, the utility of ultrasound decreases. At this time, the role of ultrasound in the diagnosis of nerve injury/entrapments in the upper limb is still evolving.

Magnetic resonance imaging (MRI) MRI technology continues to improve, resulting in more detailed imaging of the nerves. However, like ultrasound, as the nerves become smaller, the utility of the exam decreases. MRI neurogram is a technique specifically designed to image nerves and it can also provide information about the surrounding tissue (presence of ganglions, etc.).[49] MRI neurogram assesses T2-weighted images looking for increased signal that identify the area of nerve injury or entrapment.[50,51] MRI neurogram is currently useful for looking at larger nerve lesions such as thoracic outlet and cubital tunnel (Fig. 23.4).

Hybrid imaging techniques such as positron emission tomography (PET)/MRI are new innovations that expand the information provided. In this technology, the patient undergoes a PET scan and MRI of the affected area. Then the anatomic images of the MRI and the biological marker images of the PET are overlapped, providing more detail on the pathologic process[52] (Fig. 23.5).

Diagnostic blocks Diagnostic blocks with local anesthetic are the most important tool for identifying the area of pain generation. If a patient has significant pain relief after a block, then the pain generator is somewhere distal to the blocked nerve. Diagnostic blocks are also useful as blocking one nerve can unmask a second site of pain. These anesthetic blocks can be done by the surgeon or in collaboration with a pain medicine specialist. There are several steps, described below, that are needed to ensure the diagnostic block generates the most useful information.

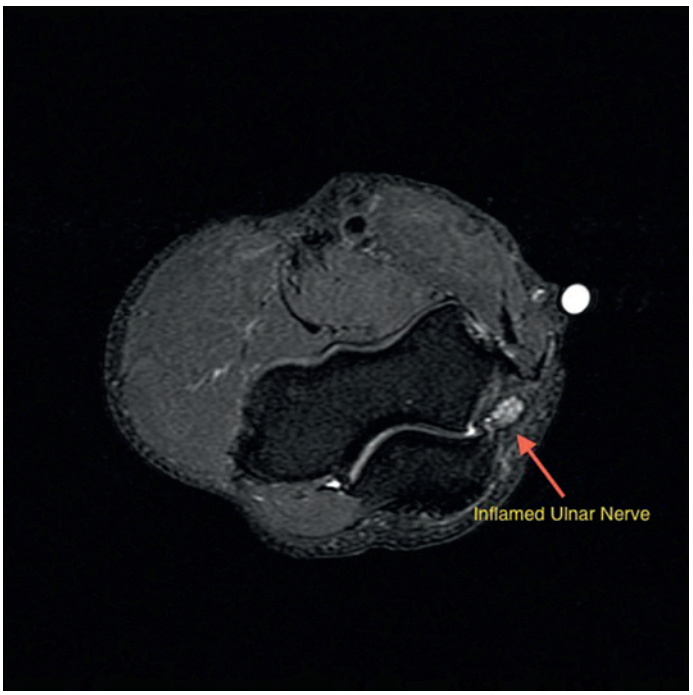

Fig. 23.4 Magnetic resonance imaging of the ulnar nerve.

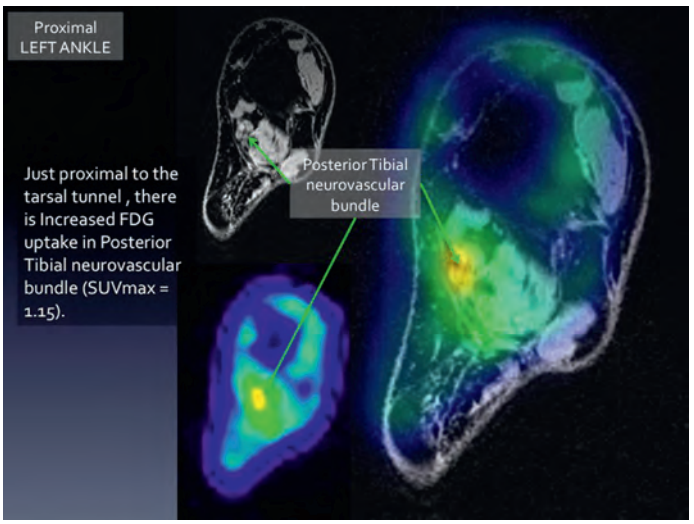

Fig. 23.5 Positron emission tomography (PET) magnetic resonance imaging (MRI) showing the merging of the bright PET signal on the anatomy of the MRI. *(Courtesy of Sandip Biswal.)*

Clinical tips

Diagnostic blocks

Provider education This is crucial if another provider is performing the block. The provider of the block needs to understand what results are useful to the surgeon.

1. First, only one nerve is to be blocked at a time. A "field block" or a brachial plexus block, which anesthetizes the whole arm, does not provide enough information on what particular nerve is generating the pain signals. If several nerves are involved, then sequential blocks separated by hours or days will allow the patient to assess the amount of pain generated by each nerve.
2. Second, the location of the block needs to be clearly documented. The surgeon needs to know where along the course of the nerve the block was placed. For example, a block of the ulnar nerve at the wrist or above the elbow will be testing very different potential pain generators.

Patient education The patient needs to understand that the primary goal of the block is to diagnose the pain generator not treat it. This means there is no expectation of prolonged pain relief after the injection. If the patient does not understand that the critical time is the first hour after the block, the patient may report the "block did not work" because the pain returned after the anesthetic wore off. During the block, the patient must also assess the distribution of numbness. This information provides quality control, ensuring the nerve of interest was blocked and its corresponding sensory distribution was numb.

Diagnostic block pearls

- Have the patient document the percentage of pain relief during the first hour after the block.
- Have the patient try the usually painful activities during the hour after the block and document the percentage of pain relief.

Perioperative treatment

There has been extensive work on the use of pharmaceuticals around the time of surgery to prevent the transition to a chronic pain process.

Pre-surgical

Preoperative administration of gabapentinoids (gabapentin and pregabalin) may reduce acute and chronic pain after surgery. Numerous studies assessing the impact of preoperative gabapentinoid administration on post-procedure pain have found these medications reduce opioid consumption and postoperative acute pain scores by as much as 50%.[53–56] The studies suggest that higher preoperative doses are more effective (900 mg for gabapentin 300 mg for pregabalin).[57]

Intraoperative

1. Preemptive neural blockade through use of local or regional anesthetic techniques can reduce the number of patients who have chronic postoperative pain.[58–61] Blocking the nerves prior to incision prevents the bombardment of the spinal cord with pain signals and theoretically decreases the excitation of the nociceptive response.
2. Ketamine is a non-competitive *N*-methyl-D-aspartate (NMDA) glutamate receptor antagonist long used as a general anesthetic agent. Several studies and a systematic review found that ketamine was a helpful adjunct to the treatment of surgical pain especially for painful procedures.[62] In addition, evidence found that ketamine decreased postoperative pain in chronic opioid users, a challenging patient population for pain management.[63–64]

Post-surgical

Multimodal pain management should be implemented if the surgeon is concerned about a patient at risk for post-surgical pain problems. The theory of multimodal treatment is to use several different medications with separate mechanisms of action.

Post-injury treatment

Despite best preventative efforts, there will be patients who develop or present with neuropathic pain and the clinical focus then turns to treatment. This requires a multidisciplinary approach including therapy, pain specialists, and psychological support. The surgeon cannot manage all facets of care but should be able to direct their patient to the appropriate resources.

Psychological

Often patients with pain have concomitant psychological pathology including anxiety, depression, post-traumatic stress disorder, or pain catastrophizing. Psychological care should be included in the treatment plan for these patients. To this end, some medications used to treat psychological problems (tricyclic antidepressants and selective serotonin and norepinephrine reuptake inhibitors) can also treat neuropathic pain. Thus, communicating with the patient's mental health provider can potentially optimize medications and allow for a more coordinated treatment plan.

In addition, several psychological interventions can help treat patients with chronic pain. These psychological treatments include mindfulness-based stress reduction, cognitive–behavioral therapy, meditation, pain education, and relaxation. These approaches often require multiple treatment sessions delivered individually or in classes.

Medication

Medications are a standard part of most pain treatment and several are effective for neuropathic pain. The administration of these anti-neuropathic pain medications differs from opioids, requiring more patience from the provider and patient. Anti-neuropathic medications compared to opioids require more time to have an analgesic effect. Also, anti-neuropathic medications often need to be started at a low and likely ineffective dose. This is because the higher, effective dose can have

intolerable side effects (sedation, dizziness), but slow titration allows these side effects to be significantly minimized. This need for patience must be explained at the outset or the patient will discard a medication that may provide pain relief.

The gabapentinoids (gabapentin and pregabalin) are very useful in the treatment of neuropathic pain. These medications appear to modulate voltage-gated calcium channels existing on presynaptic pain-carrying neurons in the dorsal horn of the spinal cord.[65] In studies of other neuropathic pain conditions, such as diabetic neuropathy and post-herpetic neuralgia, the number needed to treat for gabapentin ranged from 4 to 6½.[66] The primary issue with these medications are the cognitive side effects; however, these can be ameliorated by slow titration.

Tricyclic antidepressants (nortriptyline, desipramine) have been found in many trials to be effective in the treatment of neuropathic pain.[67] They are thought to work by central mechanisms of inhibition of noradrenaline and serotonin uptake, as well as NMDA receptor antagonism and sodium channel inhibition. They also have a lower number needed to treat than the gabapentinoids. However, these medications need to be carefully monitored due to their potential severe adverse effects including cardiac issues, especially at higher doses. The surgeon, may not be comfortable monitoring the titration of these medications and could consider starting at a low dose and initiating a referral to a pain physician for titration. In addition, if the patient has comorbid depression, the hand provider could discuss the patient with their mental health provider to see if switching to tricyclic antidepressants might be feasible.

Serotonin–norepinephrine reuptake inhibitors such as duloxetine (trade name: Cymbalta) have been found to be effective against neuropathic pain and these medications do not have the anti-cholinergic or cardiac side effects.[67]

Physical modalities

These treatments have long been a central pillar to the treatment of neuropathic pain. Standard hand therapy is useful in the patient with neuropathic pain, especially in the acute injury time period. These treatments focus on decreasing edema, promoting nerve gliding, and improving range of motion. There are also additional interventions uniquely targeting the pathologic pathways that promote neuropathic pain. Neuropathic pain causes changes at every level of the somatosensory system. Neuropathic pain-specific physical modalities attempt to modulate not only the peripheral pain generators but also the central components of the brain and spinal cord. The therapists will focus on left/right identification, graded motor imagery exercises, and mirror therapy.[68–70] Neuropathic physical treatments require a distinct approach with care to not overstimulate, using short duration and repetitive interventions.

Surgical treatment of pain

Surgeons are often hesitant to operate on pain with historic recommendations to avoid surgery as it risks "flaring" the pain. However, as time has progressed, it has become clear that if an injured or compressed nerve is contributing to pain, surgical intervention may be a critical part of the rehabilitation plan.

The key to operating on neuropathic pain is to proactively employ all the treatment options discussed earlier. These patients should have the perioperative, intraoperative and postoperative treatments planned before surgery is considered. Psychological support should be in place for those with concomitant anxiety or depression. Therapy must be available to help the patient through the post surgical rehabilitation. If a thoughtful multimodal strategy is used, the risks of worsening the pain can be significantly decreased, making the surgery's risk–benefit ratio in the patient's favor.[71–73]

Neuromas

Painful neuromas can potentially be improved with surgical correction. If possible, the best treatment for neuromas is neuroma excision followed by reconstruction with nerve grafts.[74] Another technique for a painful neuroma is end-to-side coaptation of the injured nerve to a healthy nerve, which is particularly useful for digital neuromas. Both these techniques restore a path for injured axons to reconnect with their end organs.

However, pure sensory neuromas are often distal and reconstructing the nerve is not an option. For these cases, surgical correction of a neuroma is more about recreating the injury and then attempting to alter the post-injury course to result in a non-painful neuroma. The goal is to place the new injured nerve stump in a new low-stimulation environment. The microenvironment impacts the development of the neuroma and the surgeon can optimize the neuroma placement.[75]

The literature on neuroma resection is limited and heterogeneous. A prospective study of 34 patients found that surgically treated neuromas in the upper limb resulted in a decrease of the mean visual analog scale score from 6.8 to 4.9 ($p<0.01$).[72]

Nerve compression

Nerve release is a common technique for the surgeon who cares for the upper limb. Carpal tunnel and cubital tunnel syndromes are known pain generators and easily recognized by providers. Other sites of nerve compression should be considered and treated when working with neuropathic pain of the upper limb. Radial tunnel, pronator syndrome, quadrangular space entrapment, and thoracic outlet all can be addressed surgically if conservative treatment fails.[76]

Neuro-stimulation

For the patient who has failed other treatments, neuro-stimulation can give pain relief. Neuro-stimulation is thought to work by blocking pain signals via the "gate theory". The gate theory posits that stimulation of the nerve with non-painful signals can close the "gate" preventing other painful signals from being processed.[77] Most of the information in this field is related to spinal cord stimulators, which can reduce pain by 50%.[78] Neuro-stimulation is an exciting area that is being transformed by emerging technology. The current available devices are limited by lead failure, lead migration, and limited locations to place the bulky power sources. As technology miniaturizes the power sources and eliminates the leads, there will be an increase of uses for nerve stimulators in the patient with neuropathic pain.

Future directions

Given the enormous costs to the patient, society, and the healthcare system, there is a large amount of interest in improving neuropathic pain. Interesting new avenues of research include the role of the immune system in neuropathic pain. Emerging evidence suggests that some pain may be mediated through autoimmune mechanisms.[79–80] This link may open up new avenues of treatment through immune modulators.

On a healthcare system level, pain has taken on increased importance. The Institute of Medicine recently released a report, *Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research*.[81] This report highlighted the impact of pain and presented specific timelines and goals. This focused effort will continue to push us towards improved pain care.

Nerve entrapment syndromes

Elisabet Hagert and Donald Lalonde

Access video and video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Chronic nerve entrapment syndromes in the upper extremity are common and their occurrence is only likely to increase as risk factors such as diabetes, obesity, and advanced age become more prevalent in the general population.
- In most cases, the diagnosis is based on a good history and a proper physical examination.
- For more atypical presentations, a detailed clinical examination using a clinical triad of muscle testing, scratch collapse test, and specific pain points must be performed to rule out proximal nerve entrapments in the upper extremity.
- In the event of advanced muscle atrophy, muscle fibrillations, and severe sensory disturbances, consideration should be given to other neurologic conditions that mimic nerve entrapment syndromes such as mononeuritis, Parsonage–Turner syndrome, and motor neuropathies; not only will these conditions not respond to surgical decompression, they may in fact be exacerbated by operative management.
- When the diagnosis is unclear, electrodiagnostic tests and magnetic resonance or ultrasound imaging may be of benefit.
- The purpose of this chapter is to provide the reader with a comprehensive review of the pathophysiology, clinical diagnosis, and surgical treatment of nerve entrapment syndromes of the upper extremity.

Pathophysiology of chronic nerve compression

In carpal tunnel syndrome (CTS), the initial pathophysiology in chronic nerve compression (CNC) is seen clinically as paresthesias and an elevation in the static cutaneous sensory threshold as measured by Semmes–Weinstein monofilament testing. With increased compression, localized demyelination occurs followed by more diffuse demyelination.[1] At this stage, patients will experience muscle weakness and will demonstrate increased pressure thresholds for quickly adapting fibers on vibrometry; two-point discrimination, measured in millimeters, remains unchanged. Superficial fascicles tend to undergo demyelination earlier and may explain varying patient symptoms within a single nerve distribution. In early CTS, for example, patients are more likely first to experience paresthesias in the long and ring fingers as the fascicles to these digits are most superficial within the median nerve. Wallerian degeneration and axonal damage is not seen until the final stages of CNC,[2,3] at which point the patient presents with chronic numbness and thenar atrophy.

More proximal median nerve entrapments, such as the lacertus syndrome,[4] will differ in clinical presentation as the most superficial fascicles in the nerve at the level of the lacertus fibrosus are motor fibers to the flexor carpi radialis, flexor pollicis longus, and the deep flexor of the index finger.[5] Patients with early lacertus syndrome thus complain of diffuse weakness of pinch and grip, but the sensory symptoms are not evident until later stages, when deeper sensory fibers are affected. This is why lacertus syndrome is predominantly diagnosed by demonstrating weakness of the affected muscles on proper physical examination.

Double-crush syndrome

The double-crush syndrome (DCS) is an important concept in CNC. First proposed by Upton and McComas, the double-crush concept holds that compression of a peripheral nerve at one site increases susceptibility to compression at another site along the same nerve.[6] This phenomenon appears to be the result of the disruption of anterograde or, in the case of "reverse DCS", retrograde axoplasmic flow of neurotrophic factors.[7] DCS has been demonstrated experimentally in animal models of chronic compression.[8–11] Clinically, numerous examples of multiple sites of compression along the same nerve have been described and include reports of cervical radiculopathy and median nerve compression, CTS and pronator syndrome, and cubital tunnel syndrome and ulnar nerve compression in Guyon's canal.[12–15] The DCS concept suggests that two or more simultaneous points of compression, each of which might be

insufficient to cause symptoms on its own, could together produce symptoms of clinical severity. The underlying causes of DCS may include impaired axonal transport, changes in ion channel regulation, neuro-inflammatory processes and instances of neuroma-in-continuity.[16]

The presence of DCS places a great responsibility on the surgeon or therapist to perform a thorough physical examination to delineate the levels of nerve compression, using a combination of manual muscle testing algorithms and the scratch collapse test.[17,18] In the surgical treatment of DCS, decompression of one of the two sites might be sufficient to address a patient's symptoms. The most distal nerve compression is typically decompressed first as it is usually the site of the more severe compression and lower surgical risk. If decompression in the distal extremity fails to relieve symptoms, decompression of the more proximal site, such as the intervertebral space or brachial plexus, should be considered.

Clinical examination of upper extremity nerve entrapments

The difficulty in diagnosis of upper extremity nerve entrapments lies in the variable spectrum of a patient's symptoms. Even in instances of apparent carpal tunnel syndrome, symptoms outside of the median innervated region in the hand are present in two-thirds of patients.[19] In some cases, bilateral pain is present despite only unilateral nerve involvement.[20]

Another aspect that influences a clinical presentation is the origin of the CNC, where disturbances in neural blood flow and axonal transport commonly occurs without axonal injury. This results in an inability to reliably use electrodiagnostic tools for a definitive diagnosis. Electrodiagnostics should rather be seen as a complimentary modality to a thorough clinical examination.[18] The degree of nerve injury in CNC is most commonly associated to a Sunderland degree I, or a Seddon's neuropraxia.[21] Possible loss of motor function will not be evident as muscle atrophy. However, muscle weakness can be shown through a clinical triad including: (1) manual muscle testing to delineate the level of nerve entrapment(s); (2) scratch collapse test to confirm and order the importance of nerve entrapment(s); and (3) pain and tenderness over the nerve at the level of entrapment(s).[17]

Manual muscle testing algorithm (Video 24.1)

Here is why proper physical examination with muscle testing is so important. The principle of grading of muscle strength was established by Seddon in the 1950s into six grades: M0 to M5.[22] M0 to M3 represent weaknesses that are clinically apparent and found in instances of axonotmesis or complete nerve transections. M5 represents normal power with no loss of strength. The difficulty is diagnosing the M4 grade of muscle strength, which is defined as "contraction against gravity and resistance". If we look for it, we will commonly find M4 weakness in CNC, where changes in the nerve are not dependent on axonal injury. Since this type of muscle weakness can only be found using "resistance", it is only found through clinical examination of muscle strength. Based on this, the clinical entity of M4 may be referred to as the "hidden paresis", and one we must actively look for.[23]

Out of the 60 muscles in the upper limb, about 45 are accessible to manual testing of individual strength. A simplified manageable, manual muscle testing protocol involving four positions and 12 muscles has been advocated.[17,23] The efficacy (sensitivity and specificity) of manual muscle testing of antagonist muscles to determine levels of focal neuropathies in the upper extremities have been established in randomized and blinded level II studies to 88 and 93%, respectively.[24,25] The principle is straightforward: distal to the level of nerve entrapment, distinct patterns of muscle weaknesses will be clinically present.

The four positions of muscle testing are as follows: (1) shoulder – testing of pectoralis and posterior deltoid; (2) elbow – testing of biceps, triceps and infraspinatus; (3) wrist – testing of extensor carpi ulnaris (ECU), extensor carpi radialis brevis (ECRB) and flexor carpi radialis (FCR); and (4) hand – testing of extrinsics (flexor pollicis longus, FPL; flexor digitorum profundus V, FDP V) and intrinsics (abductor pollicis brevis, APB; abductor digiti minimi, ADM) (Video 24.1).

The interpretation of each test is, of course, of outmost importance and will be delineated in each nerve entrapment section described in this chapter. Each muscle is also described in Table 24.1 related to possible level of involvement as well as in relation to position within the upper extremity (Fig. 24.1). The principle of the muscle testing algorithm is to investigate the upper extremity consistently from a proximal to a distal level of involvement, starting with the pectoralis and ending with the hand intrinsics.

Scratch collapse test (Video 24.2)

The scratch collapse test (SCT) was first described by Cheng, Beck, and Mackinnon in 2008,[26] and has since been used in several publications to clinically verify levels of nerve entrapment in the upper and lower extremities.[4,17,27–29] In carpal tunnel and cubital tunnel syndromes, the SCT has a diagnostic accuracy of 82 and 89%, respectively, rendering this test more sensitive than the commonly used Tinel's and flexion nerve compression tests.[26]

The concept of SCT is that a patient with a focal nerve entrapment has an area of skin allodynia located at the level of nerve entrapment. When scratching this area of skin, a brief spinal reflex causes a momentary loss of voluntary muscle contraction. Clinically, the patient is seated with elbows flexed to 90°, shoulders adducted and slightly externally rotated. The patient is asked to resist bilateral internal pressure applied by the examiner onto the forearms. The area of suspected nerve entrapment is then gently scratched and pressure again applied onto the forearms. In the event of a focal nerve compression, the patient will feel a distinct loss of muscle strength in the affected arm (Video 24.2).[26,27]

In instances of suspected multiple points of nerve compression, topical ethyl chloride may additionally be used to grade the hierarchy of nerve compressions. By applying ethyl chloride over the primary level of nerve entrapment, underlying and subclinical levels of entrapment may be revealed to further aid the examiner in understanding a patient's symptoms.[18] The use of SCT can thus aid the clinical diagnosis of nerve entrapment, where manual muscle testing is used to *delineate* the level of nerve entrapment and SCT is used to *verify* this level of entrapment.

Table 24.1 Interpretation of muscle exam: patterns of muscle weakness, nerve involvement, and level of entrapment

Weakness	Nerve	Level of entrapment
Pectoral	Cervical roots C6–T1	C6–T1 radiculopathy; possibly non-participating patient
Posterior deltoid	Axillary N.	Quadrilateral space
Biceps	Musculocutaneous N.	Proximal upper arm
Deltoid + biceps	Cervical roots C5–C6	C5–C6 radiculopathy
Pect + deltoid + biceps (+ triceps)	Infraclavicular brachial plexus	Subclavicular
Triceps	Radial N.	Triangular interval
Deltoid + triceps	Axillary + Radial N	Quadrilateral space + radial triangular interval
Triceps + FCR	Cervical root C7	C7 radiculopathy
Infra + supraspinatus	Suprascapular N.	Suprascapular notch
Infraspin + rhomboid	Cervical root C5	C5 radiculopathy
Rhomboid	Dorsal scapular N.	Middle scalene or proximal rhomboid edge
ECRB + EIP + EPL	Radial N.	Lateral intermuscular septum, distal upper arm
ECU	Radial N.	Radial tunnel syndrome – arcade of Frohse
EDC	Radial N.	Distal edge of supinator
FCR + FPL + FDP II	Median N.	Lacertus fibrosus
FDS III–IV	Median N.	Superficialis arcade
FPL + FDP II	Median N.	Anterior interosseous syndrome
APB	Median N.	Carpal tunnel
FDP V + ADM	Ulnar N.	Cubital tunnel
ADM	Ulnar N.	Guyon's canal zone 1
1-DIO	Ulnar N.	Guyon's canal zone 3

1-DIO, First dorsal interosseous; ADM, abductor digiti minimi; APB, abductor pollicis brevis; ECRB, extensor carpi radialis brevis; ECU, extensor carpi ulnaris; EIP, extensor indicis proprius; EPL, extensor pollicis longus; FCR, flexor carpi radialis; FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis; FPL, flexor pollicis longus.

The last part in the clinical triad is the presence of pain upon compression and/or a positive Tinel's test at the level of nerve compression to further confirm the correct level of diagnosis.

Electrodiagnostic studies (EDS)

Although EDS are widely used in the evaluation of patients with suspected upper extremity nerve entrapments, the sensitivity and specificity of nerve entrapments aside from the carpal tunnel and cubital tunnel syndromes, is only between 30–65%.[30,31] The pitfalls of EDS include technical- and operator-dependent errors, inability to distinguish mixed pattern type of nerve injuries, limitation in electromyographic studies where only a portion of muscle function is evaluated, and an inability to detect early nerve compression syndromes.[32] These shortcomings have even lead some authors to advise against EDS,[33] and rather advocate the use of clinical examination techniques.[18]

When an atypical presentation or comorbidities cloud the clinical picture, symptom criteria and provocative tests can be combined with EDS to make the diagnosis. Electrodiagnostics are of particular use in grading nerve injuries in patients with suspected diabetic or alcohol-induced polyneuropathy, in patients with advance muscle atrophies and/or in patients with peripheral muscle fibrillations where peripheral neuropathic disease may be suspected. Two aspects of electrodiagnostic tests are most often used to diagnose nerve entrapment syndromes: nerve conduction studies (NCS) and electromyography (EMG). Of the two studies, the former are especially helpful. An NCS is performed by placing two electrodes on the skin, along the course of the nerve (Fig. 24.2). The first electrode is used to stimulate a peripheral nerve to fire, and the second electrode is used to record the characteristics of the generated action potential at some distance away from the stimulation point. The electrodes typically detect only larger, faster-conducting fibers.

EMG studies assess the integrity of muscle function. Because muscle integrity is dependent on innervation, these studies help determine whether axonal damage has occurred.

Median nerve entrapments

Carpal tunnel syndrome

CTS is the most common nerve entrapment syndrome in the upper extremity, with an estimated incidence in the US of 1–3 cases per 1000 subjects per year and a prevalence of 50 cases per 1000 subjects per year.[34] The surgical release of carpal tunnel syndromes has the highest utilization rate of upper

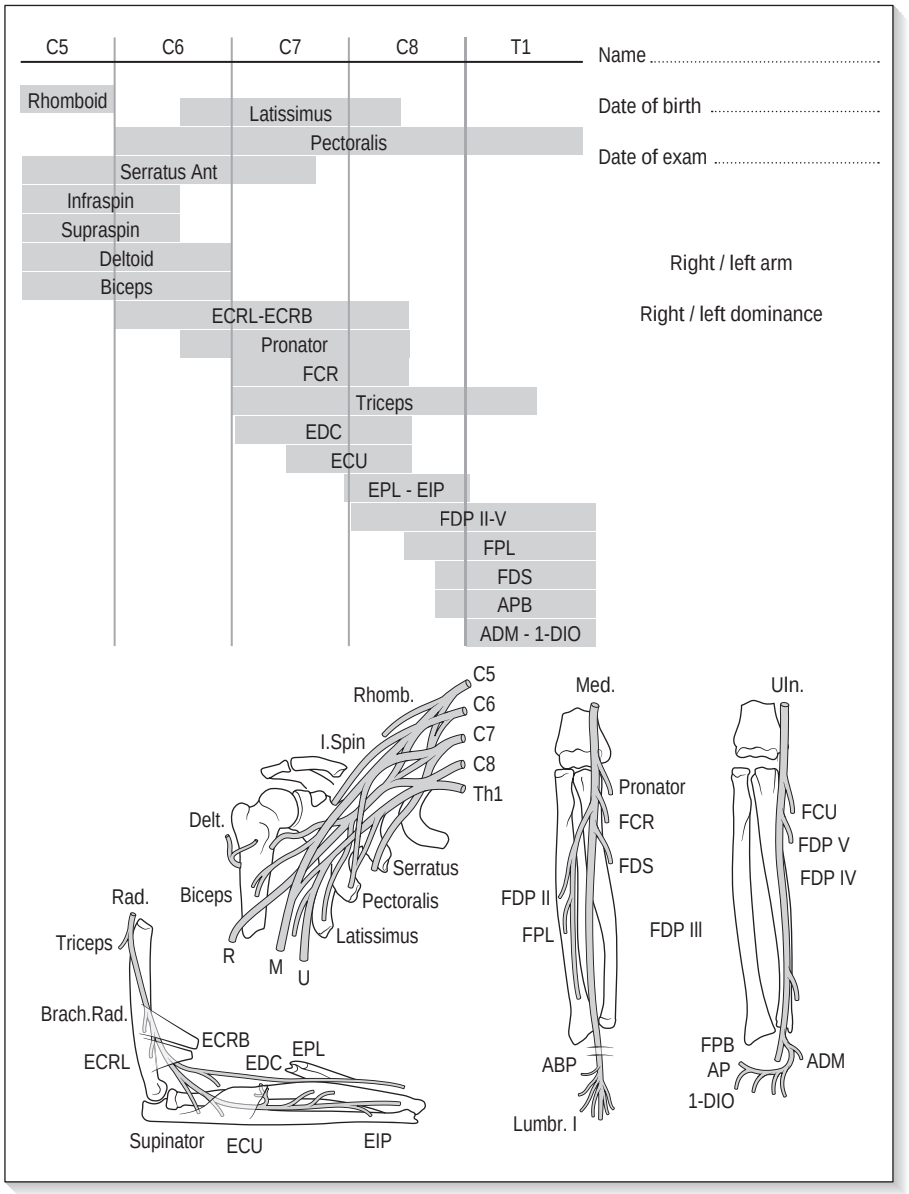

Fig. 24.1 The patient chart routinely used for nerve entrapments. The patterns of muscle weakness found in clinical testing is mapped according to dermatome, as well as position in the arm. It allows for easier visualization as to level of nerve entrapment. 1-DIO, first dorsal interosseous; ADM, abductor digiti minimi; AP, adductor pollicis; APB, abductor pollicis brevis; ECRB, extensor carpi radialis brevis; ECRL, extensor carpi radialis longus; ECU, extensor carpi ulnaris; EDC, extensor digitorum communis; EIP, extensor indicis proprius; EPL, extensor pollicis longus; FCR, flexor carpi radialis; FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis; FPB, flexor pollicis brevis; FPL, flexor pollicis longus; M, median nerve; R, radial nerve; U, ulnar nerve. *(Reprinted with kind permission from Prof. Carl-Göran Hagert, MD, PhD.)*

extremity disorders in the US, with an average of about 40 surgical releases per 10 000 subjects per year.[35] The economic burden from lost wages and productivity and treatment costs is considerable.[36] Despite the prevalence of CTS, debate remains over the accurate diagnosis and optimal treatment of the condition.

Anatomy

The anatomic boundaries of the carpal tunnel are defined dorsally by the carpus, and volarly by the transverse carpal ligament (TCL), which spans from the hamate and triquetrum on the ulnar side to the scaphoid and trapezium on the radial side. The median nerve is the most superficial structure within the canal. The median nerve may divide in the forearm or split within the carpal tunnel. Both presentations are associated with a persistent median artery. The recurrent motor branch to the thenar muscles usually arises off the median nerve in an extraligamentous position distal to the TCL (46–90%) (Fig. 24.3). Less frequently, the motor branch originates from beneath the TCL (subligamentous, 31%) or perforates the TCL (transligamentous, 23%).[37] The palmar cutaneous branch typically arises off the radial aspect of the median nerve 5–6 cm proximal to the distal wrist crease. Additional branching pattern variations of the recurrent motor branch and palmar cutaneous branch have been described.[38]

Etiology

In the vast majority of CTS cases, an underlying etiology cannot be identified. Women are more often affected than men.[39] Compression tends to be greatest at a point 1 cm distal to the distal wrist crease where the TCL is thickest.[40] In rare instances, structural causes such as a persistent median artery, ganglion cyst, hemangioma, or proximal lumbrical origin can increase pressure within the carpal tunnel.

Systemic conditions, such as renal failure, thyroid disease, rheumatoid arthritis, and diabetes mellitus, may also predispose patients to CTS. CTS can occur in up to 45% of pregnant women during the third trimester but usually

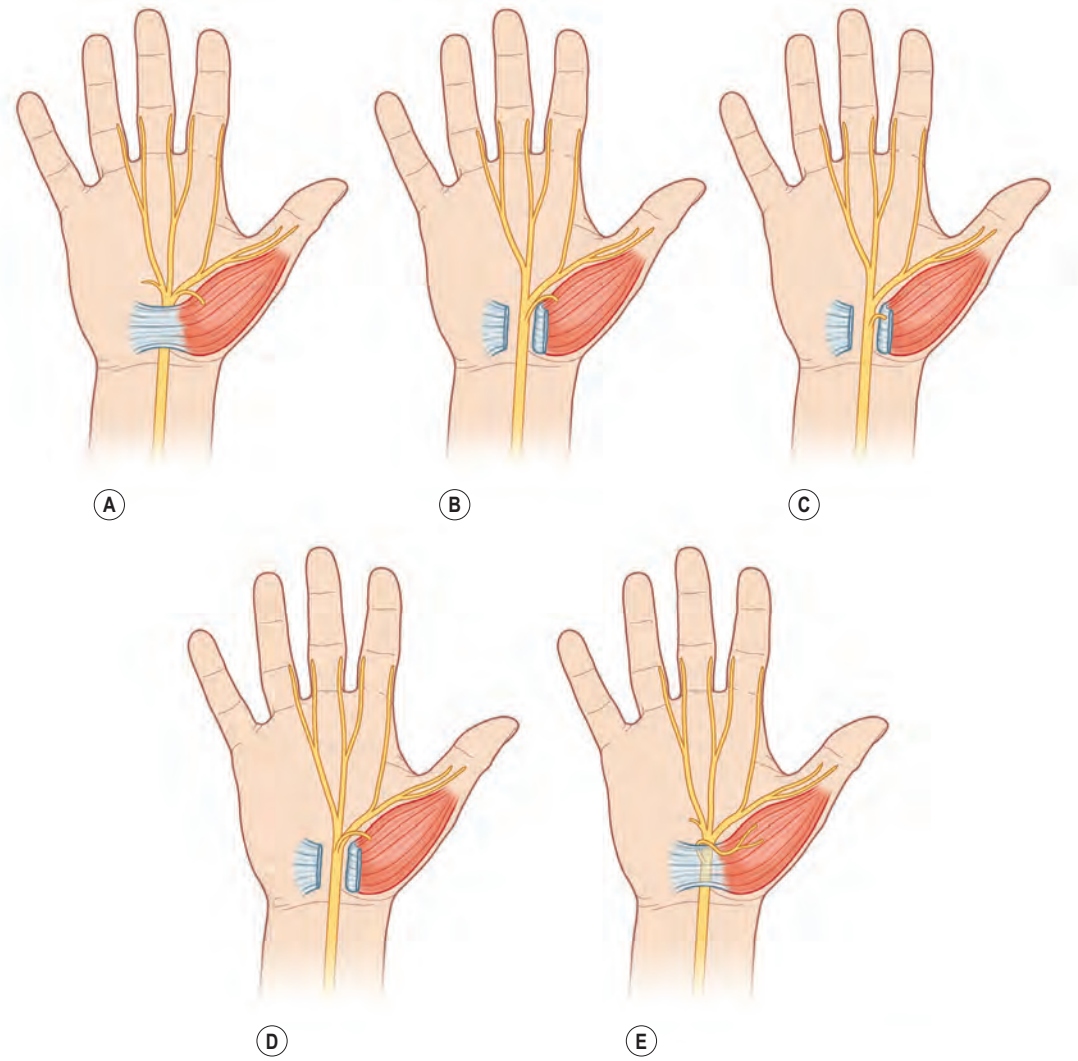

Fig. 24.3 Variations in median nerve anatomy in the carpal tunnel. **(A)** The most common branching pattern of the motor branch is extraligamentous. **(B)** Subligamentous branching pattern of the motor branch. **(C)** Transligamentous course of the recurrent motor branch. **(D)** The motor branch can rarely arise from the ulnar border of the median nerve. **(E)** The motor branch can also lie superficial to the transverse carpal ligament.

resolves postpartum.[41] In the pediatric population, mucopolysaccharidoses are a frequent cause of CTS.[42] To date, the only strong evidence linking occupation to CTS has been among operators of handheld vibratory tools.[43] Scientific support for a causative role for other repetitive work activities (e.g., typing) in the development of CTS is otherwise lacking.[44]

History

A thorough history and physical examination are central to the diagnosis of CTS. Patients with CTS report nocturnal pain, numbness, and tingling in the thumb and radial fingers. Paresthesias are usually triggered by activities involving sustained wrist flexion or extension. Shaking and wringing of the hands tend to alleviate symptoms. Bilateral symptoms are common. Occasionally, paresthesias can radiate proximally along the median nerve to the forearm and may even involve the ulnar digits.

Clinical examination

Using the clinical triad described above (muscle exam, SCT, Tinel's test), patients with CTS should be examined using the manual muscle testing protocol with particular emphasis on the median innervated muscles: FCR, FPL, FDP II and APB. In a case of CTS, a weakness of APB may be found when comparing to the contralateral side. Actual manifest thenar atrophy has a high predictive value in CTS, but is not commonly observed.[45] It is of great importance to test FCR, FPL and FDP II strength in every patient with suspected CTS to rule out concomitant DCS and proximal median nerve involvement. The SCT has an estimated 82% accuracy as a clinical provocative test in CTS,[26] and is elicited by scratching over the carpal tunnel just distal to the wrist flexion crease (Video 24.2 ▶). Tinel's sign is elicited by gently percussing over the median nerve at the carpal tunnel. A positive sign is present if the patient describes an electrical shock sensation in the median nerve distribution. The low specificity and sensitivity of the sign may in part be due to the wide intra- and interexaminer variability with which it is elicited.[46]

Other provocative tests that can be considered to aid in the evaluation of CTS include the Phalen's test and the Durkan's test. The Phalen's test is performed by having the patient place the elbow on a table and flex the wrist for 60 s. The test is considered positive if the patient reports paresthesias in the median nerve distribution. Durkan's median nerve compression test involves direct compression of the median nerve at the carpal tunnel for 30 s. A positive test is obtained if the patient reports numbness or tingling in at least one of the radial digits.[47] Other less frequently used provocative tests include the reverse Phalen's, tourniquet test and the flick maneuver.[48,49] For multiple reasons, including poor study design, variability in outcome measures, and small datasets, no single test has been identified to diagnose CTS consistently. Of the above maneuvers, Durkan's compression test performed with a calibrated pressure device demonstrates the highest sensitivity (89%) and specificity (96%).[47] The sensitivities and specificities of Tinel's sign and Phalen's test are lower.[50–52] Threshold sensory tests such as Semmes–Weinstein monofilament measurements tend to be more sensitive for detecting early CTS than innervation density measurements.[53]

Given the utility of patient symptoms and physical findings, attempts have been made to develop formal clinical criteria for the diagnosis of CTS. Graham *et al.* generated a list of six clinical criteria (CTS-6) for the diagnosis of CTS, based on a validated statistical analysis of recommendations by an expert panel. The six criteria included: (1) nocturnal numbness; (2) numbness and tingling in the median nerve distribution; (3) weakness and/or atrophy of the thenar muscles; (4) Tinel sign; (5) Phalen's test; and (6) loss of two-point discrimination.[54] Similarly, an American Academy of Orthopaedic Surgeons (AAOS) panel reviewed the available literature and developed recommendations for diagnosing CTS; high-level evidence was lacking to support the majority of recommendations.[55] The CTS-6 lacks a recommendation regarding muscle exam, which should always be considered an important part of the clinical diagnosis of CTS to rule out possible proximal median nerve involvement.

Other diagnostic tools

CTS remains a clinical diagnosis, and the role of electrodiagnostic and imaging studies remains complementary. Electrodiagnostic tests are routinely performed, yet their validity is largely unproven. EMG and NCS have been shown to be poor predictors of symptom severity or functional impairment.[56] Patients with clinical evidence of CTS and negative NCS studies have been shown to have identical clinical improvement after surgery as patients with positive NCS findings.[57] Distal motor and sensory latencies greater than 4.5 and 3.5 ms, respectively, are generally considered positive.[58]

Ultrasound is inexpensive, reproducible, available to all, and actually shows compression objectively in the live human. A recent level 1 study comparing the use of ultrasound and electrodiagnostic testing in CTS revealed an equivalent sensitivity (89%) and a greater specificity (90% vs. 80%) of ultrasound in accurately diagnosing CTS.[59] Since ultrasound can be performed by the surgeon in an office setting, independent of radiological evaluation, the cost-effectiveness and safety is promising in the diagnosis of CTS.

Clinical tips

If nerve conduction studies are positive, the patient most likely has carpal tunnel syndrome that will respond to surgery, particularly if the findings are profound. Surgery may still be helpful even if the nerve conduction studies are negative, particularly if the patient provides a classic history of numbness at night or with prolonged wrist flexion.

Patient selection

Non-operative treatment

There is a role for both non-surgical modalities in the management of CTS (Table 24.2).[55] Splinting is the most widely used. On the basis of two well-designed studies, splinting has been shown to be more effective than no treatment at relieving symptoms for at least 3 months.[60,61] No difference has been demonstrated between continuous splinting and nocturnal splinting alone.[62]

Table 24.2 American Academy of Orthopaedic Surgeons clinical practice guidelines for the treatment of carpal tunnel syndrome (CTS): recommendations

1. Non-surgical treatment is an option for early CTS. Surgery is an option when there is evidence of median nerve denervation
2. A second non-surgical treatment or surgery is recommended when initial non-surgical treatment fails after 2–7 weeks
3. There is no evidence to support specific treatment recommendations for CTS associated with diabetes, cervical radiculopathy, hypothyroidism, polyneuropathy, pregnancy, rheumatoid arthritis, or CTS in the workplace

4a. Local steroid injection or splinting is recommended prior to treatment with surgery
4b. Oral steroids and ultrasound are also options for treatment
4c. Carpal tunnel release is recommended for treatment of CTS based on level I evidence
4d. Heat therapy does not have evidence to support its use in CTS
4e. Other non-surgical treatment modalities are not recommended for treatment of CTS

5. Surgical treatment with complete division of the flexor retinaculum is recommended, regardless of the technique used
6. Skin nerve preservation, epineurotomy, flexor retinacular lengthening, internal neurolysis, tenosynovectomy, and ulnar bursa preservation are not recommended in the performance of carpal tunnel surgery
7. Use of preoperative antibiotics is an option that may be decided upon by the surgeon
8. Wrist immobilization is not recommended postoperatively after routine carpal tunnel release. No recommendation is made regarding use of postoperative rehabilitation
9. It is suggested that physicians use one or more patient response tools to assess results after carpal tunnel treatment in performing research

Clinical tips

Most patients with carpal tunnel syndrome will experience nocturnal numbness, or numbness with sustained wrist flexion as occurs with driving or talking on the telephone. Patients who experience symptomatic relief with splinting are also likely to respond well to surgery.

Steroid injection has been extensively reviewed.[63] It provides greater clinical improvement in symptoms 1 month after injection compared to placebo.[64,65] In addition, local injection provides superior symptom relief compared to systemic steroid administration for up to 3 months.[66] Two local corticosteroid injections do not provide significant added clinical benefit compared to one injection.[67] Steroid injection in combination with splinting has also been shown to be better than splinting only at 6-month follow-up.[68]

Treatment/surgical technique

Surgery is the treatment of choice when non-surgical treatments have failed or when APB weakness and/or sensory disturbance is advanced. Release of the TCL may be performed using an open or endoscopic technique. Open carpal tunnel release (OCTR) remains the most common method of decompression.

Clinical tips

For almost pain-free local anesthesia using the wide-awake approach, never advance the needle tip ahead of the infiltrated local anesthetic. Palpate the wheal of local anesthetic so it is firm ahead of the slowly advancing needle tip. Remember: "Blow slow before you go" (video 24.3 ▶).

Wide-awake OCTR

The wide-awake approach (local infiltration without sedation or tourniquet) has been shown to be safe and cost-effective and is the preferred method of the authors.[69,70] Tumescent field infiltration of 20 mL of 1% lidocaine with 1:100 000 epinephrine is performed (Fig. 24.4 and Video 24.11 ▶). A 3-cm incision is made in line with the flexed ring finger paralleling the thenar crease and ending just distal to the distal wrist flexion crease. The palmar fascia and TCL are incised longitudinally to expose the median nerve. In cases where a prominent palmaris brevis muscle is present, one should attempt to preserve it, dividing the TCL deep to it (Fig. 24.5). The ligament and forearm fascia releases are extended distally to divide all distal TCL fibers completely in the fat pad and proximally beneath the wrist flexion crease for about 1 cm into the forearm. The authors prefer to perform skin closure using buried intradermal 5-0 absorbable monofilament sutures, thereby obviating the need for suture removal (as shown in video 24.4 ▶, which also contains detailed advice provided to patients intraoperatively). A light dressing only is applied, as postoperative splinting has not been shown to improve pain relief or surgical outcome.[71] Patients are allowed to remove the dressing and shower the day after surgery. A new dressing may be applied for padding and protection for up to a week. Patients are advised to elevate and rest the hand for the first 2 postoperative days. In most cases, ibuprofen and acetaminophen provide sufficient analgesia over this time. After the second postoperative day, any residual pain is usually the result of overexertion; a gradual return to full activities is advised with pain serving as a guide. Most patients can return to full work activities by 8 weeks. Patients are advised that mild discomfort at the operative site and decreased grip strength can persist for several more months.

Endoscopic carpal tunnel release (ECTR)

ECTR techniques were developed in an attempt to avoid problems occasionally experienced following OCTR, namely

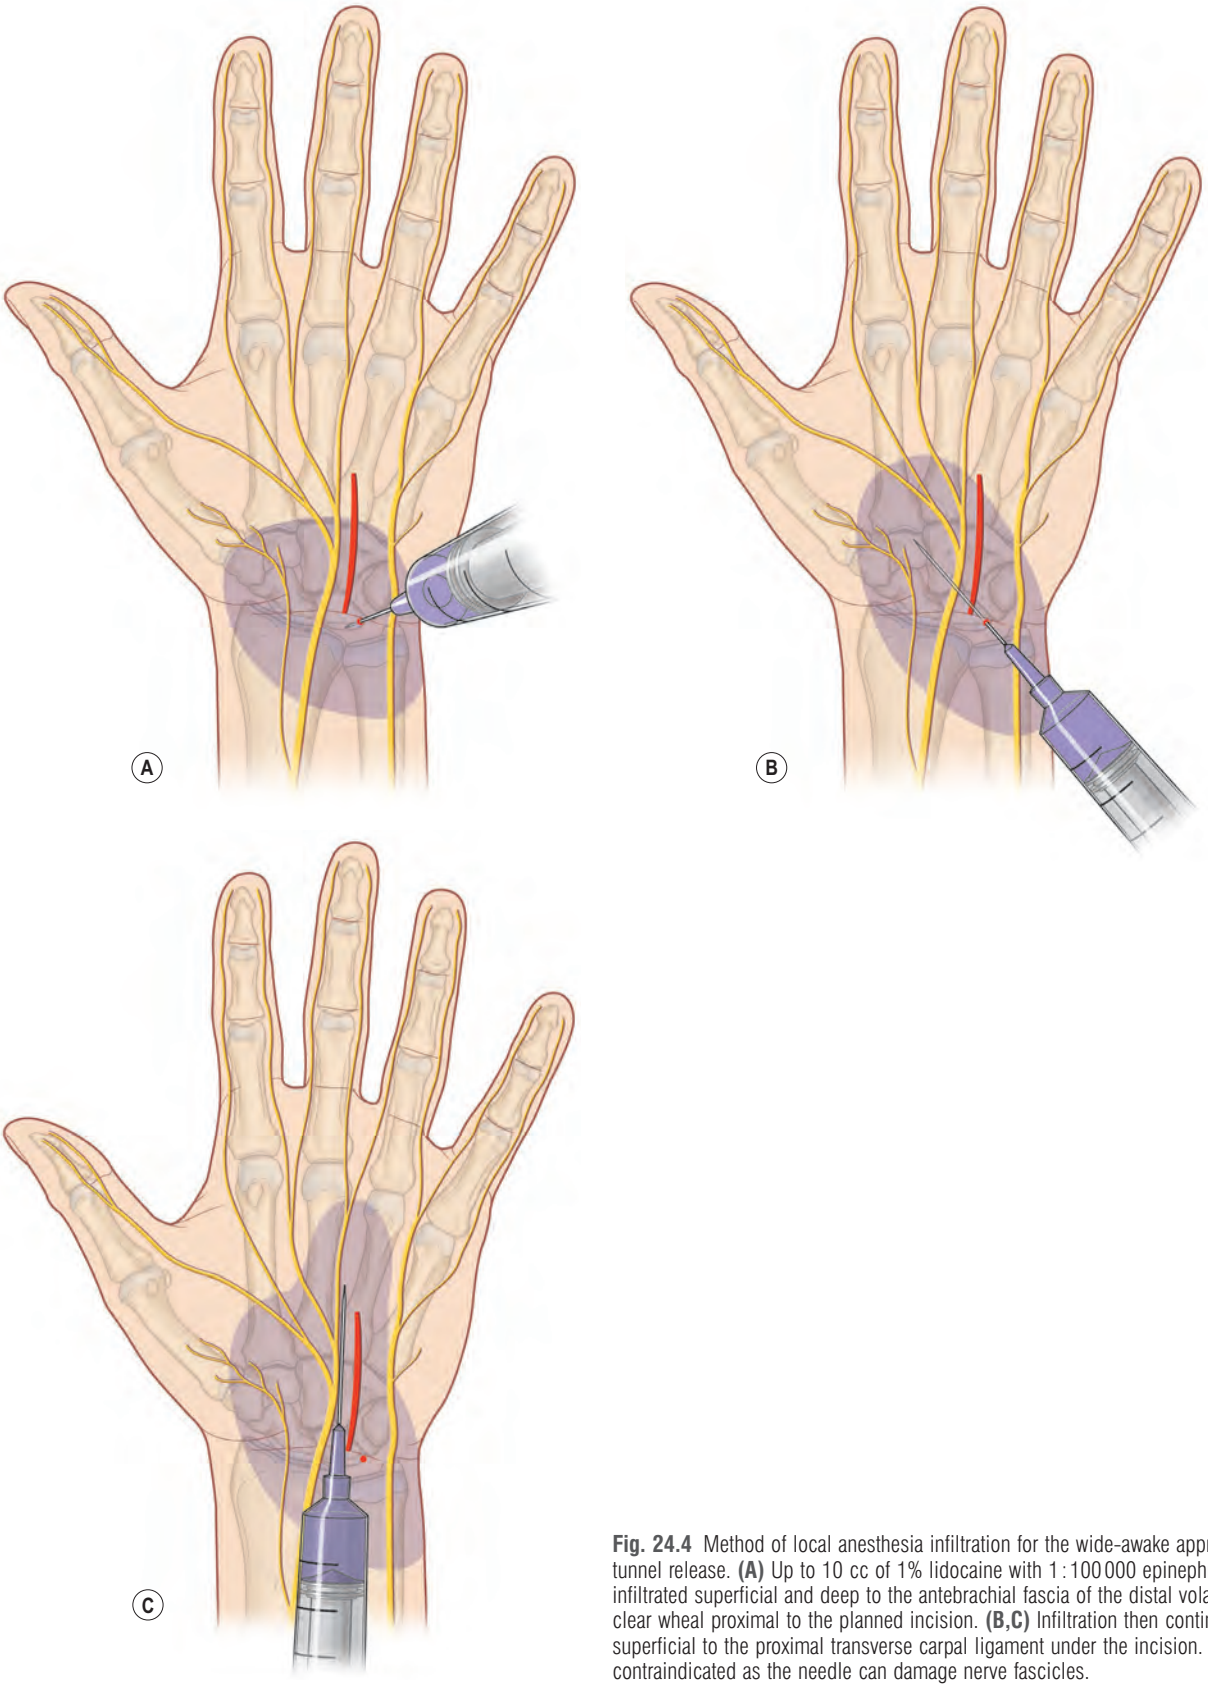

Fig. 24.4 Method of local anesthesia infiltration for the wide-awake approach to open carpal tunnel release. **(A)** Up to 10 cc of 1% lidocaine with 1 : 100 000 epinephrine local anesthetic is infiltrated superficial and deep to the antebrachial fascia of the distal volar forearm, producing a clear wheal proximal to the planned incision. **(B,C)** Infiltration then continues distally deep superficial to the proximal transverse carpal ligament under the incision. Paresthesia induction is contraindicated as the needle can damage nerve fascicles.

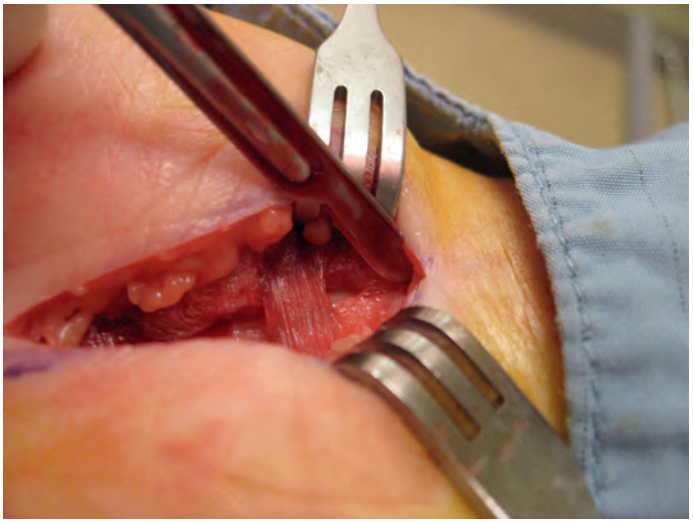

Fig. 24.5 Preservation of prominent palmaris brevis or thenar muscles during open carpal tunnel release. In the authors' experience, postoperative pain and grip strength are improved with preservation of palmaris brevis or thenar muscles encountered during dissection with no compromise of decompression. The transverse carpal ligament is divided deep to the muscle under direct visualization.

scar tenderness and pillar pain. Popular approaches include the dual-portal technique of Chow and the single-portal technique of Agee.[72,73]

Using the Chow technique, proximal and distal incisions are made deep to the TCL. The endoscope and blade assembly are passed from the proximal incision through the distal incision, deep to the TCL. The distal TCL is released using a probe knife. A second cut is made in the midsection of the TCL with a triangular knife and joined to the first cut using a retrograde knife. The endoscope is then repositioned and in a similar fashion the probe knife used to cut the proximal TCL. A retrograde knife is inserted into the midsection of the TCL and drawn proximally to complete the release.

In the Agee ECTR, a small transverse skin incision is made at the ulnar border of the palmaris longus tendon, midway between the flexors carpi ulnaris and radialis, and proximal to the wrist flexion creases. A distally based forearm fascia flap is elevated to reveal the proximal edge of the TCL. With the wrist in extension, the endoscopic blade assembly is inserted into the canal in line with the ring finger. The TCL is visualized and divided distally to proximally.

OCTR vs. ECTR

Both OCTR and ECTR are practiced widely, with proponents of both techniques continuing to debate the merits of one over the other. A common argument in favor of ECTR over OCTR has been reduced postoperative pain and a shorter return to vocational activities. Although these findings have been borne out in some studies,[74–76] other studies show that any differences between techniques in patient symptoms, function, and satisfaction equalize by 1 year.[77,78] Supporters of OCTR have, in turn, cited a higher incidence of postoperative neurovascular complications as a reason to avoid ECTR.[79] More recent studies have failed to support this higher risk in ECTR.[74,75,77,78,80] Cost has been another factor in the debate between OCTR and ECTR. A 1998 cost-effectiveness analysis comparing the two techniques concluded that ECTR is cost-effective provided major complications occur 1% less often than in OCTR.[81] Previous prospective studies have not shown a substantial cost difference between the techniques if the cost of ECTR equipment is excluded.[74,75,77]

Outcomes and complications

While advanced thenar wasting and complete anesthesia are not likely to resolve following surgery, pain associated with CTS typically does, regardless of its duration. Although response to carpal tunnel release is widely held to be worse among elderly and diabetic patients, this has not been borne out by a number of recent studies.[82–84] Overall, outcomes following carpal tunnel release are excellent, with patient satisfaction, symptom relief, and functional improvement observed in more than 94% of cases.[83,85]

Clinical tips

Patients can be advised that, although carpal tunnel release relieves most of the numbness most of the time in most patients, it does not relieve all of the numbness all of the time in all people. If constant numbness has been present for an extended period of time, return of normal sensation after carpal tunnel release is less likely. Surgery may be helpful in alleviating shoulder, arm, elbow, or forearm pain associated with the numbness.

Complications of carpal tunnel release include, but are not limited to, injuries to the motor and palmar cutaneous branches and main trunk of the median nerve; hypertrophic scarring; pillar pain; superficial palmar arterial arch injury; incomplete TCL release; tendon adhesions; infection; wound hematoma; stiffness; and recurrence. The most common complication with OCTR is pillar pain (25%), followed by laceration of the palmar cutaneous branch of the median nerve.[86] Incomplete TCL release is the most frequent complication of ECTR.[74] Recurrent CTS symptoms are seen in up to 20% of cases.[87] Ultrasound is an easy and reliable tool in evaluating the median nerve at the carpal tunnel, where an increase in cross-sectional area, hypervascularity, and reduced echogenicity are signs of persistent nerve compression.[88]

Clinical tips

All patients with failed and/or recurrent carpal tunnel release should be examined regarding strength in the FCR, FPL, FDP II to rule out a proximal median nerve entrapment at the elbow, lacertus syndrome, as a possible cause of incomplete recovery following carpal tunnel surgery (video 24.5 ▶).

Median nerve entrapments in the elbow and forearm

Background

Compression of the median nerve in the forearm and elbow has traditionally been regarded as a rare entity and far less common than CTS. Recent publications, however, are raising

an awareness regarding the presence of proximal median nerve entrapments as a cause of arm pain, hand weakness, and possible sensory deficits within the median innervated area.[4,89] The presence of median nerve entrapments has traditionally been called the "pronator syndrome", after the first description by Seyffarth in 1951 of a pronator teres compression of the median nerve.[90] Later, the pronator syndrome has become a collective entity denoting a median nerve entrapment that can exist from the upper arm to the distal forearm.[91] With the advent of more thorough physical exams in patients with upper extremity pain and dysfunctions, a delineation of entrapment levels is seen. Proximal median nerve entrapments can thus be divided into three separate entities: the lacertus syndrome[4]; the superficialis syndrome[89]; and the anterior interosseous (AIN) syndrome.[92]

Lacertus syndrome

Compression of the median nerve by the lacertus fibrosus, or bicipital aponeurosis, at the level of the cubital fossa was first described by Laha in 1978.[93] It has later been described in relation to repetitive and strenuous work with the arm in a pronated position,[94] and is slightly more common in computer workers than manual laborers.[23] In the largest published prospective study on lacertus syndrome, women and men were affected equally, as was the dominant/non-dominant hand.[95]

Anatomy

Akin to the carpal tunnel, at the level of the lacertus fibrosus the median nerve passes through a "tunnel", where the bottom is the medial trochlea of the humerus, the lateral and medial walls are the brachialis and pronator muscles, respectively, and the roof is the lacertus fibrosus (Fig. 24.6). The lacertus fibrosus thus acts like the transverse carpal ligament, being a strong fibrous band that may constrict the median nerve at the level of the elbow.[96] According to Sunderland,[5] at this level, the median nerve is organized such that the branches to the pronator teres and FCR are located anteriorly, and the branches to the FPL and FDP II, medially, whereas the sensory branches are located more deeply in the nerve. The motor symptoms will therefore appear before sensory symptoms in the instance of lacertus syndrome.

History

The most common complaints in patients with lacertus syndrome is a loss of key- and tip-pinch strength, a loss of fine motor skills, and sense of clumsiness (dropping objects). It is rarely associated with transient paresthesias in the median nerve-innervated region of the hand and there are no nocturnal symptoms of numbness as in CTS.[23] The presence of volar forearm pain is common in the later stages of lacertus syndrome, usually located in the cubital fossa and proximal volar forearm. It may at times be mistaken for medial epicondylitis due to the pain distribution in the medial elbow region.

Clinical examination

The clinical triad of muscle testing, SCT, and pain upon compression will reveal the following in a patient with lacertus syndrome: (1) distinct weakness when manually testing the strength of the muscles innervated by the median nerve distal to the lacertus fibrosus, especially the FPL, FDP II and FCR; (2); a positive SCT over the median nerve at the level of the lacertus fibrosus; and (3) pain upon external pressure of the median nerve at the proximal edge of the lacertus fibrosus (video 24.5 ▶).

Non-operative treatment

In patients with early onset of symptoms, a trial of local triamcinolone injections at the edge of the lacertus fibrosus may have success in reducing, even eliminating, symptoms. The effect of local cortisone is most likely a combination of reduced swelling around the nerve, as well as an effect in reducing the neuro-inflammatory response in the nerve.[97]

Wide-awake surgical release

The surgery is performed according to the wide-awake technique (video 24.5 ▶), with an awake patient and no tourniquet: 20–30 min preoperatively, the patient is anesthetized using 30–40 mL 1% lidocaine (10 mg/mL) with epinephrine (5 µg/mL) with 2–3 mL sodium bicarbonate (50 mg/mL) solution added. Using a 27-inch gauge needle, the anesthesia is slowly infiltrated from the medial elbow crease and obliquely 4 cm distally and centrally to cover the course of the lacertus fibrosus. A 2–3 cm transverse incision is placed in the flexion crease of the cubital fossa, from 1 cm medial of the biceps tendon to 2 cm lateral of the medial epicondyle. Careful dissection is made subcutaneously to the pronator teres (PT) fascia, taking great care to identify and protect branches of the medial antebrachial cutaneous nerve (MACN). The PT fascia is incised and followed laterally, allowing exposure of the lacertus fibrosus, which is subsequently divided. By retracting PT medially, the median nerve is readily seen. Any focal adherences to the underlying brachialis muscle may then be released. At this point, the strength of the FPL and FDP II is again tested intraoperatively before the skin is closed, as return of muscle strength is usually immediate after proper release of the nerve (video 24.5 ▶).

Intraoperative examination of the superficialis sling actively flexing on the surgeon's small finger in the wound of the lacertus release can delineate further compression at this point. It could be released through a separate incision if identified.

After cauterization, the wound is closed with intradermal 4-0 monocryl sutures, a small soft dressing applied, and immediate mobilization encouraged. Patients with non-manual labor return to work within 1–2 days postoperatively.

In a retrospective 10-year follow-up of surgically released median nerves at the level of the lacertus fibrosus vs. conservatively treated patients, the surgical patients had no return of symptoms but only 30% of the conservatively treated patients had relief of symptoms.[98] The surgical release at this level can thus be considered safe, minimally invasive, and effective.

Superficialis syndrome – AIN syndrome

In the traditional release of pronator syndrome, this fibrous flexor digitorum superficialis (FDS) arch has been considered one of the important pressure points to release. About 6 cm distal to the cubital fossa and medial epicondyle, the FDS arch

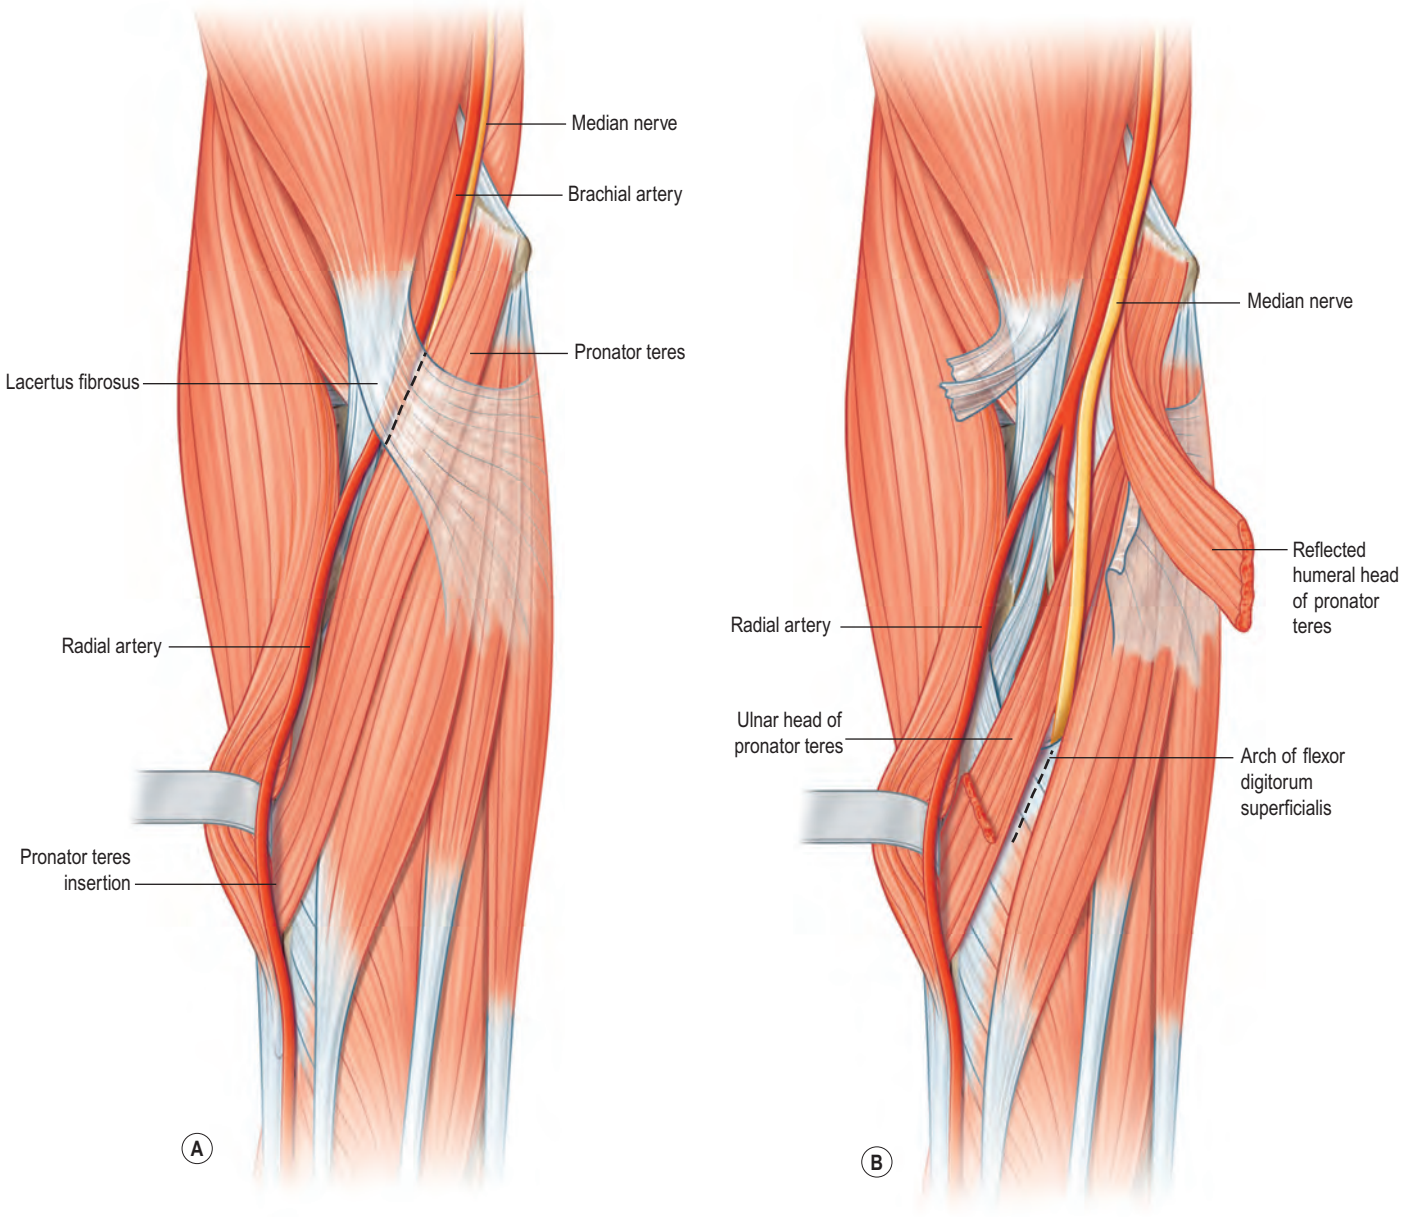

Fig. 24.6 Anatomy of proximal median nerve entrapments. **(A)** The lacertus syndrome is entrapment at the level of the lacertus fibrosus, resulting in weakness in the flexor carpi radialis, flexor pollicis longus (FPL) and the deep flexor to the index finger (FDP II). During surgery, the lacertus fibrosus should be completely transected. **(B)** The arch of the flexor digitorum superficialis (FDS) is the level of entrapment for the superficialis syndrome, with weakness in FDS IV and often paresthesias in the hand. This arch should be completely opened when performing superficialis syndrome surgery.

is found as a fibrous structure between the PT and FDS (see Fig. 24.6). The FDS arch is always located proximal to the bifurcation of the main median nerve and the anterior interosseous nerve. Originally, the AIN syndrome was described to occur under the fibrous arch of the FDS or the PT, but median nerve compression at these levels will not only involve the AIN but also the main median nerve and should be referred to as the superficialis syndrome. Pure AIN entrapment thus occurs distal to the FDS arch, after the bifurcation between the AIN and the main median nerve (see Fig. 24.6). Isolated entrapment of the AIN is the most uncommon of the proximal median nerve entrapments.

History

Like the lacertus syndrome, the patient with a median nerve entrapment at the FDS arch will complain of volar forearm pain and weakness in pinch. One distinct difference in presentation is that the superficialis syndrome also is associated with sensory disturbances within the median innervated region of the hand.

Contrarily, the AIN presents with a pure motor weakness and no sensory disturbance. There may be a history of forearm pain preceding the motor weakness. If instead there is a history of transient shoulder pain following a viral infection

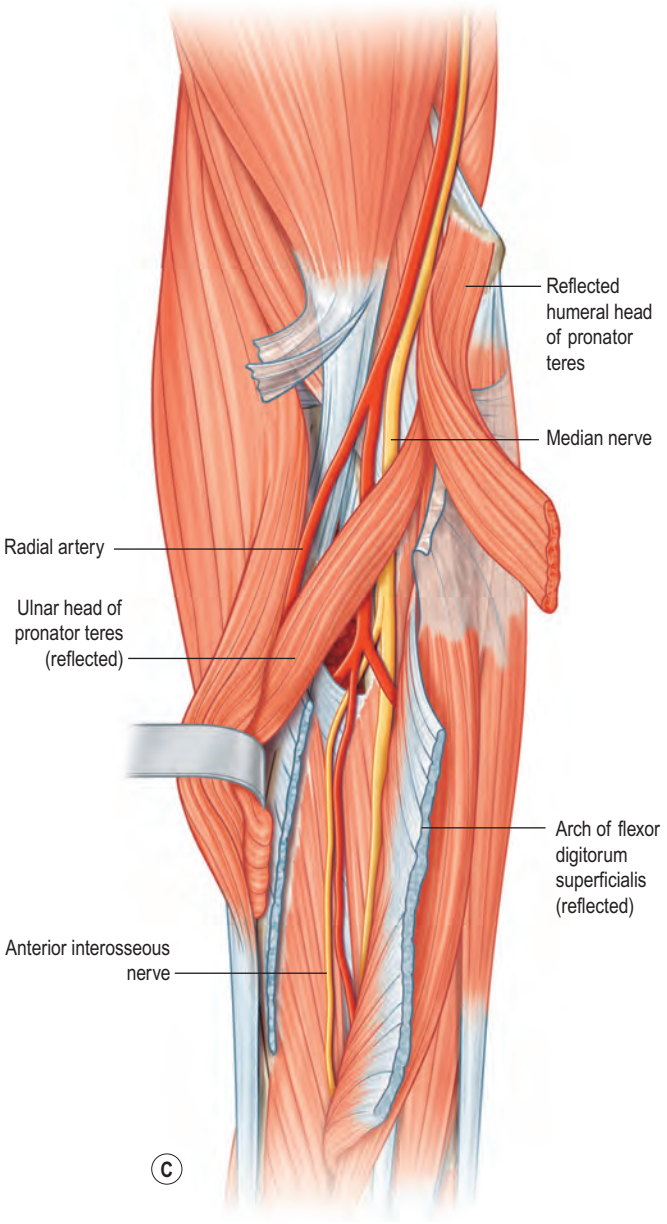

Fig. 24.6, cont'd (C) Anterior interosseous nerve (AIN) syndrome is a rare compression of the motor nerve, resulting in FPL, FDP II and pronator quadratus weakness but no paresthesias. After releasing the FDS arch, the AIN is followed distally to ensure proper release.

that precedes the motor weakness, the surgeon should consider the possibility of Parsonage–Turner syndrome (brachial neuritis or neuropathic amyotrophy).[99,100]

Clinical examination

The muscle testing of a superficialis syndrome will reveal a weakness in FPL and FDP II but, contrary to lacertus syndrome, a distinct weakness in FDS IV and no weakness in the FCR. The SCT is positive at the level of the FDS arch, and external compression over the median nerve will cause numbness in the hand. Tinel's is often positive at the same level. Superficialis sling compression of the median nerve can also be palpated internally at the time of a wide-awake lacertus release, as described in the lacertus section above. The patient flexes the long and then the ring fingers while the surgeon has his/her fifth finger under the superficialis sling through the lacertus wound after lacertus release. Superficialis compression can be released at the time of lacertus release through a separate incision if identified with active movement during surgery.

Because the AIN innervates the FPL, FDP II–III, and pronator quadratus, patients with a complete AIN palsy should exhibit no motor function in these three muscles unless a Martin–Gruber connection or ulnar contribution to the middle finger, FDP III, is present.[101] In incomplete AIN palsy, isolated FPL involvement is most typically observed. SCT will be positive over the branch of the AIN, about mid-forearm. Pressure over the AIN may elicit pain, but should never elicit sensory symptoms (negative Tinel's test).

Non-operative treatment

The conservative management of superficialis and AIN syndrome is identical to that of the lacertus syndrome, with a trial of steroid injections, physiotherapy, and activity-modification regimes. In the event of a Parsonage–Turner as a cause of the AIN palsy, the conservative management should also take into consideration any possible involvement of the shoulder girdle, such as adhesive capsulitis, to ensure a proper return of function in the entire upper extremity.[102]

Surgical release

The surgical release of the median nerve at the level of the FDS arch is usually performed using the Zancolli mini-invasive approach[89] and following the principles of wide-awake anesthesia. Lidocaine–epinephrine 1%, 30–40 mL buffered with 2–3 mL bicarbonate, is slowly infiltrated from about 2 cm distal to the cubital fossa and about 5 cm distally and centrally in the forearm, over the level of the FDS arch. A 3-cm transverse skin incision is placed over the FDS arch. Blunt dissection is made with careful retraction of the MACN, to the lateral edge of the PT fascia that is incised, to allow medial retraction of the muscle. Between the PT and FDS, the fibrous arch is found. Then the median nerve proximal to this edge is located and the nerve followed for about 3 cm distally, to ensure complete release.

In an AIN syndrome, following the release of the FDS arch, a more distal approach is undertaken to securely identify and release the AIN distal to the bifurcation from the main median nerve. Skin closure and postoperative management follows that of the lacertus syndrome.

Ulnar nerve entrapments

Ulnar nerve compression in Guyon's canal

Background

Compression of the ulnar nerve in Guyon's canal may also be called "ulnar tunnel syndrome".[103] The most common cause of ulnar nerve compression at the wrist is external compression by a space-occupying lesion, most commonly a ganglion.[104] The zone within which the ganglion arises can typically be determined on the basis of patient symptoms and

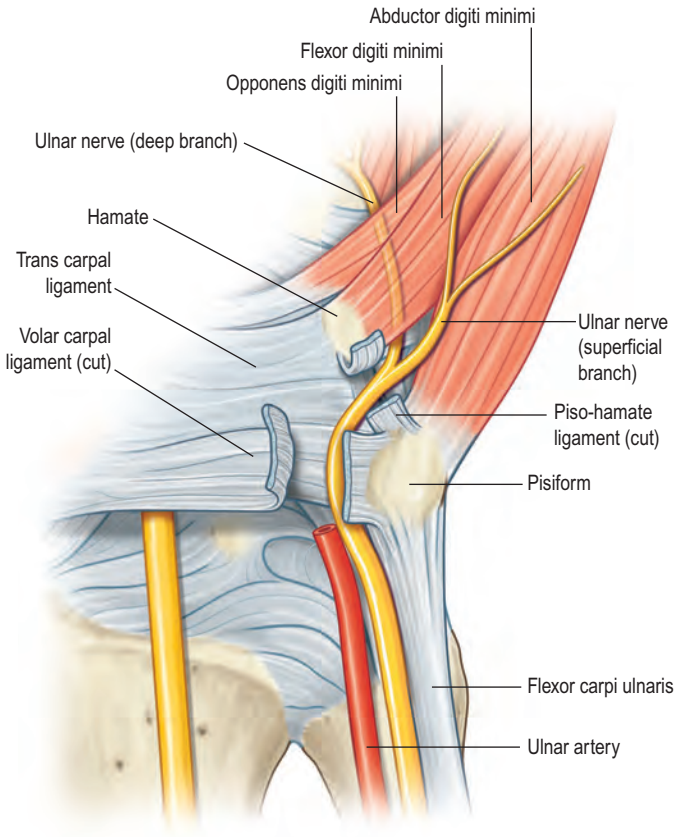

Fig. 24.7 Guyon's canal. The relationship of the ulnar nerve and artery to the hook of hamate, pisiform, opponens digiti minimi, abductor digiti minimi, flexor digiti minimi, and flexor carpi ulnaris is clearly depicted.

clinical examination alone.[105] Following space-occupying lesions, entrapment in Guyon's canal may also be caused by excessive or repetitive external pressure to the ulnovolar aspect of the hand. Hypothenar hammer syndrome is one such instance where repetitive trauma can be associated with compression of the ulnar nerve in Guyon's.[106] Another common sports-related cause of entrapment is the "handlebar palsy", where long-distance cyclists develop ulnar nerve entrapment in Guyon's canal due to excessive pressure on the hand.[107] Other less common causes of ulnar nerve compression at Guyon's canal include rheumatoid arthritis and carpal (in particular, hook of hamate) fractures.[108,109]

Anatomy

Guyon's canal is defined radially by the hamate, volarly by the volar carpal ligament, dorsally by the TCL and the piso-hamate ligament, and ulnarly by the pisiform, flexor carpi ulnaris (FCU) tendon, and the proximal belly of the ADM. More distally, nerve branches course deep to the hypothenar muscles (Fig. 24.7). Depending on the location of the compression with Guyon's canal, symptoms may be a combination of motor and sensory (zone I), purely motor (zone II), or purely sensory (zone III).

Zone I contains both sensory fibers to the ulnar ring and little fingers and motor fibers to the hypothenars and interossei, and extends from the proximal edge of the volar carpal ligament to the bifurcation of the ulnar nerve.

Zone II is defined by the deep motor branch of the ulnar nerve. It extends from the level of the bifurcation to the fibrous arch formed by the flexor and abductor digiti minimi muscles radially and distally. Soon after passing under the fibrous hypothenar arch, the deep motor branch wraps radially around the hook of the hamate and passes beneath the piso-hamate ligament, where it can become compressed. The motor branch innervates the interossei, lumbricals IV–V, adductor pollicis, and deep head of the flexor pollicis brevis.

Zone III is located ulnar to zone II and is bordered volarly by palmaris brevis and dorsally by the hypothenar muscles. The superficial branch contained in zone III is predominantly sensory with only a few motor fibers to palmaris brevis. Loss of palmaris brevis function is rarely, if ever, noticed by patients, and so for practical reasons the superficial branch is considered to be purely sensory.

History

Patients with ulnar nerve compression in Guyon's canal may present with a history of paresthesias in the small and ring fingers, ulnar-sided wrist pain, decreased grip strength, or clawing of the ring and little fingers. A history of wrist trauma, long-distance cycling, or vocational exposure to repetitive hand vibration is not uncommon. Patients with ulnar nerve entrapment at the wrist may also suffer from CTS; carpal tunnel release can often eliminate ulnar symptoms as it has been shown to decompress Guyon's canal indirectly.[110]

Clinical examination

The manual muscle testing should include an evaluation of the FDP V to rule out a more proximal involvement of the ulnar nerve (at elbow level). Furthermore, the muscle exam will help delineate the level of Guyon's canal involvement. Weakness of the ADM is associated with a zone I entrapment; normal strength in the ADM but weakness in the first dorsal interosseus signifies a zone II entrapment.

Physical examination should also include a thorough sensory assessment. The absence of dorsoulnar hand sensation suggests a site of compression proximal to the branching of the dorsal sensory branch of the ulnar nerve. The SCT can also be used to stage the entrapment in Guyon's canal, as it will be positive at the wrist crease level in zone I, at the level of the hook of the hamate in zone II, and in the ulnovolar region distal to the pisiform in zone III. Tinel's test will be positive for zone I and III, but negative in a zone II entrapment.

In addition to the above testing, an Allen test should be performed to assess for potential ulnar artery thrombosis (hypothenar hammer syndrome). Palpation of the ulnar wrist may reveal a ganglion, tumor, aneurysm, or hook of hamate fracture.

Ultrasound is a useful tool in Guyon's canal entrapments as it can directly reveal potential ganglion cysts as well as evaluate the blood flow in the ulnar artery.[111] Computed tomography and magnetic resonance imaging (MRI) is of use primarily in suspected carpal fractures or in the absence of ultrasound. Electrodiagnostic tests may be an adjunct to confirm the level of entrapment,[112] but physical examination is the foundation for proper diagnosis.

Surgical release

Although conservative methods such as non-steroidal anti-inflammatory drugs (NSAIDs) and splinting are often an option, if an anatomic cause of nerve compression is present, surgical intervention is warranted. A 6–7-cm incision is marked between the hook of the hamate and pisiform extending into the ulnar forearm. Proximally, the FCU is retracted ulnarly to expose the ulnar artery and nerve that are then traced distally. The volar carpal ligament and palmaris brevis are incised. A careful examination is made for any ganglion or tumor. The deep motor branch is subsequently decompressed by dividing the fibrous edge of the hypothenar muscles and any fascial bands arising from the hook of hamate. The sensory branch is then traced superficial to the fibrous hypothenar arch where it is most commonly impinged upon by an aneurysm or thrombosis of the ulnar artery or a ganglion in Guyon's canal.

Postoperatively, patients are allowed to remove the dressing and shower the day after surgery. A dressing may be reapplied for padding and protection for a week. Patients can return to work when they no longer experience pain while performing their duties, usually by 8 weeks.[113]

Cubital tunnel syndrome

Compression of the ulnar nerve at the cubital tunnel is very common and second only to CTS in incidence. The diagnosis of cubital tunnel syndrome is primarily clinical, as electrodiagnostic tests can often be negative despite significant symptoms and exam findings.

Clinical tips

Patients can be advised that the results following cubital tunnel surgery are not as good as those following carpal tunnel surgery and that numbness (or muscle power) may not improve significantly after surgery. By performing cubital tunnel surgery, we may at least prevent further nerve damage and disease progression.

Anatomy

In the upper arm, the ulnar nerve travels posterior to the medial intermuscular septum anterior to the medial head of the triceps. The arcade of Struthers is a deep brachial fascial band that joins the intermuscular septum and invests the ulnar nerve approximately 8 cm proximal to the medial epicondyle. This is a rare but potential site of ulnar nerve compression about the elbow. The medial antebrachial cutaneous nerve passes posterior to the ulnar nerve immediately proximal to or at the epicondyle; injury to this nerve can result in significant postoperative neuroma and pain. The ulnar nerve travels posterior to the medial epicondyle and medial to the olecranon to enter the cubital tunnel. The tunnel roof comprises a tight fascial layer that extends from the FCU to the arcuate ligament of Osborne, while the floor is defined by the ulnar collateral ligament. Upon exiting the cubital tunnel, the ulnar nerve travels into the forearm between the ulnar and humeral FCU heads, then deep to the deep flexor pronator aponeurosis. The most common site of entrapment for the cubital tunnel syndrome is at the ligament of Osborne, just distal to the medial epicondyle.[27]

History

A thorough history should include the onset of symptoms, presence of grip or pinch weakness, numbness, aggravating and alleviating activities, comorbidities (i.e., diabetes, peripheral neuropathies), and previous elbow trauma. Perhaps the single most important feature on history, however, is the chronicity of the symptoms. Intermittent symptoms elicited by elbow flexion are likely due to transient ischemia of the nerve and will respond well to treatment. Constant numbness or weakness responds less predictably to surgery.

Clinical examination

The manual muscle testing is important to exclude more proximal nerve involvement, and should always include a thorough examination of shoulder and elbow strength. In the presence of a cubital tunnel syndrome, the focus of the muscle exam should be on the FDP V and ADM to delineate if the entrapment is at the elbow or wrist level. A cubital tunnel syndrome will correspond to a weakness of both the FDP V and ADM.

In addition to the muscle exam, the SCT is of use in staging the level of ulnar nerve entrapment at the cubital tunnel. The most common site of entrapment, and the focus of potential nerve release, is at Osborne's ligament.[27] The Tinel's sign is also of aid in staging the site of nerve entrapment.

Another provocative test is the elbow flexion pressure test. The sensitivity of Tinel's sign is 70%, while that of the elbow flexion pressure test is 98%.[114] The latter test is considered positive if symptoms are elicited after 60 s of digital pressure applied over the cubital tunnel with the elbow in flexion.

Radiographs may be obtained to assess for elbow arthritis or post-traumatic deformity. Electrodiagnostic testing can be helpful to confirm the diagnosis or rule out a peripheral neuropathy or other sites of compression. An ulnar nerve motor conduction velocity across the elbow of less than 50 m/s is generally considered positive. Electrodiagnostic results must be interpreted carefully, however, as they have been shown to have a false-negative rate of more than 10% in the setting of cubital tunnel syndrome.[33] Patients with clinical symptoms but negative electrodiagnostic results should still be considered for surgical release as this renders positive outcomes and resolution of symptoms.[115]

Non-surgical treatment

Patients with mild or intermittent symptoms can often be successfully treated with local steroid injections, activity modification, splinting, and physiotherapy (nerve mobilization techniques).[116] Nocturnal splinting to prevent elbow flexion of more than 45° can be particularly helpful. Surgical intervention should be considered if non-operative modalities fail to improve symptoms after more than 2–4 months or if symptoms worsen during the period of conservative treatment.[113]

Surgical release

Controversy persists as to the optimal surgical management of cubital tunnel syndrome, a fact underscored by the

numerous techniques currently used by experienced surgeons to treat the condition. These techniques include *in situ* and endoscopic decompression, submuscular transposition, intramuscular transposition, subcutaneous transposition, and/or medial epicondylectomy. Since the most common site of nerve compression is just distal to the medial epicondyle, at Osborne's ligament, our preferred approach is a simple, *in situ* decompression using wide-awake techniques.

In situ decompression – the authors' preferred technique

We prefer to perform this procedure using the wide-awake approach (local infiltration without sedation or tourniquet). If the release is planned to the Osborne's ligament and distal of the medial epicondyle alone, the following is used: field infiltration of 20–40 mL of 1% lidocaine with 1:1–200 000 epinephrine buffered with 2–4 mL of bicarbonate, infiltration from the level of the sulcus to about 5 cm distal of the medial epicondyle. After waiting 20–30 min, a 3-cm skin incision is made just distal of the sulcus.[117] Blunt dissection is made to the FCU fascia where Osborne's band is identified. Just proximal of this, the ulnar nerve can be seen and followed distally as Osborne's and other constricting bands are released (Video 24.12 ▶).

Simple decompression

In a patient where more proximal ulnar nerve involvement is suspected, we prefer a simple decompression (videos 24.6 ▶ and 24.7) with the use of 0.5–1% lidocaine with 1:200 000 epinephrine beginning 8–10 cm proximal to the medial epicondyle to ensure anesthesia in the MACN distribution. Care should be taken to avoid branches of this nerve during subsequent dissection. Beginning proximally, the arcade of Struthers is released, followed by Osborne's ligament and the FCU fascia. The ulnar nerve is left undisturbed in its bed. The elbow is placed through a range of motion to check for any residual compression sites or subluxation of the nerve. If the latter is present, we prefer to perform a medial epicondylectomy (see below) to ensure that the ulnar nerve rolls smoothly over the medial border of the elbow.

Endoscopic decompression

Endoscopic decompression techniques make use of a small 15–35-mm incision over the ulnar nerve at the level of the condylar groove.[118–120] Tunneling forceps are used to create a space superficial to the fascia covering the nerve and deep to the subcutaneous tissue. An endoscope is placed in this space and blunt scissors used to release any points of constriction over the nerve under direct visualization.

Submuscular–subcutaneous transposition

With elbow flexion, the ulnar nerve is placed under tension and compression as the cubital tunnel volume decreases. The goal of transposition is to move the nerve anterior to the axis of elbow flexion, thereby decreasing tension on the nerve. Critics of this technique feel that dissection of the nerve from its bed compromises the segmental blood supply of the nerve.[121]

In the submuscular transposition, the proximal nerve is identified and traced distally following release of the arcade of Struthers. To prevent the formation of a new compression site proximally, a segment of the intramuscular septum is excised. The nerve is then unroofed to the level of the deep flexor pronator aponeurosis. The nerve is dissected free from its bed and transposed anterior to the medial epicondyle. The motor branches to the FCU and the FDP are preserved. The flexor pronator muscle mass is divided 1–2 cm distal to the medial epicondyle. The median nerve must be identified and preserved. The flexor pronator mass is repaired over the transposed nerve with a stepwise lengthening technique to avoid causing a new compression site.

In the subcutaneous transposition, instead of elevating the flexor pronator mass, the ulnar nerve is instead maintained in its transposed position by suturing the loose epineurium to the forearm fascia.

Medial epicondylectomy

The medial epicondylectomy technique is primarily used following a simple decompression with a tendency for ulnar nerve subluxation. The principles of anesthesia and nerve release follow that of the simple decompression. The medial epicondyle is exposed in a subperiosteal plane, maintaining the origin of the flexor pronator mass with the periosteum. The anteromedial edge of the epicondyle is scored with an osteotome. The epicondylectomy is performed along a plane midway between the sagittal and coronal planes of the humerus, all the while preserving the attachments of the ulnar collateral ligament. The flexor pronator origin is then reattached over the epicondylectomy site[113] (Fig. 24.8).

Outcomes and complications

Controversy over the optimal operative management of cubital tunnel syndrome is ongoing, with numerous comparative studies demonstrating no statistical difference in outcomes with any given technique. Simple decompression has been shown to be effective in treating cubital tunnel syndrome, with results equivalent to those of anterior transposition.[122–124] Goldfarb *et al.* recently demonstrated a 93% success rate with *in situ* decompression.[125] Similarly, a retrospective study comparing medial epicondylectomy alone with medial epicondylectomy and anterior subcutaneous transposition showed no statistical differences.[126]

Recurrent or unrelieved symptoms are much more frequent than with CTS. Predictors of revision surgery include previous elbow fractures and should be assessed for prior to planning surgery.[127] The posterior branch of the MACN is at potential risk of injury, and can result in a painful neuroma and hyperesthesia.[128] Ulnar nerve subluxation following simple decompression can lead to persistent pain. Hematoma is more frequently observed following the endoscopic technique than open approaches.[119,120] Medial epicondylectomy is complicated by persistent elbow pain in up to 45% of patients.[129]

Radial nerve entrapments

The radial nerve originates from the posterior cord in the brachial plexus. It traverses posterior of the shoulder and upper arm, transverses into the anterior compartment through the lateral intermuscular septum (LIS) in the distal

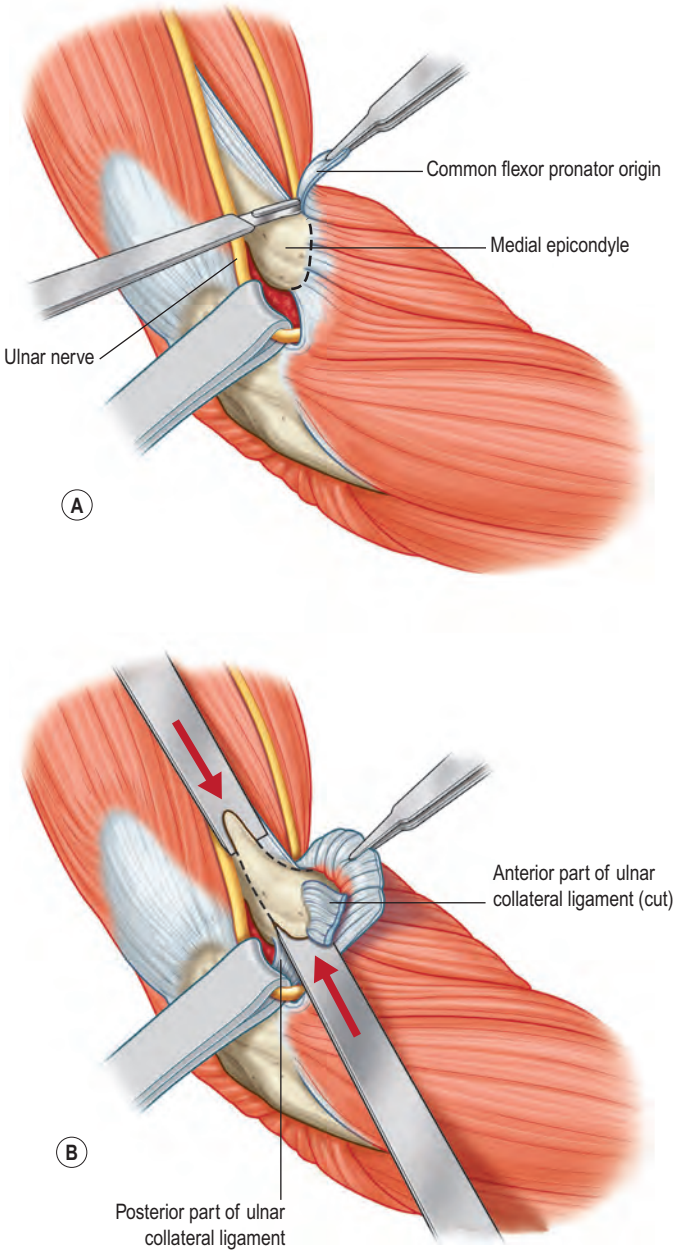

Fig. 24.8 Medial epicondylectomy technique. **(A)** The ulnar nerve is protected while the common flexor pronator origin is elevated from the medial epicondyle. **(B)** The proper plane of the osteotomy is between the sagittal and coronal planes.

forearm and continues deep under the brachioradialis (BR) where it divides into the posterior interosseous nerve (PIN) and sensory branch of the radial nerve (SBRN). Along its course, the radial nerve may become compressed at two locations in the upper arm, three in the forearm, and one at the wrist. In this section, we will describe four of the more common radial nerve entrapments encountered: two in the upper arm – triangular interval syndrome and lateral intermuscular syndrome; one in the forearm – radial tunnel syndrome (PIN entrapment); and Wartenberg syndrome (SBRN entrapment).[17]

Wartenberg's syndrome – entrapment of the SBRN

Anatomy

The SBRN travels down the forearm immediately deep to the BR. It emerges into the subcutaneous plane approximately 9 cm proximal to the radial styloid by passing between BR and extensor carpi radialis longus (ECRL) (Fig. 24.9). It is at this arcade that the nerve becomes compressed. The SBRN provides sensation to the dorsum of the three radial digits to the level of the proximal interphalangeal joints.

History and clinical examination

Patients with Wartenberg's syndrome report isolated pain or dysesthesias over the dorsoradial aspect of the hand. The presence of motor weakness suggests a more proximal site of compression. There may be a preceding history of trauma to the area (i.e., handcuffs, forearm fracture). It is important to differentiate Wartenberg's syndrome from de Quervain's tenosynovitis, as both may present with radial wrist pain.[130] Since Finkelstein's test will elicit pain in both of these diagnoses, it may further lead to a misinterpretation of symptoms.[131] The key differences between the two lie in the presence of a positive Tinel's test at the BR–ECRL arcade in Wartenberg's syndrome and no pain upon palpation of the first dorsal extensor compartment.[132] A positive SCT will usually also be present at the level of the BR–ECRL arcade.

Non-surgical treatment

Spontaneous resolution of symptoms is common in Wartenberg's syndrome. Indeed, many cases respond by simply eliminating the inciting factor, such as a tight watchband or bracelet. Rest, splinting, and NSAIDs are also effective. Evidence to support the use of corticosteroids is limited and should be considered carefully, as steroid injections at this level may cause subcutaneous and skin atrophies.[133]

Surgical release

In patients who fail to respond to conservative treatment, surgical decompression may be considered. Wide-awake surgical technique using 10–20 mL lidocaine–epinephrine is advantageous as the patient then can cooperate during surgery to ensure proper gliding of the SBRN following release. A longitudinal incision is made from 5 cm proximal of the radial styloid and 4–5 cm proximally, making sure to stay slightly volar to the Tinel's sign, thereby avoiding injury to the lateral antebrachial nerve and preventing tethering of the incision scar over the superficial radial nerve. The fascia between the brachioradialis and ECRL is divided and the superficial radial nerve carefully freed from its bed. At times, a radial slip of the BR tendon must be removed to allow adequate passage of the nerve. In addition to nerve gliding, postoperative care may involve a desensitization program. An overall success rate of 74% has been reported following surgical decompression.[130]

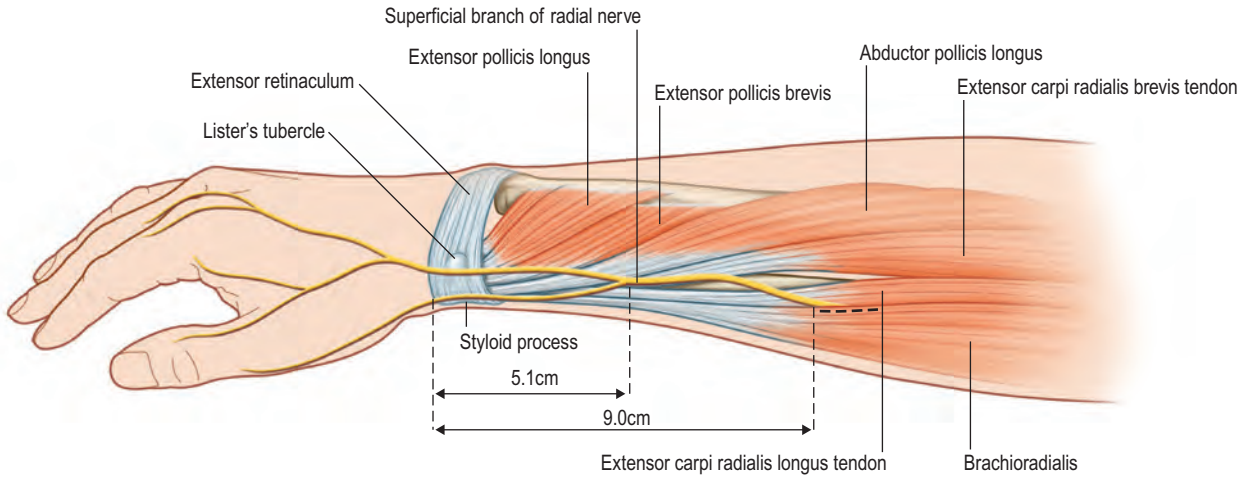

Fig. 24.9 Anatomy of the superficial sensory branch of the radial nerve. The fascia between the extensor carpi radialis longus and brachioradialis is released in patients with Wartenberg's syndrome.

Radial tunnel syndrome – PIN compression in the proximal forearm

Radial nerve entrapment in the proximal forearm, at the arcade of Frohse, the fibrous proximal edge of the supinator muscle,[134] is referred to by several names: radial tunnel syndrome (RTS); posterior interosseous nerve (PIN) syndrome; and supinator syndrome. Regardless of label, this compression signifies an entrapment of the PIN.

Anatomy

The PIN arises from the bifurcation of the radial nerve in the proximal forearm. The PIN has traditionally been considered a "pure motor nerve", which is not entirely correct. While it is true that the PIN contains the motor innervation to the forearm extensors distal to the elbow and the abductor pollicis longus, the terminal branch of the PIN contains important sensory innervation of the dorsal wrist joint,[135] and is a source of both proprioceptive[136] and nociceptive[137] afference from the wrist.

The PIN does not innervate the ECRL, ECRB, BR, or anconeus muscles; these muscles instead receive their innervation from the main radial nerve. Immediately distal to the bifurcation, the PIN travels through the radial tunnel, a 5-cm space originating at the level of the radiocapitellar joint and traversing between the superficial and deep layers of the supinator muscle.[138]

Within the area of the radial tunnel there are described five potential sites of compression: (1) fibrous bands to the radiocapitellar joint between the brachialis and brachioradialis; (2) the recurrent radial vessels, or so-called leash of Henry; (3) the proximal edge of the ECRB; (4) the proximal edge of the supinator, or so-called arcade of Frohse; and (5) the distal edge of the supinator. The arcade of Frohse is by far the most common site of PIN compression, where high pressures (up to 200 mmHg) on the nerve may be elicited during active contraction of the supinator muscle.[139] Compression of the PIN at the distal edge of the supinator is exceedingly rare and should be considered an entirely separate nerve entrapment as it presents with completely different symptoms than the RTS.

History

RTS is frequently found in conjunction with, or misdiagnosed as, lateral epicondylitis,[140] with a reported prevalence of 95% failed epicondylitis-treated patients in a series of surgically released RTS.[23] It is not uncommon that both conditions may exist in the same patient, and in our experience, RTS should always be considered in cases where lateral epicondylitis patients have failed to respond to conservative treatments.

The most common complaint in RTS is pain in the dorsal and proximal aspect of the forearm, with pain presenting primarily after exertion and at night. In lateral epicondylitis, tenderness is localized to the ECRB insertion, while in radial tunnel syndrome the point of tenderness is 3–4 cm distal over the mobile wad.[141] In a retrospective review of surgically treated RTS, the syndrome was found to be more common in men, manual workers, and affecting the dominant hand.[23]

Clinical examination

The most superficial fascicle in the radial nerve at the level of the arcade of Frohse is the branch to the ECU.[5] Based on this, the testing of strength in the ECU has been reported as a reliable clinical test (video 24.8 ▶).[142,143] With the patient seated, shoulder at 90° elevation and extended elbow, the patient ulnarly deviates the wrist. The examiner places one hand over the radial aspect of the distal radius, the other on the ulnar side of the hand, and then asks the patient to resist as the examiner radially deviates the wrist.[23] Always compare the strength in the healthy arm before testing the affected arm to facilitate examination and diagnosis. SCT is positive at the level of the arcade of Frohse, about three fingerbreadths distal to the lateral epicondyle, and pain upon compression is evident at the same level.

Clinical tips

In a patient with chronic lateral epicondylitis, "tennis elbow", that fails to respond to conservative treatments, always test the strength of the extensor carpi ulnaris (ECU). Weakness of the ECU is indicative of a radial tunnel syndrome, a diagnosis that is a source of pain in the lateral elbow and proximal forearm and frequently misdiagnosed as lateral epicondylitis.

Non-operative treatment

An initial treatment of local corticosteroid at the level of the arcade of Frohse may be therapeutic. Indeed, one study showed a 72% response rate to local injection in patients with radial tunnel syndrome at 6 weeks of follow-up; in the majority of these responders, pain relief persisted for more than 2 years.[144] Conservative management such as avoidance of aggravating activities, hand therapy management (stretching, nerve gliding, splinting), adaptation of the workplace, and use of NSAIDs have been shown to be helpful.[145]

Surgical release

Surgery is recommended for RTS if there is no appreciable improvement in motor function by 2–3 months, or even earlier in cases of nocturnal and residual pain. Our preferred technique for is the posterior approach, as this allows an easy exposure of the proximal edge of the supinator, ability for possible concomitant release of a tense ECRB edge, and results in more aesthetically pleasing scars as compared to the volar approach (Fig. 24.10).

The procedure is usually done in general anesthesia and using a tourniquet. However, the wide-awake approach is also possible. If performing a wide-awake release, 20–30 mL lidocaine–epinephrine should be infiltrated in the dorsal proximal forearm, from just distal to the lateral epicondyle and about 5 cm distally and obliquely. We also inject 10 mL lidocaine–epinephrine in the volar aspect of the brachioradialis muscle, over the volar aspect of the radial nerve, to block possible pain sensation when releasing the PIN toward the volar aspect of the supinator.

An oblique dorsal incision is made distal to the lateral epicondyle. Following incision of the forearm extensor fascia, blunt dissection is performed between the ECRB/L, and the muscles retracted. Identify the SBRN and follow this proximally to the radial nerve bifurcation to identify the PIN. This can then be followed distally, to the point where it enters into the arcade of Frohse, beneath the proximal edge of the supinator. Release 2–3 cm of the proximal supinator fascia to complete the neurolysis. Immediate mobilization is encouraged, but limited to 1 kg loading during the first 2 weeks postoperatively. Full load is generally allowed 4 weeks postoperatively.

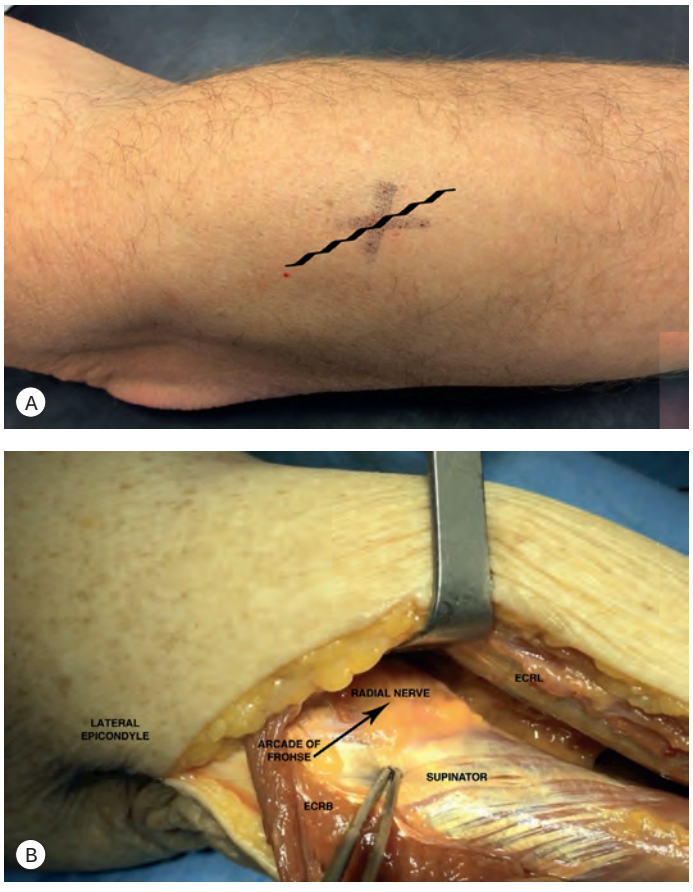

Fig. 24.10 The posterior approach to the radial tunnel. The plane between the extensor carpi radialis and longus is developed. The proximal edge of the supinator is released, slightly to the side of the nerve to avoid direct scarring. ECRB, Extensor carpi radialis brevis; ECRL, extensor carpi radialis longus.

Outcomes following surgery

Hashizume *et al.* demonstrated full recovery in 16 of 17 patients who underwent surgical decompression of the PIN after symptom onset.[146] Hagert and Hagert reported complete return of ECU strength and pain relief in 40 of 45 patients released (88%).[23] Interestingly, Simon Perez *et al.* reported identical results in their recent publication, with good to excellent results in 37 of 42 patients (88%).[147]

In their systematic review of observational studies, Huisstede *et al.* noted the success of surgical decompression ranged from 67% to 92%.[148] This variability in success rates may be due in part to the presence of concomitant lateral epicondylitis in some patients; other studies have shown poorer outcomes among patients with coexistent lateral epicondylitis.[140,149]

Lateral intermuscular syndrome – radial compression in the distal upper arm

Anatomy

In the distal upper arm, as the radial nerve passes from the dorsal to the volar compartment of the upper arm, it passes through the LIS. This septum is a taut fascia, covering the lateral aspect of the humerus from the deltoid insertion proximally, to the lateral epicondyle distally. The radial nerve pierces the LIS approximately 10 cm proximal to the lateral epicondyle[150] to exit between the brachialis and BR volarly (Fig. 24.11).

History and clinical examination

The primary complaint is of an aching pain in the distal, lateral upper arm.[151] The pain is usually aggravated with physical exertion, such as repetitive elbow extension/flexion. This type of radial nerve entrapment is most commonly encountered in manual laborers and athletes.[151,152]

When performing the muscle exam, a pattern of muscle weakness involving wrist extension and thumb/index finger extension is found (video 24.9 ▶). It is important to thoroughly examine the triceps strength, as simultaneous weakness of the triceps will denote a more proximal radial nerve involvement. Positive SCT is found where the radial nerve pierces the septum, about 10 cm proximal of the lateral epicondyle. The level of positive SCT and maximum point of tenderness upon

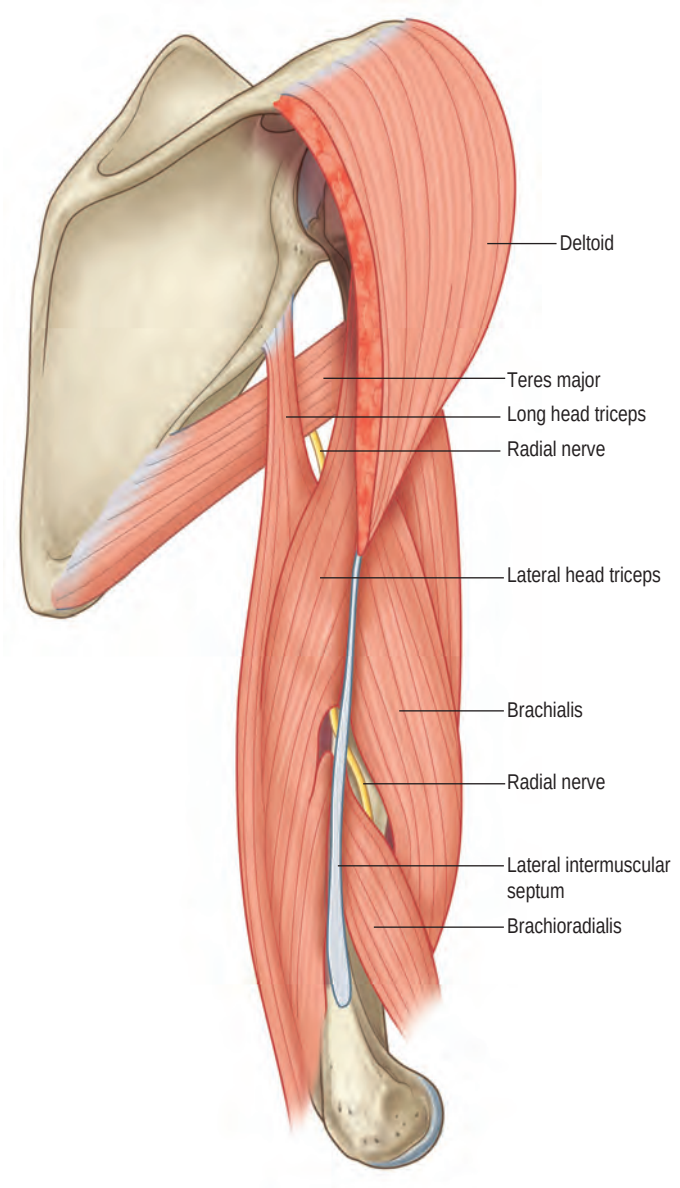

Fig. 24.11 The anatomy of the radial nerve in the upper arm. Proximally, the radial nerve enters into the triangular interval, bordered by the teres major cranially, the long head of triceps medially and the lateral head laterally. Distally, the radial nerve passes through the lateral intermuscular septum to exit between the brachialis and brachioradialis.

compression over the nerve will guide the surgeon in planning the level of surgical release.

Non-surgical treatment

In an acute onset of lateral upper arm pain and weakness, a resolution of symptoms can be expected with local steroid injections, NSAIDs, activity modifications, and rest. In a majority of patients, the onset of symptoms is more gradual. Conservative management should always be attempted before proceeding to surgical release.

Surgical release

The procedure is usually done under general anesthesia. The use of a tourniquet is optional, but generally facilitates the surgical procedure. The skin incision is planned from about 5 cm proximal of the lateral epicondyle and about 10 cm in a proximal direction. Perform blunt dissection to the triceps, incise the fascia, and retract the muscle posteriorly. Identify the posterior antebrachial cutaneous nerve in the distal aspect of the wound, superficial to the fascia. Follow the cutaneous nerve proximally, as it will lead to the radial nerve. After identifying the bifurcation, the main radial nerve can be followed distally while releasing constricting fibrous bands compressing the nerve at the LIS.[17] The patient is allowed to start immediate motion without load to allow nerve gliding through the septum. Manual work is restricted until 4–6 weeks postoperatively.

Triangular interval syndrome – radial compression in the proximal upper arm

Anatomy

In the proximal upper arm, just distal to the shoulder girdle, the radial nerve passes through the triangular interval that is bordered medially by the long head of the triceps, laterally by the lateral head of the triceps, and by the teres major cranially (Fig. 24.11). Entrapment of the radial nerve at this level is relatively rare but has been described in physically active adults,[153] and is sometimes referred to as the triangular interval syndrome (TIS).[154]

History and clinical examination

Pain of a dull and aching character located to the dorsolateral aspect of the upper arm, slightly distal to the axilla, is the principal symptom in radial nerve entrapment at this level. The patient may describe worsening of pain following strenuous use of the triceps, either in relation to work or athletic activity. Nocturnal pain is common. Intermittent paresthesias in the dermatome of the radial nerve, from the upper arm into the forearm, may also occur.

Like the lateral intermuscular syndrome described above, the manual muscle testing will reveal weakness of wrist and finger extension, but also when testing the strength in the triceps. The triceps is examined with the patient in a seated position, adducted arms and elbows flexed to 90°. The examiner holds underneath the forearms of the patient from behind, while the patient tries to push the arms beyond 90° flexion. If the symptoms have persisted over time, electrodiagnostic examinations can be helpful to reveal EMG changes in the triceps indicative of a proximal radial nerve entrapment.

Non-surgical treatment

As with other radial nerve entrapments, the principal of conservative management includes local steroid injections at the site of the triangular interval, activity modifications, and physiotherapy. In a majority of instances, the conservative management will be successful in resolving the pain.

Surgical release

If the patient has failed conservative management for about 3 months and pain is persistent, surgical management is indicated.

In general anesthesia and with the patient in a semi-prone position, a dorsolateral skin incision is performed from the distal edge of the deltoid and about 5–6 cm distally. If the patient has a concomitant axillary nerve entrapment, the skin incision used for the axillary release may be extended distally. The edge of the posterior deltoid muscle is identified as the most superficial and cranial muscle. By lifting this edge, the teres major (TMa) can be identified underneath. The radial nerve is seen just distal to the edge of TMa, before it enters into the triangular interval. A muscular septum connecting the lateral and long heads of the triceps is the primary cause of compression at this level. The fascial edge is released while carefully protecting the radial nerve. Skin closure and postoperative management is identical to that described in the lateral intermuscular syndrome.

Clinical tips

In a patient with clinical signs of high radial nerve involvement (weakness in the triceps, wrist and finger extension, paresthesias in the radial innervated region), always perform a muscle exam to test the strength in shoulder abduction. Concomitant axillary nerve entrapment and high radial nerve entrapment may exist and should be treated simultaneously.

Other nerve compressions of the upper extremity

Axillary nerve entrapment

Anatomy and etiology

The quadrilateral space (QS) is defined by the teres minor (TMi) superiorly, the neck of the humerus laterally, the long head of triceps medially, and the upper border of TMa inferiorly (Fig. 24.12). The axillary nerve and the posterior circumflex humeral artery (PCHA) travel through this space. In the QS, the nerve branches into an anterior division that innervates the middle and anterior deltoid, and a posterior division. The posterior division supplies motor innervation to the posterior deltoid and TMi and is the portion most commonly compressed.

Reported causes of entrapment include ganglion, muscle hypertrophy, scapular fracture, and glenoid labral cysts; however, fibrous bands are the most common cause of compression.[155–159] Compression of the axillary nerve in the QS is a nerve compression most commonly found in young active adults, such as overhead-throwing athletes.[160,161] Axillary nerve compression has also recently been highlighted as a possible cause of shoulder pain in spinal cord-injured patients where manual wheelchair propulsion appears to predispose to hypertrophy and scarring of the quadrilateral space.[162]

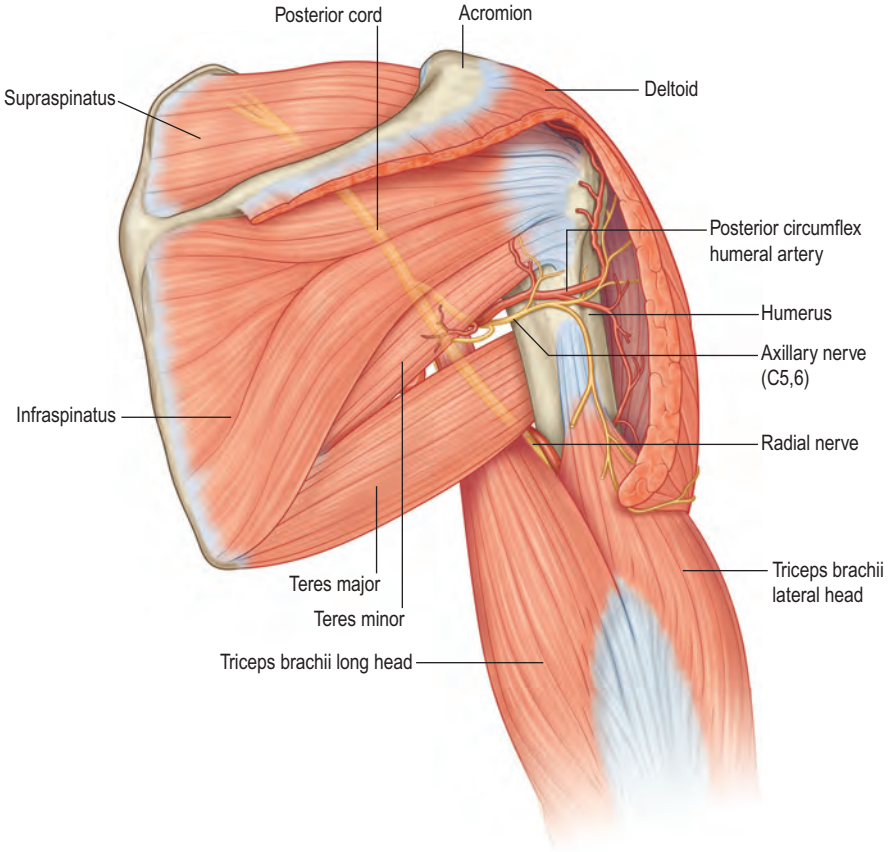

Fig. 24.12 Anatomic boundaries and contents of the quadrilateral space.

History

Patients with QS syndrome present with a gradual increase in diffuse pain over the posterior aspect of the shoulder, commonly nocturnal pain with an inability to sleep on the affected shoulder. Paresthesias over the deltoid may also be a complaint, as is a feeling of weakness in shoulder strength and endurance.[17,163]

Clinical examination

The manual muscle testing will reveal a weakness in the posterior deltoid when comparing to the contralateral side (video 24.10 ▶). With the patient seated, arms elevated to 90° and slightly abducted, the patient is asked to resist as the examiner pushes on the forearms inward. It is important to rule out weakness of the pectoralis, as combined weakness of pectoralis and posterior deltoid is indicative of a brachial plexus affliction. Furthermore, strength in the infraspinatus should be tested, as a combined posterior deltoid and infraspinatus weakness indicates a C5/C6-radiculopathy, or a combined axillary and suprascapular compression, rather than an isolated axillary nerve entrapment (Fig. 24.13).

When performing the SCT test, scratching posteriorly over the QS may elicit a positive response. Tenderness is usually noted over the QS posteriorly. In severe cases, wasting of the deltoid may be present.

Other diagnostic tools

EMG has been shown to be insensitive but specific for QS syndrome.[164] Originally, angiography was considered the investigation of choice, as PCHA occlusion was considered pathognomonic of the condition.[163] However, as fibrous bands and scarring are the most common cause of entrapment, angiography is usually negative. MRI findings of TMi atrophy and presence of fatty infiltrations may also confirm the diagnosis.[165,166] Recently, the use of ultrasound to look for fatty infiltrations in the TMi and performing Doppler examination of the PCHA has been advocated as a reliable and cost-effective modality.[167]

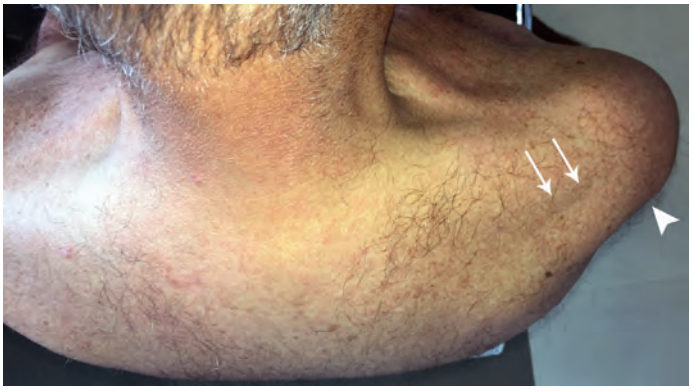

Fig. 24.13 Clinical image. Patient with right-sided supraspinatus (arrows) and posterior deltoid (arrowheads) atrophy due to C5–C6 radiculopathy.

Non-surgical treatment

In cases of early onset QS syndrome, an initial trial of steroid injections, activity modifications, NSAIDs, and strengthening exercises are often effective in relieving pain and restoring function. In patients with significant deltoid atrophy or with a clear structural compression, however, a surgical approach is indicated.

Surgical release

In a recent review of QS syndrome, it has been suggested that it should be separated into a neurogenic and a vascular syndrome depending on the cause of compression.[168] In the instance of a vascular etiology, a ligation of the artery with or without thrombolysis is advocated.

Since the neurogenic component with fibrous entrapment of the axillary nerve is most commonly seen, a nerve release in the QS is our treatment of choice (video 24.10 ▶).[17]

In general anesthesia and with the patient in a lateral, or three-quarters prone, position, a 10-cm dorsal skin incision is made along the inferior border of the posterior deltoid. Perform blunt dissection to the posterior deltoid and lift the posterior edge. The TMi will be seen underneath. Locate and release the axillary nerve branch innervating the TMi, then follow this branch toward the axilla, as it will facilitate identification of the axillary nerve as it exits the QS. Release the fibrous bands around the nerve but be cautious as the PCHA is adjacent to the nerve. The patient is allowed to start immediate motion without load; full load is allowed 4–8 weeks postoperatively.

Musculocutaneous nerve compression

Anatomy and etiology

The musculocutaneous nerve arises from the lateral cord of the brachial plexus. Shortly after its origin, it innervates the coracobrachialis muscle. The musculocutaneous nerve then pierces through a tight muscle fascia to innervate the biceps brachii and brachialis muscle. Where the musculocutaneous nerve pierces through the fascia between the coracobrachialis and short head of the biceps is a potential site of nerve entrapment.[169,170] The terminal branch of the musculocutaneous nerve is the lateral antebrachial cutaneous nerve, which pierces through the distal fascial edge of the biceps, just proximal of the elbow, providing sensation in the volar lateral aspect of the forearm.

Isolated entrapment of the musculocutaneous nerve is a relatively rare clinical entity. It has been reported as a complication following shoulder arthroscopy and proximal biceps tenodesis,[171,172] as well as a complication following heavy weightlifting or strenuous overuse of the biceps.[173,174]

History and clinical examination

The patient usually presents with a complaint of arm weakness, at times upper arm pain and paresthesias in the lateral forearm.

Clinically, bilateral testing of biceps strength will reveal a weakness on the affected side. SCT may be positive where the musculocutaneous nerve passes between the coracobrachialis and biceps brachii, about 8–10 cm distal to the shoulder joint.

Fig. 24.14 Clinical image. Patient with right-sided biceps (arrows) atrophy due to musculocutaneous nerve entrapment. *(Reprinted with kind permission from Prof. Carl-Göran Hagert, MD, PhD.)*

Pain upon compression at this site may elicit painful paresthesias into the forearm. EMG is helpful to determine possible atrophy of the biceps muscles (Fig. 24.14). In the event of normal biceps strength but paresthesias in the volar lateral forearm, an isolated entrapment of the lateral antebrachial cutaneous nerve should be suspected.[175] If a biceps weakness is found in combination with weakness of the pectoralis and posterior deltoid, a more proximal brachial plexus entrapment is probable.

Non-surgical treatment

The choice to treat conservatively is based on the degree of biceps involvement. In early stages of entrapment, a conservative regime of NSAID and activity modifications are usually sufficient.

Surgical release

Should atrophy of the biceps muscles be evident, clinically and/or at EMG, surgical release of the musculocutaneous nerve is indicated.

With the patient in a supine position, shoulder abducted, an incision is made from about 2 cm distal to the coracoid process and about 10 cm distally into the upper arm. The distal edge of the pectoralis minor is elevated to reveal the coracobrachialis muscle. At this level, the bifurcation of the musculocutaneous nerve and lateral cord to the median nerve can be identified. By following the musculocutaneous nerve through the coracobrachialis, the tight fibrous bands over the nerve and between the coracobrachialis and biceps brachii can be released. Skin closure and postoperative management includes early range-of-motion exercises but refraining from elbow flexion with load during the first 4–8 weeks.

Suprascapular nerve compression

Anatomy and etiology

Although compression of the suprascapular nerve is considered a rare entity and a diagnosis of exclusion,[176] this nerve entrapment has received much attention in recent years as a cause of shoulder pain in elite athletes. With the advent of arthroscopic management of suprascapular nerve entrapments, this rare nerve compression syndrome has become among the most published nerve disorders in the past 3 years.

From its origins from the upper trunk of the brachial plexus, the suprascapular nerve courses through the posterior cervical triangle to reach the suprascapular notch (Fig. 24.15).

The suprascapular notch is found medial to the coracoid process and bordered superiorly by the transverse scapular ligament. Recent investigations into the anatomy of the transverse scapular ligament has this as a primary source of nerve compression.[177] After innervating the supraspinatus muscle, the nerve reaches the spinoglenoid notch at the lateral base of the scapular spine. This is bordered by the spinoglenoid ligament, and serves as a second common site of suprascapular nerve compression.[178,179]

History and clinical examination

Suprascapular compression neuropathy should be suspected in younger athletes, in particular overhead-throwing athletes, or laborers who perform repetitive overhead activities. The most common causes of suprascapular compression is trauma, inflammation, pressure from ganglion cysts, or in relation to rotator cuff injuries.[180] Patients commonly present with dull

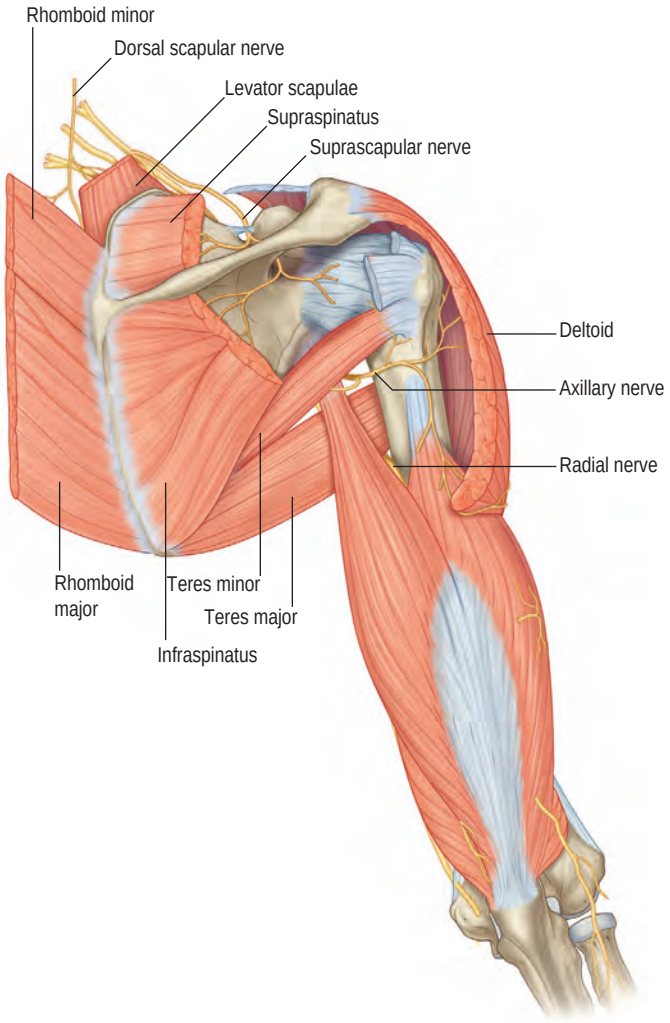

Fig. 24.15 Anatomy of the dorsal scapular and suprascapular nerves. The dorsal scapular nerve passes underneath the medial scalene muscle and more distally, just underneath the proximal edge of the rhomboids, medial to the medial upper corner of the scapula. Both muscles can compress the dorsal scapular nerve. The suprascapular nerve passes under the transverse scapular ligament and through the suprascapular notch. Similarly, the spinoglenoid notch is covered by the spinoglenoid ligament. Both ligaments can compress the suprascapular nerve.

posterolateral shoulder pain and dysfunction. The diagnosis can be delayed by months as treatment is erroneously directed towards the cervical spine, rotator cuff, or glenohumeral joint.

The clinical examination should include muscle testing of the infraspinatus, where weakness in external shoulder rotation is evident. Supraspinatus strength may also be reduced and is tested with the shoulder abducted to 60° as the patient tries to resist and adduction motion by the examiner. Supraspinatus strength is, however, rather difficult to assess as deltoid function often masks an underlying supraspinatus weakness. In advanced cases, infra- and supraspinatus atrophy may be evident. SCT may be positive over the suprascapular notch, and pain may be exacerbated by arm adduction and internal rotation that tighten the spinoglenoid ligament.[181]

Other diagnostic tools

MRI studies are the primary imaging modality in suprascapular entrapments as they can reveal atrophy and fatty infiltration in the infraspinatus, as well as concomitant rotator cuff injuries.[182] Ultrasound may also be of use to examine for possible presence of ganglion cysts and changed, hypoechoic, appearance in the suprascapular nerve.[183] EMG studies may also be obtained but carry an increased rate of false-negative and -positive findings,[184] and is not found to correlate to outcomes of treatment.[180]

Non-surgical treatment

Most patients with suprascapular neuropathy have an underlying etiology of overuse, and activity modification, NSAIDs, and strengthening exercise is adequate to relieve pain and restore function in up to 80% of patients.[185] If a ganglion cyst is the cause of nerve entrapment, an ultrasound-guided aspiration of the cyst may relieve the symptoms.[180] In patients with significant muscle atrophy or with a clear structural compression, however, a non-surgical approach is unlikely to be of benefit and may in fact lead to further dysfunction.[186]

Surgical release

Traditionally, the suprascapular notch has been decompressed via a trapezius-splitting incision along the scapular spine.[187] Although the arthroscopic approach carries with it a learning curve,[188] the advantages with smaller incisions and visualization of the suprascapular nerve is now rendering arthroscopic suprascapular nerve release the treatment of choice. Iannotti and Ramsey have described the arthroscopic decompression of the suprascapular nerve at the spinoglenoid notch.[189] Bhatia and colleagues have recently demonstrated an arthroscopic approach to release both suprascapular and spinoglenoid notch.[190] Several long-term studies are showing favorable results with arthroscopic release, both with regard to pain relief, return to activities, and normalization of EMG.[180]

Dorsal scapular nerve compression

Anatomy and etiology

The dorsal scapular nerve originates from the C5 root, just proximal to the upper cord of the brachial plexus. The nerve pierces the middle scalene muscle, a potential point of compression, to pass posteriorly beneath the levator scapulae, which it innervates (see Fig. 24.15). After the levator, the nerve passes beneath the proximal edge of the rhomboid major, just medial to the medial upper corner of the scapula, at which point the nerve is most commonly entrapped.[191]

Although a rare entrapment, compression of the dorsal scapular nerve should be recognized as a cause of unilateral interscapular pain and discomfort. Some authors believe the presence of the dorsal scapular nerve entrapments to be grossly underestimated.[191,192] The most common cause of entrapment is related to traction injuries of the neck, repetitive overhead exertions, or direct pressure on the nerve.[192–194] Recently, dorsal scapular nerve entrapment has been recognized as a source of interscapular pain in spinal cord-injured patients.[162]

History and clinical examination

The clinical presentation is one of gradual onset of dull pain along the medial border of the scapula, at times radiating into the posterior neck.[195] Paresthesias are not a common finding as the dorsal scapular nerve is primarily a motor nerve.

The most common clinical finding is a subtle lateralization of the scapula, giving an appearance of mild scapular winging.[193,196] Winging may become more noticeable as the arm is lowered from an elevated position.[197] SCT may be positive just medial to the medial upper corner of the scapula, where the nerve moves underneath the proximal edge of the rhomboids. Pain is usually evident upon compression at this level. It is important to test the strength in the infraspinatus as concomitant scapular winging and infraspinatus weakness may be a sign of C5-radiculopathy. Electrodiagnostics may be of use, but the accuracy of these studies is limited to about 50%.[192]

Non-surgical treatment

As with the suprascapular nerve entrapment, patients with dorsal scapular nerve involvement frequently have a history of overhead overuse, and activity modifications, strengthening exercises of the rhomboids, and local steroid injections can provide resolution of symptoms.

Surgical release

Before planning a release of the dorsal scapular nerve, it is important to delineate if the primary point of compression is at the middle scalene muscle or at the proximal edge of the rhomboid muscles. In the former, a complete division of the middle scalene muscle has been advised with good resolution of symptoms. In our experience, the latter is more common and will be described below.

The surgical release at the level of the medial scapular corner is suitable for the wide-awake approach. With the patient in a lateral position, the affected scapula upward, an infiltration of 40 mL lidocaine–epinephrine is performed from the cranial edge of the levator scapulae to 3–5 cm caudal of the upper medial scapular corner. A straight incision is made on the medial upper aspect of the scapula. Identify the levator scapulae and lift the distal edge to identify the cranial border of the rhomboid major muscle. Here, the dorsal scapular nerve rides around the medial upper corner of the scapula, about 1.5 cm from the medial edge,[198] and beneath the tight

fascial edge of the rhomboids. The fascial edge is released and the patient is asked to actively move the scapula to ensure proper nerve gliding.

Future directions

Since electrodiagnostics are frequently inaccurate in diagnosing entrapments other than carpal or cubital tunnel syndromes, a combination of thorough clinical examination (manual muscle testing, SCT, and provocative tests) must be the foundation for a proper diagnosis and treatment. This chapter on nerve compressions has focused on recognizing the importance of clinical examination skills in patients with upper extremity pain and/or dysfunctions. One future challenge lies in constructing clinical studies reporting on the efficacy of various diagnostic algorithms and subsequent conservative and/or surgical treatments.

The advent of higher-resolution MRIs (8-Tesla) and refined ultrasound techniques will likely become increasingly important diagnostic tools in nerve entrapment syndromes, with a higher accuracy to find fatty muscle infiltrations due to discreet denervations, changes in nerve echogenicity and the presence of possible externally compressing factors.

The area of nerve compression syndromes offers the curious researcher and clinician ample opportunity to investigate, explore, and discover. As the 1906 Nobel Prize winner Dr. Santiago Ramón y Cajal wrote, "Even granting that the genius subjected to the test of critical inspection emerges free from all error, we should consider that everything he has discovered in a given domain is almost nothing in comparison with what is left to be discovered."

Congenital hand I: Embryology, classification, and principles

Michael Tonkin and Kerby Oberg

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Consistency of terminology is necessary for optimal communication.
- Limb outgrowth and patterning are controlled by specific signaling centers within the developing limb bud via the activation and interaction of molecular messengers.
- Anomalies of limb development result from:
  - spontaneous mutation of genetic material
  - inheritance of abnormal genes
  - subtle or gross insult to the limb bud.
- The anomaly may be isolated or syndromic.
- The International Federation of Societies for Surgery of the Hand (IFSSH) has recommended that the Swanson classification (previously approved by the IFSSH) be replaced by the Oberg, Manske, Tonkin (OMT) classification, which separates malformations from deformations and dysplasias. Malformations are further sub-divided according to the axis of limb development that is primarily involved and whether the insult affects the whole of the upper limb or the hand plate only. This classification incorporates our increasing understanding of the molecular basis of limb development.
- Assessment and treatment are specific for each child and family but are based on a detailed understanding of the processes of limb development, the psychological and physical effects of limb anomalies, and simple surgical principles.

Introduction

Limb development

The upper limb bud appears during the fourth week of development as an outgrowth on the sides of the embryo. Cells of the somatic lateral plate mesoderm form the skeletal framework of the limb, while mesoderm from the somite migrates in to form the muscular component and contributes to the limb's vascular network. Over the next 4 weeks, growth and differentiation transform the limb bud into an elegant asymmetric organ that is one of the defining features of the human species. The limb bud growth and differentiation are under the control of signaling centers, specialized areas within the limb that dictate, in concert, the appropriate sequential events of development.

The establishment of signaling centers and their subsequent behavior are under genetic control. The genes and the morphogens (proteins) they encode control the process of limb growth and differentiation and act as messengers between signaling centers and developing cells.

As knowledge of the process of limb development becomes more sophisticated, an understanding of the causation of limb anomalies becomes clearer.

Genetic mutations can disrupt the molecular function of a number of proteins orchestrating limb development, including secreted proteins (ligands), ligand receptors, and transcription factors. The mutation may be inherited or may arise spontaneously. Environmental factors, such as thalidomide, which resulted in an epidemic of limb malformations during the 1960s, radiation, nutritional defects, and infections may affect the molecular pathways of development or be responsible for a more gross insult resulting in tissue hemorrhage and/or necrosis. For example, if such direct damage occurs obliterating the apical ectodermal ridge (AER), an important signaling center that directs limb outgrowth, transverse truncation will result.

Classification

Congenital anomalies in the hand demand a reproducible and consistent terminology, a universal language that allows discussion of complex clinical entities, indications for treatment, and comparisons of results.

Swanson's classification was adopted by the IFSSH in 1976 as the standard system by which congenital hand anomalies were described.[1] It is derived from ideas existing in the 1960s regarding limb embryology and is largely based on morphological appearance. Knight and Kay[2] have presented an extended version, attempting to incorporate a list of all

congenital anomalies. Regrettably, this classification is intrinsically unsuited to alterations based on causation and etiology at a molecular level.

In 2014, the IFSSH Scientific Committee for Congenital Conditions recommended that the Oberg, Manske, Tonkin (OMT) classification replace that of Swanson.[3] This system utilizes dysmorphological terminology, separating congenital upper limb anomalies into *malformations*, *deformations*, and *dysplasias*. Malformations, the majority of encountered anomalies, are further sub-divided according to which axis of formation and differentiation is primarily affected and whether the consequence affects primarily the hand plate alone or the whole upper limb. It is probable that the causation of some anomalies will confound our attempts to assign a specific site in the molecular pathway and/or the anatomical site in the limb bud and the time at which the aberration occurs. However, the OMT system would appear to be a more logical approach to classification.

Assessment and principles of treatment

It is clear that the terminology applied to congenital anomalies should reflect a language common to, and understood by, the geneticist, the anatomist, the pathologist, and the surgeon. For this reason, these authors have chosen to link the terminology of embryology of the limb bud at the molecular level, the terminology of dysmorphology, and the terminology of classification. This consistency would appear to provide less controversy in a rapidly changing field of knowledge. Furthermore, such an approach is of benefit when attempting to explain to parents how the limb normally forms and how any particular anomaly may occur. This process plays a vital role in the assessment of any specific anomaly and leads to a sensible plan of management.

Limb development (embryology)

Overview of upper limb morphogenesis

Around day 26 (4 weeks) after fertilization (Carnegie stage 12), the upper limb bud appears as an oblong ventrolateral bulge on the body wall between somites 9–12 (C5–8) (Fig. 25.1).[4] The emerging limb bud is composed of somatic lateral plate mesoderm covered by ectoderm. Subsequent limb bud growth and differentiation are described in terms of three coordinate axes: proximodistal, dorsoventral (dorsovolar), and anteroposterior (or radioulnar) (Fig. 25.2), each controlled by distinctive regions – signaling centers.

The ectoderm overlying the distal edge of the limb bud at the dorsovolar boundary thickens and forms a distinct ridge of stratified ectoderm, the AER.[5] The thickened AER is critical for proximodistal outgrowth and also adds mechanical rigidity to the distal rim of the limb bud, flattening it along the dorsovolar axis. Excision of the AER in chicken embryo limb buds prevents further proximodistal outgrowth and results in limb truncation.[6] Underlying the AER, the distal undifferentiated mesoderm has been termed the progress zone (PZ). Cells in the PZ ultimately differentiate into specific cell types and are directed to specific positions within the limb.

The dorsal ectoderm is a critical signaling center for directing formation of dorsal and volar characteristics of the limb.

Table 25.1 Timing of hand formation

Time after fertilization	Hand development
27 days	Development of arm bud
28–30 days	Further development of arm bud
34–36 days	Elongation of arm bud
34–38 days	Formation of hand paddle
38–40 days	Early separation of digits
44–46 days	Digits separated
Week 9–10	Formation of fingernails begins

(Reproduced from Gupta A, Kay SPJ, Scheker LR (eds). *The Growing Hand: Diagnosis and Management of the Upper Extremity in Children.* London: CV Mosby; 2000:25.)

Excision and rotation of dorsal ectoderm cause the formation of dorsal structures on the limb ventral surface.[7] Another collection of mesodermal cells at the distal ulnar (posterior) margin is called the zone of polarizing activity (ZPA). Although not morphologically distinct, these cells direct radioulnar patterning and coordinate asymmetric limb patterning with the other signaling centers during development. Removal of the ZPA in animal models leads to loss of the ulna and the ulnar digits.[8] Conversely, transplantation of these cells to the anterior (radial) aspect of limb buds of chicken embryos will result in formation of a mirrored complement of ulnar digits radially.[9]

Over the next week, the limb bud expands and elongates, particularly along the proximodistal axis (Table 25.1). By day 33 of development (Carnegie stage 14), differential growth and programmed cell death transform the distal portion into a paddle-shaped hand plate. There is also progressive mesodermal condensation along the proximodistal axis, forming a tripartite skeleton composed of a proximal section, the stylopod (humerus), a middle section, the zeugopod (radius and ulna), and a distal section, the autopod (hand). The joints become fully evident about day 51 (Carnegie stage 20) when the elbow and wrist joints flex, and by day 56 (end of the eighth week, Carnegie stage 23), the major morphologic features of the limb are complete (see Fig. 25.1).

The molecular control of limb outgrowth and patterning

During early embryonic development, Hox transcription factors set up a segmental body plan along the cranial–caudal axis.[10] By the fourth week of development the presumptive upper limb fields are established, triggering the expression of Tbx5, which initiates limb formation and determines forelimb identity.[11] Tbx5 upregulates Fgf10 in the limb mesoderm and Wnt3 in the distal ectoderm.[12,13] Mesodermal Fgf10, in conjunction with ectodermal Wnt3, TP63, Dlx5/6, and radical fringe (R-fng), transform the distal ectodermal at the dorsovolar boundary into the thickened AER.[14–17] Formation of the AER initiates the expression of AER-related Fgf proteins (including Fgf2/4/8/9/17),[18–19] which, in turn, act on the mesoderm just underneath the AER to sustain Wnts and Fgf10 expression in the PZ. This reciprocal loop of ectodermal and mesodermal Fgf/Wnt proteins promotes progressive proximodistal outgrowth[20,21] (Fig. 25.3). In the absence of Wnt3 or

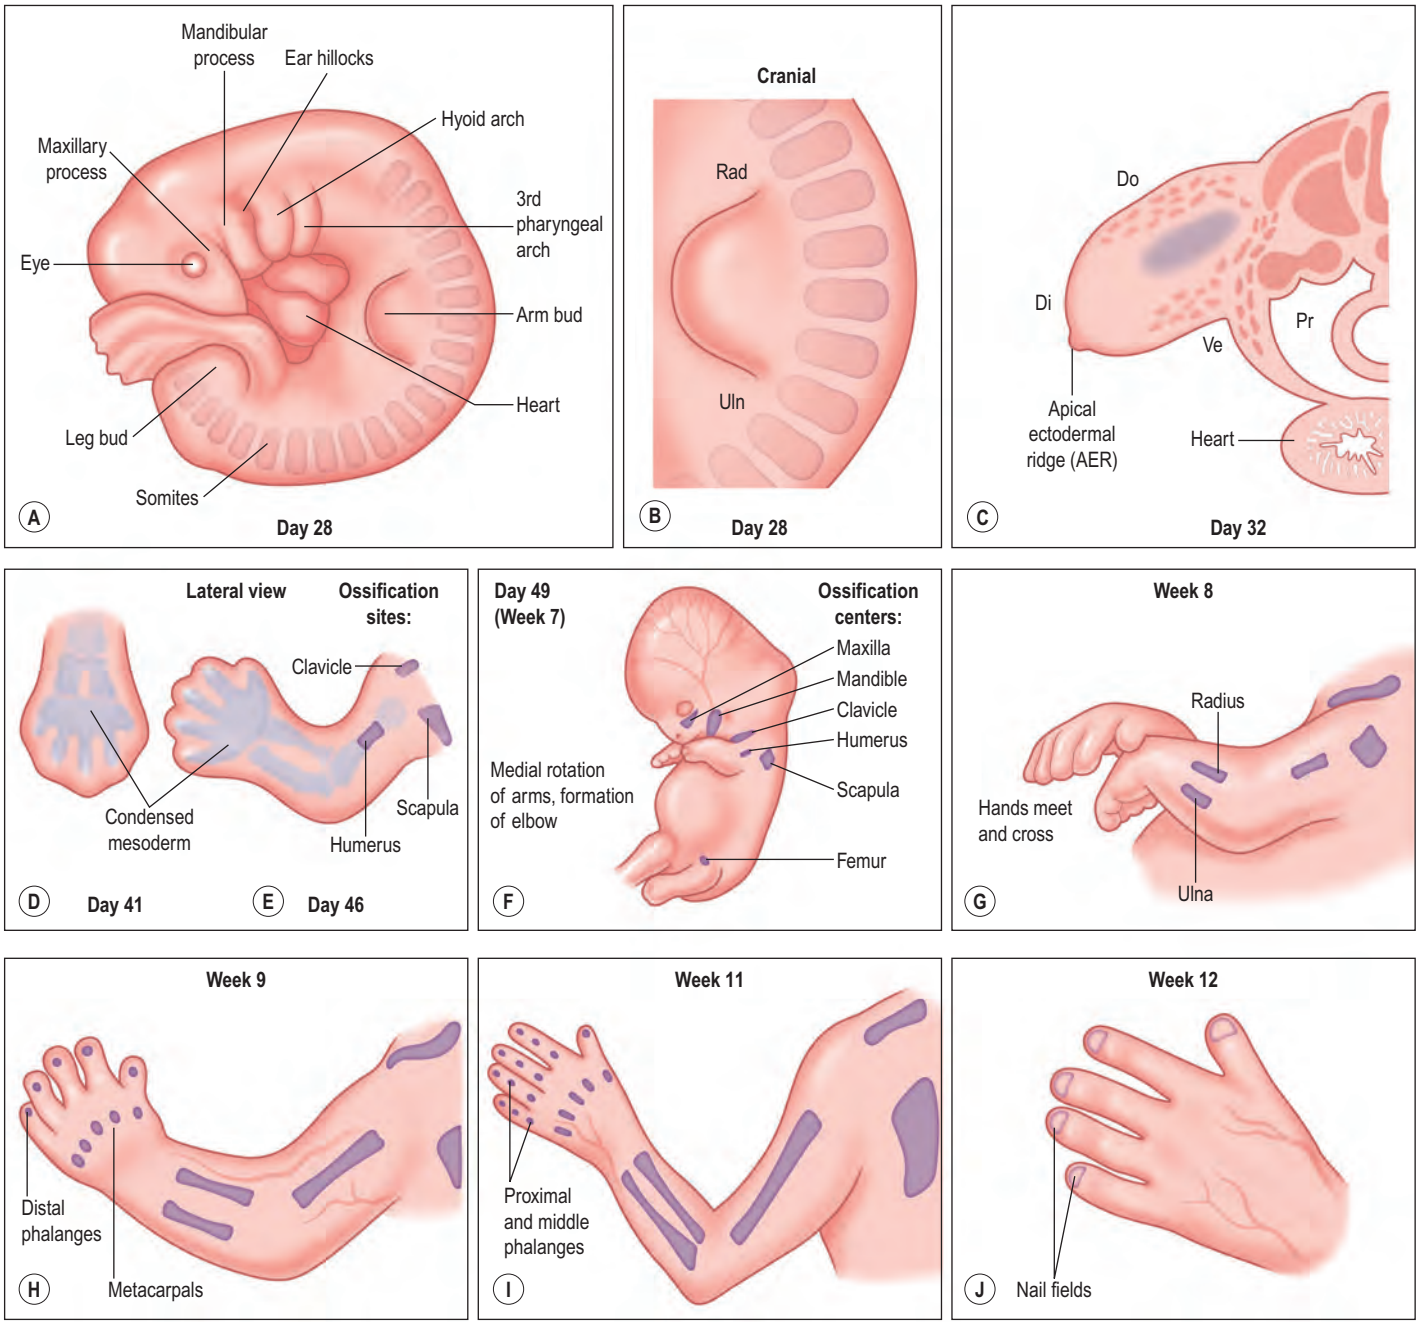

Fig. 25.1 Upper limb and hand development. **(A)** Human embryo at Carnegie stage 13 (about 28 days of development), showing early limb buds. **(B)** Close-up dorsal view of the arm bud. The anterior or radial (Rad) aspect is cranial and the posterior or ulnar (Uln) aspect is caudal. **(C)** Cross-section through an upper limb bud at 32 days of development (Carnegie stage 14), showing dorsal (Do)–ventral (Ve) limb bud flattening and the thickened apical ectodermal ridge at the distal tip of the limb bud (that runs along the dorsal–ventral border from anterior to posterior). Pr, proximal; Di, distal. **(D)** The hand plate at 41 days of development (Carnegie stage 17). The scalloped edge conforms to the condensing digital mesenchyme. **(E)** Limb at 46 days of development (Carnegie stage 19). Separate fingers are evident. The proximal limb skeleton is well developed and ossification has begun in the humerus and shoulder girdle. **(F)** The embryo at 49 days of development (Carnegie stage 20), showing ossification centers in the upper limb, lower limb, and face. Note that upper limb development is more advanced than lower limb development. **(G)** Upper limbs at week 8 (Carnegie stage 22). The fingers are completely separate and ossification centers have developed in the forearm, i.e., radius and ulna. **(H)** The upper limb at week 9 (Carnegie stage 23). Metacarpal and distal phalangeal ossification has begun. **(I)** The upper limb at week 11. Ossification in proximal and middle phalanges is now evident in addition to distal phalanges and metacarpals. **(J)** The hand at week 12, showing developing nail fields (nails become visible during week 16). *(Portions redrawn from England MA.* A Colour Atlas of Life Before Birth*. London: Year Book Medical Publications; 1983.)*

Fgf10, limbs fail to develop and tetra-amelia results.[22,23] Application of Fgfs to the distal chick limb bud after AER removal will return proximodistal limb outgrowth.[19] Within the PZ, mesodermal cells persist in an undifferentiated or receptive state, allowing the signaling centers to direct their fates.

The ZPA in the posterior (ulnar) limb mesoderm secretes a potent morphogen, sonic hedgehog (Shh), that regulates radioulnar patterning[24] (see Fig. 25.3). Shh induces posterior (ulnar) proliferation of the limb bud expanding its width.[25,26] Moreover, Shh posteriorizes (ulnarizes) the developing

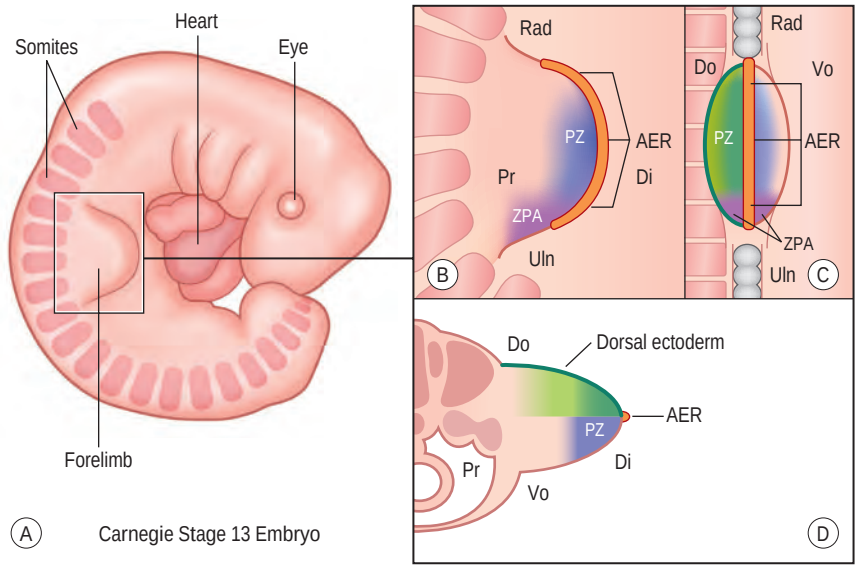

Fig. 25.2 Limb bud coordinate axes and signaling centers: **(A)** The forelimb (boxed region) of a Carnegie stage 13 embryo depicting the three coordinate axes – each with its own signaling center: the apical ectodermal ridge (AER) coordinating proximodistal (Pr–Di) outgrowth and differentiation; dorsovolar (Do–Vo) asymmetry is regulated by dorsal ectoderm; radioulnar asymmetry is controlled by the zone of polarizing activity (ZPA). Within the progress zone (PZ) the fate of mesodermal cells is determined by these signaling centers. The axes and signaling centers are shown in three different orientations: **(B)** dorsal view, **(C)** lateral, end-on view, and **(D)** axial cross-section. *(Modified from Oberg KC, Greer LF, Naruse T. Embryology of the upper limb: the molecular orchestration of morphogenesis.* Handchir Mikrochir Plast Chir. *2004;36:98–107.)*

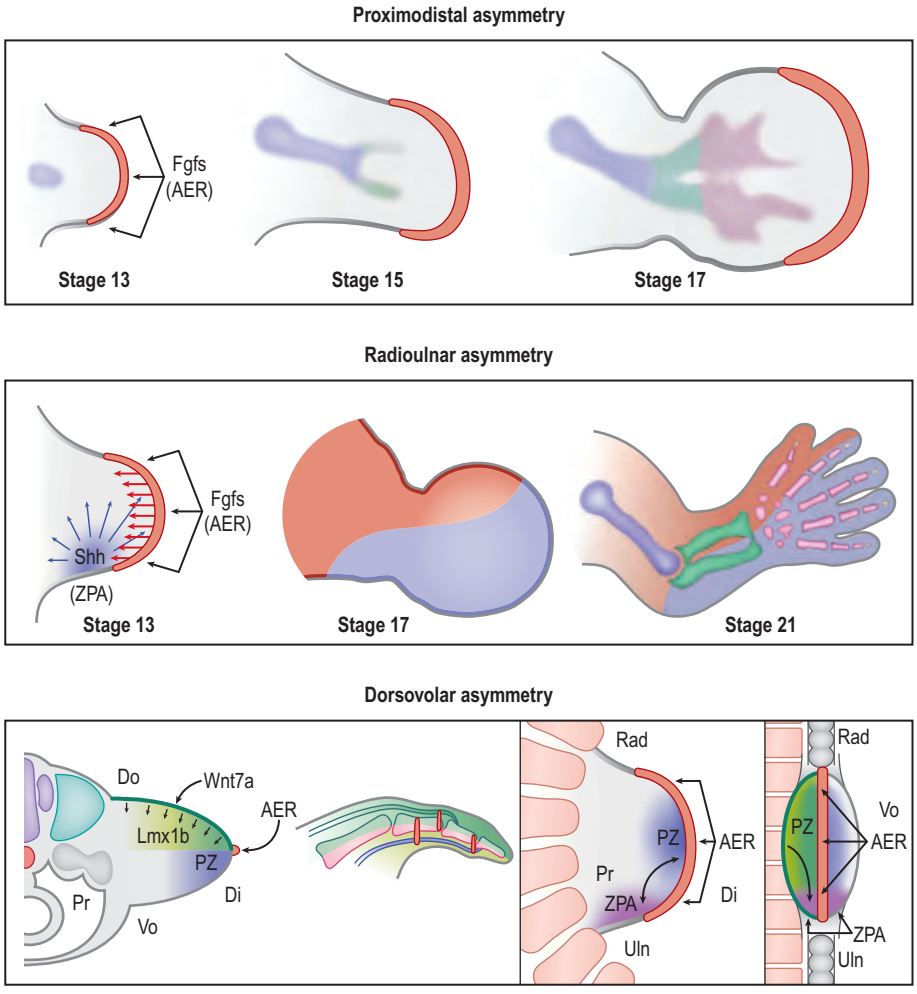

Fig. 25.3 Morphologic impact of signaling centers. Upper panel: Role of apical ectodermal ridge (AER)-related Fgfs (orange) on skeletal outgrowth (humerus, blue; radius and ulna, green; hand, magenta). Middle panel: Role of Shh secretion from the zone of polarizing activity (ZPA): influence on the forearm and digits (depicted in purple). Lower left panel: Role of Wnt7a (medium green) and Lmx1b (light green), from the dorsal ectoderm and mesoderm respectively, in tendon and ligament formation in a digit. Do, dorsal; Vo, volar; Pr, proximal; Di, distal; PZ, progress zone. Lower right panel: Illustration depicting communication between signaling centers – reciprocal Shh–Fgf loop (black bidirectional arrow). Wnt7a influence on Shh expression (black unidirectional arrow). Rad, Radial; Uln, ulnar.

forearm and defines the identity of the ulnar four digits. In a naturally occurring chicken mutant, limb-specific Shh expression is lacking and the upper limbs develop without ulnas and without digits.[27] Application of exogenous Shh to the posterior (ulnar) aspect of the limb bud can fully recover normal limb morphology. Furthermore, application of Shh to the anterior margin produces mirrored duplication of ulnar digits radially.[24]

The AER and the ZPA are also closely linked by a reciprocal feedback loop that maintains Shh expression at the distal posterior (ulnar) border of the limb bud adjacent to the AER during progressive outgrowth.[28–30] Removal of the AER causes regression of Shh expression and ablation of the ZPA induces a loss of Fgf signaling.[29] Secretion of Wnt7a from the dorsal ectoderm induces the homeodomain transcription factor Lmx1b in the underlying mesoderm and asymmetrically dorsalizes the developing limb[31,32] (see Fig. 25.3). Wnt7a also contributes to the maintenance of Shh secretion from the ZPA,[33] linking the dorsovolar and radioulnar axes. Removal of dorsal ectoderm reduces Shh expression and disrupts posterior (ulnar) patterning.[34] Thus, Shh plays a pivotal role during limb development linking dorsovolar, proximodistal, and radioulnar axes during outgrowth.[34]

Around the end of the fifth week of development, the hand plate becomes visible. Current data suggest that digit number is established by an intrinsic Turing-type pattern generator within the hand plate using reciprocal activator (Bmps) and inhibitor (Wnt) interactions to define the alternating digit and interdigit pattern[35,36] (Fig. 25.4). Interplay between Hox transcription factors (particularly Hoxd9–13 and Hoxa9–13) and the Shh/Gli3 pathway subsequently establishes digit morphology[37–40] (Fig. 25.5). Shh also induces an ulnar to radial (posterior to anterior) gradient that appears to involve Bmps in at least two roles in the formation and differentiation of digits. First, Bmps induce programmed cell death or apoptosis via discrete interdigital signaling centers, in part by repressing Fgf expression in the overlying AER.[41–43] In addition, Bmps play a role in completing digital identity via the phalanx-forming region, a region overlying the distal digital anlagen that regulates Sox9 expression and chondrogenesis.[44] Applying a Bmp-laden bead or transplanting Bmp-expressing interdigital tissue from the third interdigital space to the second transforms the second digit into a third digit.[41] The phalanx-forming region also maintains digit-associated Fgf expression in the overlying AER for continued digital outgrowth.[44] With regression of the phalanx-forming region and loss of overlying Fgf, the terminal phalanges form at the distal tip of each digit, invoking a unique mechanism of ossification that includes membranous ossification in addition to anlagen formation.[45,46] The terminal phalanx is also demarcated by persistent expression of Msx1 in the mesoderm, and Sp8 in the ectoderm.[47]

The development/differentiation of specific tissues

Limb bud formation and the progressive morphologic changes evident externally are accompanied by differentiation of various tissues internally that are regulated by the coordinate signaling centers described above. Differentiation of these tissues is coincident, but will be discussed separately to add clarity and to relate timing of formation to tissue-specific malformations.

Limb vasculature

As the limb bud grows, nutrients and oxygen are needed to maintain rapid cell proliferation and the secretory activity of

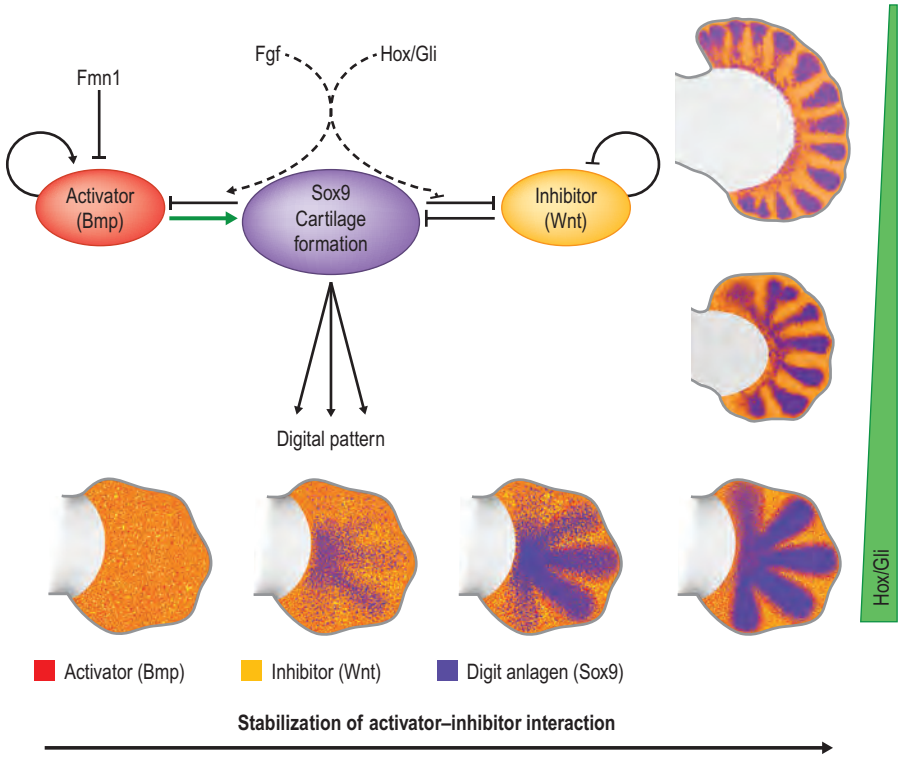

Fig. 25.4 Determining the number of digits. An intrinsic Turing-like patterning mechanism for digit formation has been proposed using computational modeling and experimental evidence.[35,36] In the upper left-hand corner is a diagram of a diffusion-driven instability model proposed by Turing. In the limb, evidence suggests that Bmp (red) is the activator while Wnt (yellow) is the inhibitor of diffusion-driven instability. Both factors are regulating the expression of Sox9 (blue), the precursor of cartilage formation. Fgfs and the Hox/Gli pathway modulate the relative influence of the activator and inhibitor. Fgfs from the apical ectodermal ridge (AER) determine digit length and in concert with the distal Hox/Gli pathway limit digit number (green bar/gradient on the right). In addition, Fmn1 restricts Bmp expression and mutations in Fmn1 cause increased levels of Bmp with disruption of normal forearm (radioulnar synostosis) and hand (oligosyndactyly) patterning.[143,144] The bottom of the illustration has a series of hand plates (note hand plate development remains static in this illustration to aid in illustrating features of the model) that show the progression from fluctuating activator-inhibitor interactions (noise) to a stabilized 5-digit pattern. On the right, progressive loss of digit suppressing HOX/GLI transcription factors (green bar) causes an increase in the number of digits patterned by the autonomous patterning mechanism. *(Modified from Oberg KC, Ros MA, Goldfarb CA. New Insights on upper limb development: digitizing the hand.* IFSSH Ezine. *2014;4(2):16–22.)*

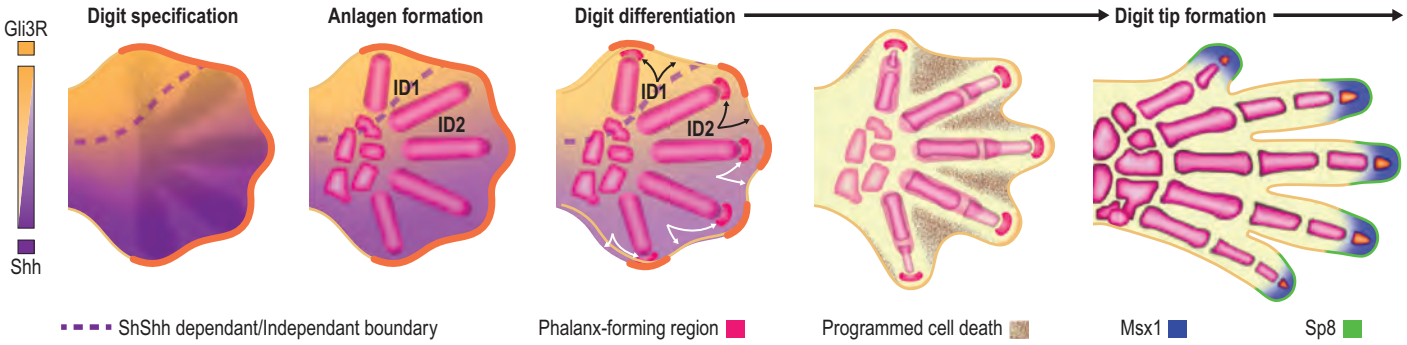

Fig. 25.5 Hand plate development. After the digit number has been established by intrinsic Turing patterning, the Shh pathway (with Gli3 repressor counter gradients) defines dependent/independent domains (boundaries indicated by dashed line) that determine digit morphologies. Interdigital mesoderm (ID1–ID5) regulates regression of the overlying apical ectodermal ridge (AER; orange) and digit morphologies of the adjacent anterior condensing digit via the phalanx-forming region (PFR; magenta) capping the distal tip of each anlagen. The PFR, in concert with the AER, determines phalanx size, length and joint position. The interdigital tissue subsequently undergoes Bmp-mediated programmed cell death (speckled regions). As the AER overlying the digit regresses, the distal or ungual phalanx forms and is demarcated by expression of mesodermal Msx1 (blue) and ectodermal Sp8 (green). *(Image adapted from Oberg KC, Feestra JM, Manske PR, et al. Developmental biology and classification of congenital anomalies of the hand and upper extremity.* J Hand Surg [Am]. *2010;35:2066–2076.)*

the signaling centers. Induction of a primitive vascular system in the limb begins with transformation of mesoderm into angioblasts, cells that express the basic helix–loop–helix transcription factor Tal-1 and the vascular endothelial growth factor (VEGF) receptor Flk1.[48] A dense meshwork of primitive vascular channels forms *de novo* from angioblasts in the limb mesoderm.[49,50] Angioblasts formed in nearby somites also migrate into the limb bud and contribute to the formation of new limb vessels through continued vasculogenesis.[51] As angioblasts aggregate, differentiate into endothelium, and form primitive vascular tubes, new vascular markers emerge. Flk1 persists to allow further remodeling by VEGF, Tal-1 diminishes and VE-cadherin, a cell–cell adhesion molecule, is upregulated.

The primitive vascular network undergoes significant remodeling as the limb develops. By stage 13, the vascular channels coalesce proximally to form a central artery (subclavian) that connects to the dorsal aorta via the seventh intersegmental artery[52] and two peripheral veins form that drain into the posterior cardinal system.[50] In addition to vasculogenesis, angiogenesis, i.e., vessel sprouting from a preformed vessel, also contributes to the definitive architecture of the limb vasculature.

Construction of the vascular pattern is under the direction of the coordinate signaling centers and involves the regulation of specific VEGF family members and VEGFR3 receptors.[52–54] The final vascular pattern progresses from proximal to distal (Fig. 25.6) – with formation of the axillary artery by stage 17 and the brachial and major forelimb branches by stage 19. The median artery is prominent in the forearm.[55] Distally the capillary plexus persists. Ulnar differentiation precedes radial differentiation and is evident distally by the radial artery merging with an extensive primitive capillary plexus radially, while the ulnar side of the axis is already forming the palmar arch which communicates with the ulnar associated capillary plexus.[56] The median and interosseous arteries decrease in size. The median artery degenerates, providing blood supply to the median nerve only.[55]

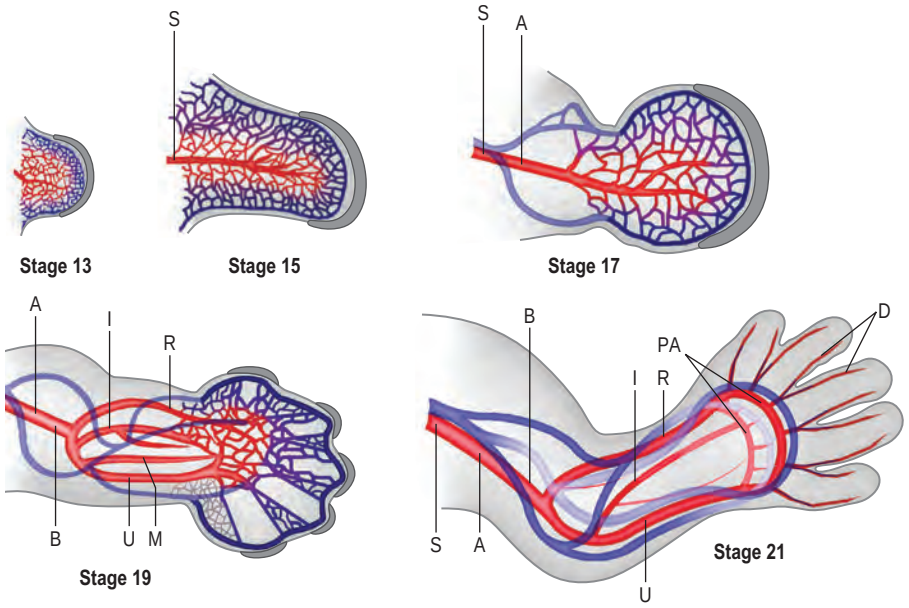

Fig. 25.6 Vasculogenesis of the developing upper limb. Progressive vascular remodeling from Carnegie stage 13 through 21, showing: subclavian artery (S), axillary (A), brachial (B), median (M), radial (R), ulnar (U), interosseous (i), palmar arches (PA), and digital (D) arteries (red). Note the primitive vascular plexuses persist distally on the radial aspect at stage 19. The veins have also remodeled during this period, from a distal sinus and anterior (radial) and posterior (ulnar) marginal veins, into the distinctive veins of the limb (illustrated in blue).

The vascular network must include arteries, capillaries, and veins. The diameter of each is dictated by blood flow, blood pressure, shear stress, and the accumulation of vascular smooth muscle around the vessel.[49] Formation of vascular smooth muscle around limb arteries lags behind vessel formation by about 2 days. It is unclear whether these muscle cells are derived from the endothelial cells or are condensations of the surrounding mesoderm. Furthermore, the mechanism underlying differential smooth-muscle accumulation in arteries and veins is unknown. Arteries are also differentiated from veins by the expression of Ephrin B2, a membrane-bound ligand, while the Eph-B4 receptor highlights veins. Presumptive capillaries will be negative to both Ephrin B2 and the Eph-B4 receptor.

By stage 21, the major vessel architecture is complete. The majority of vascular anomalies arise between stages 17 and 21, i.e., between days 41 and 52 or largely within the seventh and early eighth week of development. Lymphatics follow a similar course, albeit less well delineated, and are also composed of angioblasts that migrate into the limb from somitic mesoderm.[51] A defining molecular difference in lymphatic vessels is the coexpression of PROX-1 and LYVF-1.[57]

Skeletogenesis

Under the influence of the limb signaling centers, Sox9, a high-mobility group transcription factor, is upregulated in a targeted population of limb mesoderm.[58] Sox9 transforms these cells into chondrogenic precursors and induces condensation, the first step in limb skeletogenesis.[59,60] Chondrogenesis occurs in a proximal to distal progression (Fig. 25.7). The expression of Sox5 and Sox6 is required for further differentiation of chondrogenic precursors into chondrocytes to form cartilage anlagen.[61]

At precise locations within the forming skeletal anlagen, synovial joints form. Hoxa transcription factors (Hoxa9–13) exhibit expression patterns along the proximodistal axis that correlate with skeletal segmentation.[61] In addition, several molecules are known to participate in the process of joint formation, including Wnt14 and Gdf5. The first morphologic evidence of joint formation is the compact cellular condensation called the interzone that expresses Wnt14.[62] In addition, Gdf5 is induced in the proximal portion of the interzone, covering the distal end of the proximal anlagen.[63,64] The central region of the interzone begins to expand, accumulates hyaluronan, and becomes hypocellular in a process termed cavitation.[65,66] The two cellular regions of the interzone begin to differentiate into the opposing articular cartilage surfaces. Patterning signals and movement work in concert to shape the joint into its definitive morphology[64] (Fig. 25.8). Mesoderm surrounding the developing joint condenses to form the joint capsule.[67]

Endochondral ossification converts the cartilage anlagen into the skeletal framework of the growing limb. This process is under precise regulation and involves Runx2, Twist1, Fgfs, Indian hedgehog (Ihh), and vascular endothelial growth factors (Vegfs).[60] Chondrocytes are induced to proliferate, undergo hypertrophy, and then die, leaving an extracellular cartilage matrix. This matrix is subsequently invaded by blood vessels, osteoclasts, and differentiating osteoblasts. Osteoblast differentiation is also under the control of Runx2 and Osterix (Osx), a bone-specific transcription factor.[68] Ossification begins within the diaphysis of anlagen at the primary ossification center during early fetal development. Subsequently, vascular invasion of the proximal epiphysis occurs, followed by the distal epiphysis forming secondary ossification centers later in development. Each metacarpal and digital phalanx has two ossification centers, a primary center within the diaphysis and a single secondary center that develops postnatally.

Bony malformations are most likely to involve the disruption of Sox9 and the progressive proximal to distal anlagen formation, i.e., radiohumeral synostosis would occur earlier in development than polydactyly or syndactyly.

Myogenesis

Muscular development of the upper limb is a coordinated effort between segment-specific tendon primordium, migrating myocytes, and migrating motor neurons.[69,70] There are

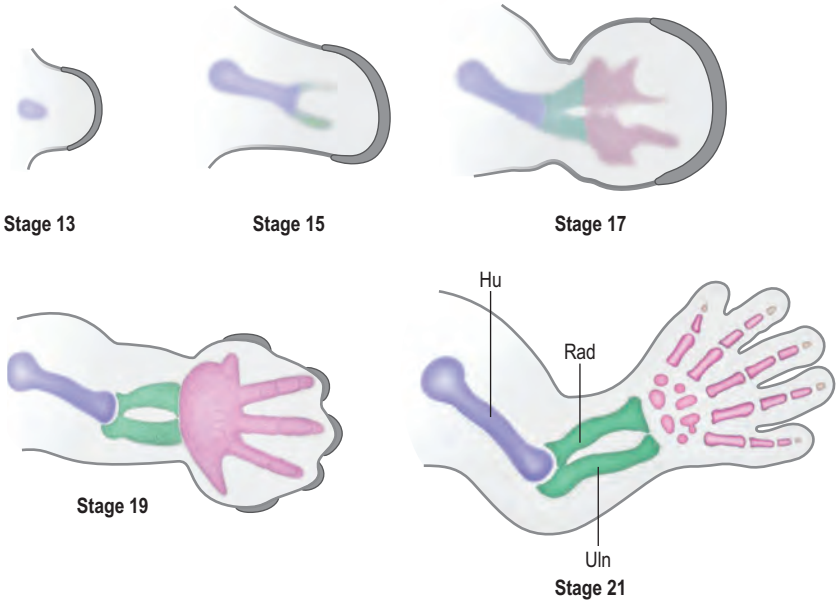

Fig. 25.7 Skeletogenesis of the developing upper limb. By Carnegie stage 17 there is partial rotation of the humerus (Hu, blue) at the shoulder and the elbow joint is starting to form. Radius (Rad, green); ulna (Uln, green); hand, magenta.

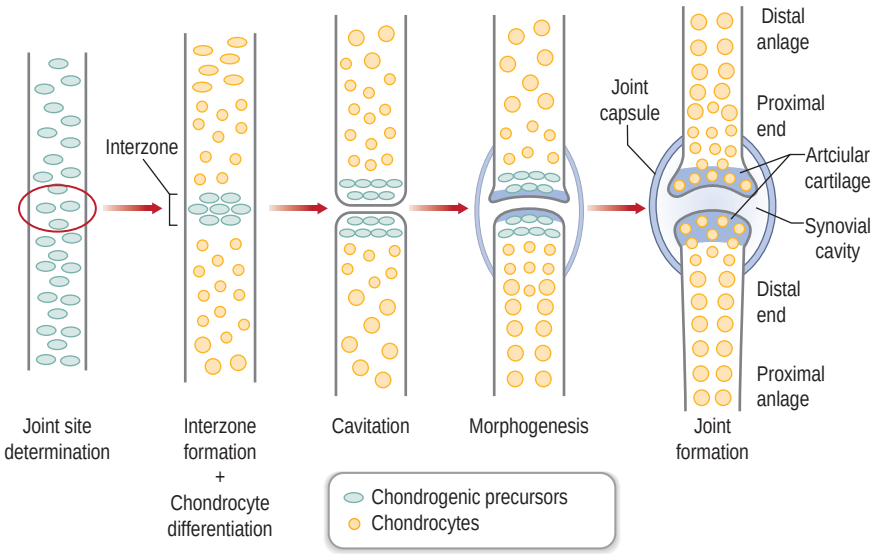

Fig. 25.8 Joint formation. *(Modified from Pacifici M, Koyama E, Iwamoto M. Mechanisms of synovial joint and articular cartilage formation: recent advances, but many lingering mysteries.* Birth Defects Res C Embryo Today. *2005;75:237–248.)*

three phases to myogenesis.[71] Embryonic myogenesis establishes the primary myotubes and the basic muscle layout. Later, a second wave of myogenesis occurs with secondary myofibers surrounding primary myofibers and contributing to the bulk of the muscle mass present at birth. Finally, satellite cells that take up residence in the basal lamina surrounding myofibers will contribute to postnatal growth and muscle regeneration.[72]

During early limb bud formation, limb mesoderm condenses to form the proximal tendon primordium (PTP), establishing a target and an initial scaffold for migration of myocytes.[69] Myocyte precursors of the limb arise from the dorsolateral aspect of associated somites (the dermomyotome subdivision) and express the Pax3 transcription factor. Muscle precursors for the limb and body wall express c-Met, a surface receptor that is modulated by scatter factor initially emanating from the lateral plate mesoderm and then later from other sites, including the PZ. Scatter factor acts as a chemoattractant to promote myocyte precursor migration. A population of the myocyte precursors further differentiates into limb-specific precursors, demarcated by Lbx1 expression[73] (Fig. 25.9).

During embryonic myogenesis, limb-specific myocytes migrate into the proximal limb bud, initially as dorsal and ventral masses (Fig. 25.9). Continued migration, however, is not haphazard; rather, myocyte precursors are directed into muscle anlagen by the tendon primordium, e.g., the ventral mass migrates into the biceps and brachialis under the direction of the PTP (Fig. 25.10, Carnegie stage 15). With continued proliferation and differentiation, the myocytes upregulate MyoD and Myogenin, declaring their commitment as myocytes. These myocytes will then coalesce to form fibers and

SK, Sclerotome; SF, scatter factor; Do, dorsal; Vo, volar; Pr, proximal; Di, distal; Cut, cutaneous; Proprio, proprioception.

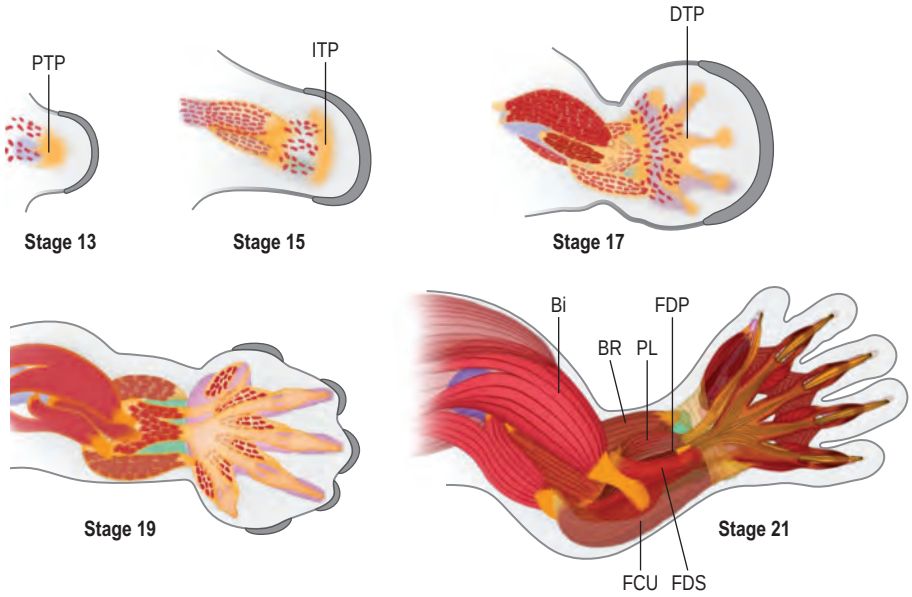

Fig. 25.10 Muscular development in the upper limb. Progressive myocyte migration and muscle formation between Carnegie stages 13 through 21 showing the ventral or volar surface. Note the resting flexed position of the upper limb in the stage 21 embryo rotates the upper arm so that the elbows shift from dorsal to caudal and the forearm rotates medially at the elbow. The palmaris longus and flexor carpi radialis are not shown. PTP, Proximal tendon primordium; ITP, intermediate tendon primordium; DTP, distal tendon primordium; Bi, biceps; Tri, triceps; B, brachialis; BR, brachioradialis; PL, flexor pollicis longus; FDP, flexor digitorum profundus; FCU, flexor carpi ulnaris; FDS, flexor digitorum superficialis.

begin to produce myosin filaments. Satellite cells, important for later growth and muscle regeneration, take up residence just under the basal lamina of the developing myofibers.[72] Concurrently, the tendon primordia further define the shape of specific muscles with discrete tendinous attachments. For example, expression of Lmx1b within the dorsal tendons directs the unique pattern of extensor attachments[74] and it is likely that each upper limb muscle is shaped by a unique combination of patterning factors.[75]

As in other aspects of upper limb development, there is progressive differentiation from proximal to distal. Thus, as the muscles of the upper arm take shape, migrating myocytes invade the forearm to associate with the PTP and a new mesodermal condensation forming at the presumptive wrist, the intermediate tendon primordium. In the forearm, the superficial muscles differentiate before the deep muscles. By Carnegie stage 17, the distal tendon primordia form and associate with migrating myocytes destined to be muscles of the hand (see Fig. 25.10). The intrinsic muscles arise from five embryonic muscle layers, which differentiate and fuse in a complex but logical manner.[76,77] Following embryonic myogenesis, a second wave of myocyte precursors migrate into the limb and coalesce around primary myofibers, forming secondary myofibers and adding bulk to the muscle masses as the fetus grows. It is during this secondary or fetal myogenesis that formation of motor endplates occurs and neuromuscular communication begins, further differentiating the forming muscle with slow and fast fiber types.[78,79]

Innervation

Outgrowth of nerves into the limb bud lags behind muscle migration (Fig. 25.11) and involves both motor and sensory neurons.[80] Motor neurons are specified early during spinal cord development by exposure to Shh, initially from the notochord and later from the floor plate of the developing

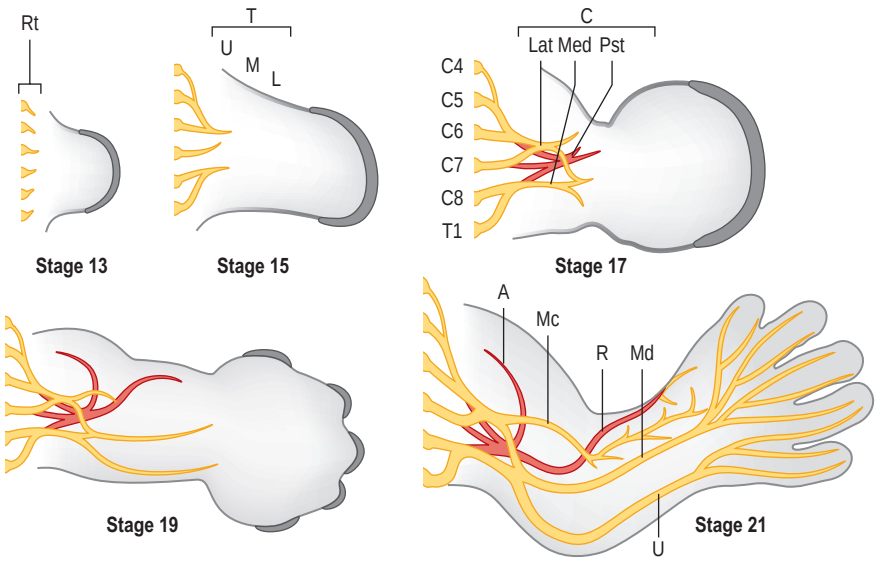

Fig. 25.11 Nervous development in the upper limb. Progressive innervation of the upper limb and formation of the brachial plexus. neural tube.[81,82] Motor neurons begin to express a combination of transcription factors (e.g., Hb9/Mnx1, Lhx3/4) that promote motor neuron migration into discrete columns within the spinal cord and direct their axons to specific muscle groups.[70] Within the limb fields (specified by Hox6 in the forelimb and Hox10 in the hindlimb), a Hox accessory factor, FoxP1, is expressed that assists in deciphering the subsequent Hox-specific code within the limb for appropriate axon targeting.[83] As the axons of the motor neurons enter the limb, those expressing Lim1 (Lhx1) will project into the dorsal Lmx1b-expressing compartment of the limb to target dorsal extensor muscle groups. The remaining axons express Isl1 and will enter the ventral compartment to target flexor muscles of the limb.

Sensory processes accompany the axons of motor neurons into the limb. The cell bodies of sensory neurons reside within the dorsal root ganglion (DRG), which is derived from neural crest cells. Specification of sensory neurons within the DRG is characterized by upregulation of neurogenin1 and 2 (Ngn1/2) and brain-specific homeobox/POU domain protein 3A (Brn3a). Furthermore, cutaneous sensory neurons also express a runt homeodomain transcription factor 1 (Runx1), while neurons involved in proprioception express Runx2.

The nerve roots, containing motor and sensory processes from C4 to T1, coalesce to form a meshwork or plexus that eventually leads to the formation of three major trunks in the upper limb – upper, middle, and lower (see Fig. 25.11, Carnegie stage 15). The segregation of dorsal and ventral processes as the nerves project into the limb divides the plexus into dorsal (posterior) and ventral (anterior) divisions, which form the posterior, lateral, and medial cords, whose names relate to their anatomic positions in the adult. The posterior cord gives rise to the axillary and radial nerves. The lateral cord gives rise to the musculocutaneous nerve and contributes to the median nerve. The medial cord forms the ulnar nerve and combines with processes from the lateral cord to form the median nerve.

The initial trajectory of processes is independent of neuromuscular communication and instead depends on a combinatorial expression of transcription factors that guide processes to targets expressing specific patterning factors within the limb.[80] However, during secondary or fetal myogenesis, patterning factors, motor endplate formation, and neuromuscular communication are required for fiber-type differentiation and survival of both muscles and nerves[70,73,78]

Anomalies of limb development and their classification

Background

Congenital anomalies in the hand and upper limb demand a reproducible and consistent terminology, a universal language that allows discussion of complex clinical entities, indications for treatment, and comparisons of results. The terminology of dysmorphology offers a basis for understanding the etiology of congenital limb anomalies.[84] A *malformation* is an abnormal formation of tissue resulting from abnormal cell formation. *Deformation* differs from a malformation as the insult is to cells that have already formed normally. It is a deformation of normal tissue. *Dysplasia* is a lack of normal organization of cells into tissue. Dysmorphologists describe a fourth term, *disruption*. As this process involves alteration of tissue that is already formed, for the purposes of classification it is reasonable to include those conditions that are considered to be disruptions alongside those considered to be deformations. Although the pathogenesis of some specific anomalies remains obscure, the concept of separating malformations, deformations, and dysplasias provides a sound structure for categorizing congenital upper limb anomalies.

Ideally, a classification of congenital hand anomalies would be based on etiology, with such a classification indicating the site in the molecular pathway and/or the anatomical site in the limb bud at which the aberration occurs, and one that also is indicative of the timing of the causative disruption.

The first classification was probably that of Isidore St. Hilaire in 1832.[85] This introduced terms such as "phocomele" (seal limb), "hemimele" (part of the limb missing), and "ectromele" (limb absence). Frantz and O'Rahilly based their classification on skeletal appearance.[86] They introduced the concepts of terminal and intercalary defects, subsequently adding the subcategories of transverse and longitudinal deficiencies and including the involvement of pre- or postaxial position within the limb.[86] Kelikian has summarized the contributions of many authors in his classic text, *Congenital Deformities of the Hand and Forearm*, but acknowledged that "We have not as yet attained enough latitude of knowing about congenital hand anomalies to formulate a comprehensive classification."[87]

Subsequently, the currently accepted surgical classification of upper limb anomalies was that based on the proposals of Swanson *et al.* in 1968,[88] refined by Swanson and colleagues in 1976[1] and 1983,[89] accepted by the IFSSH and then expanded by Knight and Kay in 2000[2] and Upton in 2006[90] to encompass all anomalies. Although this system served us well, an increasing number of surgeons, pathologists, and geneticists working in the field of congenital limb anomalies began to question the adequacy of this classification and have suggested alternative approaches.[91–94]

Problems of the Swanson classification

The Swanson classification was derived from an understanding of normal embryological development that was available in the 1960s and 1970s. The system is based upon clinical and radiological assessments that describe failures in certain anatomical structures. The two major groupGs of this classification do offer an indication of the timing of the causative insult by separating "failure of formation" from "failure of differentiation". However, formation and differentiation occur together, and it may be impossible to determine whether any specific anomaly is one or the other. Furthermore, the need to create separate groups for "duplication", "undergrowth", and "overgrowth" is illustrative of the inherent limitations of using these descriptive terms as components of a classification system, as these anomalies could also be considered as failures of formation and/or differentiation.

A system based on appearance is unable to incorporate changes based on our increasing understanding of etiology and causation at a molecular level. Attempts to do so create contradictions that are difficult to resolve. A consideration of central clefting and symbrachydactyly is illustrative. The

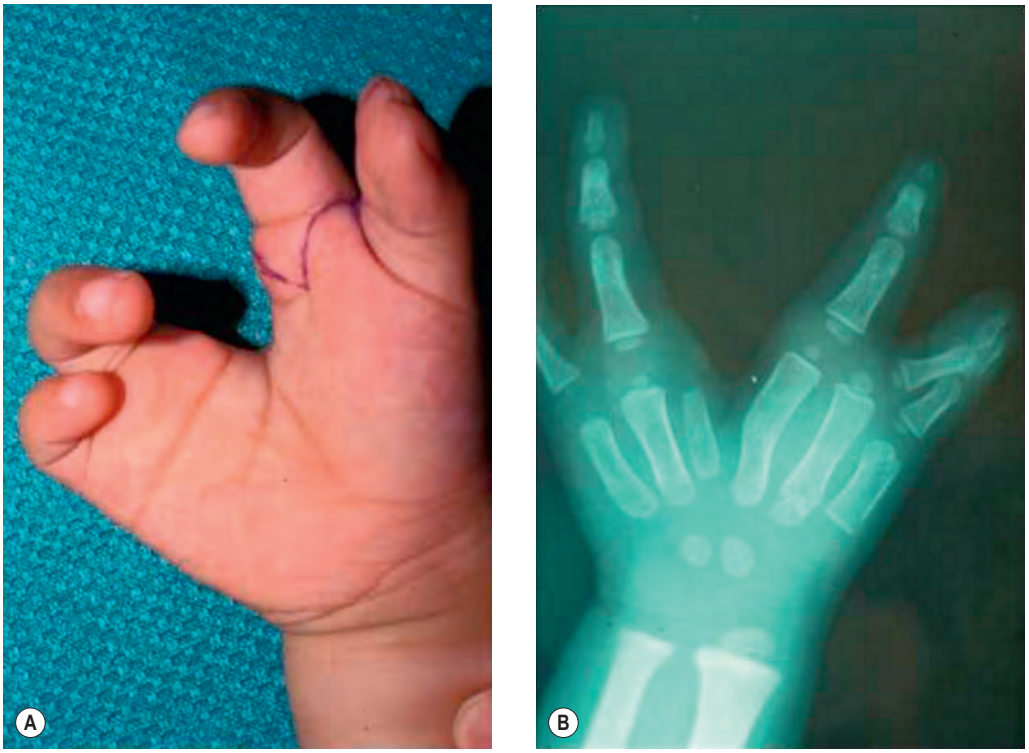

Fig. 25.12 (A,B) Clinical and radiological appearance of the association of clefting, syndactyly, and polydactyly.

Swanson classification places central clefting of the hand within the "failure of formation" group as a "central longitudinal deficiency". However, many would not view this condition as a longitudinal deficiency in the manner of radial and ulnar longitudinal deficiencies for the following reasons: the limb anomalies are usually confined to hands and feet; the terminology erroneously suggests the presence of a central axis within the developing limb; the elegant experimental work and clinical observations of Miura,[95] Ogino,[96] and others have drawn attention to the association of clefting with syndactyly and polydactyly (Fig. 25.12). Consequently, the Japanese Society for Surgery of the Hand (JSSH) introduced an extra group within the Swanson classification, this being an "abnormal induction of rays".[97] Although the introduction of this new group was attractive and well based, such modifications of the IFSSH classification introduced significant contradictions.

In this new subclassification of the JSSH, central polydactyly became an "abnormal induction of rays". However, radial and ulnar polydactyly remained under the group "duplication". Morphologically, the process of duplication, be it central, radial, or ulnar, appears to be similar (Fig. 25.13). All could be considered as an "abnormal induction of rays".

Syndactyly, be it simple or complex with phalangeal synostosis, was moved from "failure of differentiation" to "abnormal induction" (Fig. 25.14). Yet under the system proposed by the JSSH, symbrachydactyly, which has a component of syndactyly, became a "transverse failure of formation". Brachydactyly, which may include symbrachydactyly as a subcategory, remained within group 5, "undergrowth". Carpal synostoses and symphalangism remained within "failure of differentiation", although they both occur commonly in symbrachydactyly. All could be considered as an "abnormal induction of rays". Indeed, a longitudinal radial deficiency in the forearm could be considered as an abnormal induction of forearm radial structures. Whether any particular condition is a failure of formation, a failure of differentiation, or an abnormal induction is probably a dated and unhelpful concept, the differences being those of semantics.

In the search for evidence to support the suggestion that syndactyly, central polydactyly, and clefting should be classified within a single and new group, it is helpful to review the conditions with these characteristics that have a known genetic basis. Synpolydactyly (syndactyly type II) is caused by an identified gene – HoxD13 – mapped to a known chromosomal locus – 2q31–32.[98] Clefting has not been described as an association of this genetic abnormality. Central longitudinal deficiency (clefting or split-hand/foot malformation) is also inherited in an autosomal-dominant manner. Its locus is known and differs from that of the synpolydactyly gene mutation. Type I syndactyly, in which there is non-separation of digits 3 and 4 in the hands, often accompanied by non-separation of digits 2 and 3 in the feet, also involves an abnormal gene, not yet identified, but which has been mapped to yet another locus.[99] From this, it becomes apparent that a particular phenotype may result from abnormalities in several genes at different chromosomal loci in one or many of the complex pathways involved in normal hand development, rather than from one constant gene abnormality. There may also be variations in phenotypic expression of single-gene mutations. It would appear that complex interactions involving formation of extra digits and joining of those digits are associated with cleft formation.[100] However, it is less certain that an inexorable teratogenic sequence obligatorily links isolated cases of polydactyly and syndactyly with clefting.[101]

The separation of symbrachydactyly from brachydactyly, noted above, also imposes apparent contradictions. The JSSH considers symbrachydactyly to be synonymous with

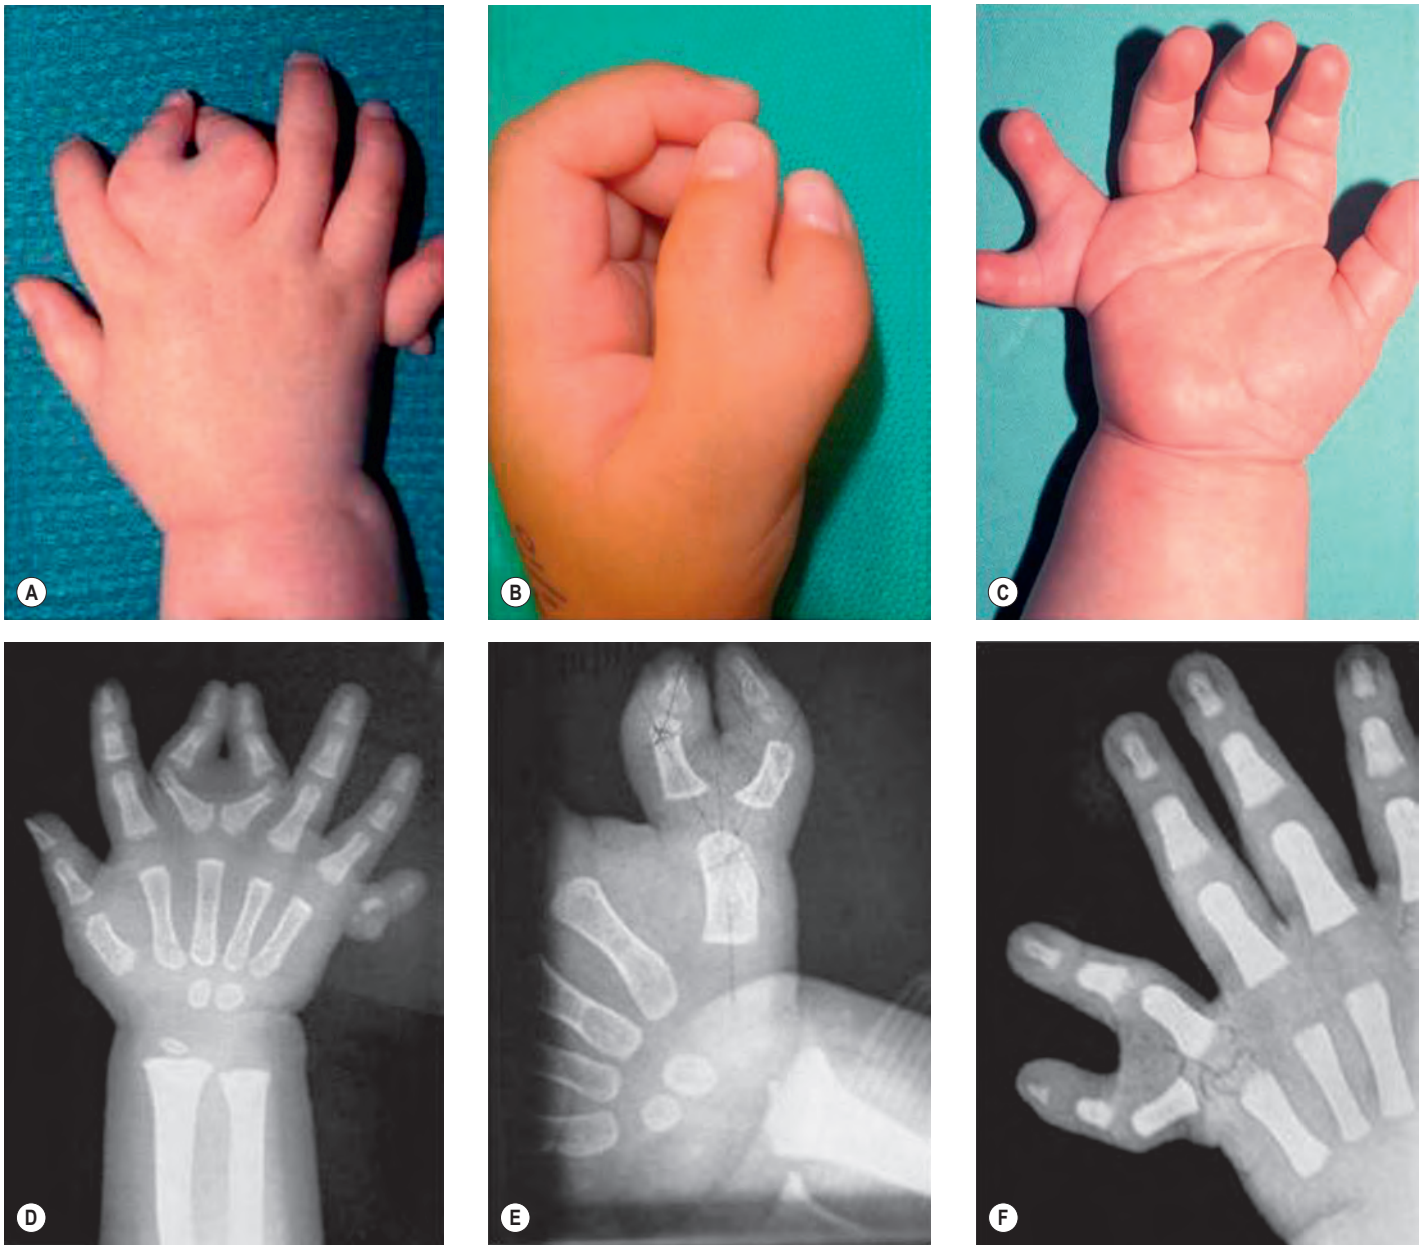

Fig. 25.13 **(A–C)** Clinical and **(D–F)** radiological appearance of central, radial, and ulnar polydactyly at the proximal phalangeal level.

"transverse failure of formation" and therefore suggested that symbrachydactyly be moved from group 5, "undergrowth", to group 1 of the Swanson classification.[97,102] This necessitates combining transverse deficiencies, in which terminal ectodermal elements are absent, with symbrachydactyly, in which the initial deficiency is middle phalangeal and, even in severe cases, terminal elements – nail and terminal phalangeal remnants – remain (Fig. 25.15). The Japanese allow for this by adding a "peripheral hypoplasia type" to the five types of the symbrachydactyly subclassification, so that all transverse deficiencies are included as a form of symbrachydactyly. Others consider this to be contradictory, believing symbrachydactyly to be a distinct entity, and to have a clear definition of intersegmental failure, which does not encompass terminal transverse deficiencies.[103] Regardless, the term "undergrowth" represents an appearance only and is unable to embrace the above concepts.

The groups documented as "duplication", "overgrowth", and "constriction ring syndrome" suffer from similar limitations. It became clear that increasing problems with the Swanson classification demanded an alternative approach.

The OMT classification

Oberg, Manske and Tonkin developed a classification system that incorporated newer knowledge of the etiology, molecular genetics, and developmental biology of congenital limb anomalies,[93,94] which was presented in the third edition of this text.[104] This system has undergone three major objective assessments, which have resulted in some modifications.[105–107]

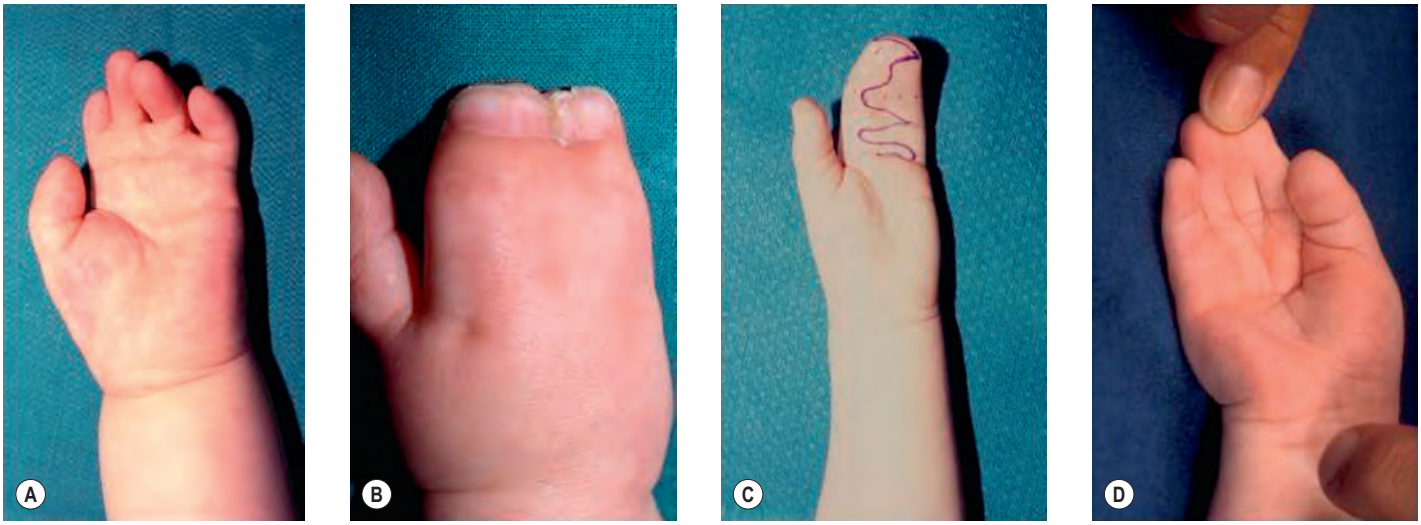

Fig. 25.14 Syndactyly in association with **(A)** symbrachydactyly short finger type; **(B)** mitten hand; **(C)** ulnar longitudinal deficiency; **(D)** Greig cephalopolysyndactyly syndrome.

The main alteration involves those conditions that were previously placed separately as not primarily involving one of the three specific axes (unspecified axis). These have been incorporated into the two main malformation subgroups – upper limb and hand plate alone. Other more minor modifications and additions are included in Table 25.2. The reviews have confirmed the efficacy of the OMT classification with good inter- and intra-observer reliability.

All anomalies are placed within one of three groups defined at the beginning of this section: group 1, malformations; group 2, deformations; and group 3, dysplasias (see Table 25.2).

The anomalies that were documented under groups 1, 2, 3, and 5 in the Swanson scheme become malformations (group 1). This classification scheme does not attempt to separate an abnormal formation from an abnormal differentiation. Malformations are subdivided according to whether the insult affects the upper limb as a whole or the hand plate alone, and whether it primarily involves one of the three axes of growth and patterning described in the preceding section of this chapter. This approach incorporates an understanding of the mechanism of insult and the site within the developing limb that is primarily affected.[93,94] Symbrachydactyly, for instance, is an example of abnormal tissue formation and differentiation within the proximal–distal axis, as are the other transverse failures of formation (Fig. 25.16). Radial longitudinal deficiency involves primarily the radial–ulnar axis (Fig. 25.17) and loss of dorsalization of hand and upper limb structures in nail–patella syndrome involves the dorsal–ventral axis. In all of these anomalies, the whole of the upper limb may be involved, e.g., thumb hypoplasia with radial aplasia. Duplications that affect the whole of the upper limb, such as ulnar dimelia, are malformations with abnormal axial patterning

Table 25.2 Modified classification of congenital anomalies of the hand and upper limb (updated January 28, 2015)

I. Malformations

A. Abnormal axis formation/differentiation – entire upper limb

1. Proximal–distal axis
   - i. Brachymelia with brachydactyly
   - ii. Symbrachydactyly
     - a) Poland syndrome
     - b) Whole limb excluding Poland syndrome
   - iii. Transverse deficiency
     - a) Amelia
     - b) Clavicular/scapular
     - c) Humeral (above elbow)
     - d) Forearm (below elbow)
     - e) Wrist (carpals absent/at level of proximal carpals/at level of distal carpals) (with forearm/arm involvement)
     - f) Metacarpal (with forearm/arm involvement)
     - g) Phalangeal (proximal/middle/distal) (with forearm/arm involvement)
   - iv. Intersegmental deficiency
     - a) Proximal (humeral – rhizomelic)
     - b) Distal (forearm – mesomelic)
     - c) Total (phocomelia)
   - v. Whole limb duplication/triplication
2. Radial–ulnar (anterior–posterior) axis
   - i. Radial longitudinal deficiency – thumb hypoplasia (with proximal limb involvement)
   - ii. Ulnar longitudinal deficiency
   - iii. Ulnar dimelia
   - iv. Radioulnar synostosis
   - v. Congenital dislocation of the radial head
   - vi. Humeroradial synostosis – Elbow ankyloses
   - vii. Madelung deformity
3. Dorsal–ventral axis
   - i. Ventral dimelia
     - a) Furhmann/Al-Awadi/Raas–Rothschild syndromes
     - b) Nail–patella syndrome
   - ii. Absent/hypoplastic extensor/flexor muscles
4. Unspecified axis
   - i. Shoulder
     - a) Undescended (Sprengel)
     - b) Abnormal shoulder muscles
     - c) Not otherwise specified
   - ii. Arthrogryposis

B. Abnormal axis formation/differentiation – hand plate

1. Proximal–distal axis
   - i. Brachydactyly (no forearm/arm involvement)
   - ii. Symbrachydactyly (no forearm/arm involvement)
   - iii. Transverse deficiency (no forearm/arm involvement)
     - a) Wrist (carpals absent/at level of proximal carpals/at level of distal carpals)
     - b) Metacarpal
     - c) Phalangeal (proximal/middle/distal)
2. Radial–ulnar (anterior–posterior) axis
   - i. Radial deficiency (thumb – no forearm/arm involvement)
   - ii. Ulnar deficiency (no forearm/arm involvement)
   - iii. Radial polydactyly
   - iv. Triphalangeal thumb
   - v. Ulnar dimelia (mirror hand – no forearm/arm involvement)
   - vi. Ulnar polydactyly
3. Dorsal–ventral axis
   - i. Dorsal dimelia (palmar nail)
   - ii. Ventral (palmar) dimelia (including hypoplastic/aplastic nail)
4. Unspecified axis
   - i. Soft tissue
     - a) Syndactyly
     - b) Camptodactyly
     - c) Thumb in palm deformity
     - d) Distal arthrogryposis
   - ii. Skeletal deficiency
     - a) Clinodactyly
     - b) Kirner's deformity
     - c) Synostosis/symphalangism (carpal/metacarpal/phalangeal)
   - iii. Complex
     - a) Complex syndactyly
     - b) Synpolydactyly – central
     - c) Cleft hand
     - d) Apert hand
     - e) Not otherwise specified

II. Deformations

A. Constriction ring sequence

B. Trigger digits

C. Not otherwise specified

III. Dysplasias

A. Hypertrophy

1. Whole limb
   - i. Hemihypertrophy
   - ii. Aberrant flexor/extensor/intrinsic muscle
2. Partial limb
   - i. Macrodactyly
   - ii. Aberrant intrinsic muscles of hand

B. Tumorous conditions

1. Vascular
   - i. Hemangioma
   - ii. Malformation
   - iii. Others
2. Neurological
   - i. Neurofibromatosis
   - ii. Others
3. Connective tissue
   - i. Juvenile aponeurotic fibroma
   - ii. Infantile digital fibroma
   - iii. Others
4. Skeletal
   - i. Osteochondromatosis
   - ii. Enchondromatosis
   - iii. Fibrous dysplasia
   - iv. Epiphyseal abnormalities
   - v. Others

38. Rubinstein–Taybi
39. Saethre–Chotzen
40. Thrombocytopenia absent radius
41. Townes–Brock
42. Trichorhinophalangeal (types 1–3)
43. Ulnar–mammary
44. VACTERLS association

B. Others

*The specified syndromes are those considered most relevant; however, many other syndromes have a limb component categorized under "B. Others".
VACTERLS, vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies, and limb abnormalities.
(Source: http://ifssh.info/2015_OMT_Classifiction_Congenital_Report.pdf)

within the radial–ulnar axis. All of these are classified within group 1A, according to the axis involved, unless the axis is unspecified.

Alternatively, the primary defect may reside within the hand plate alone and not involve proximal limb components. It may affect one of the axes of development or be of unspecified axis. This approach allows incorporation of Swanson group 3 "duplications", radial and ulnar polydactyly, into a group that indicates intuitively the anatomical site and the axis in which the aberration occurs (Fig. 25.18). The triphalangeal thumb may best be included in this group. Dorsal dimelia of the little finger is an example of hand plate involvement involving the dorsal–ventral axis (Fig. 25.19). All of these conditions are classified within group 1B. The cleft hand complex, isolated syndactyly, and central synpolydactyly are examples of hand plate conditions of unspecified axis. This satisfies the concern that cleft hand complex is not a longitudinal deficiency but rather a primary insult to the hand plate (Figs. 25.12 & 25.20).

Fig. 25.17 Radial longitudinal deficiency affecting arm, forearm, hand, and digits of both limbs in brothers with Holt–Oram syndrome.

Group 2 in Table 25.2 allows the classification of amniotic band sequence (constriction ring syndrome) as a deformation, separating it from the malformations of group 1. The insult affects a part already formed (Fig. 25.21).

Group 3, dysplasias, includes many otherwise difficult-to-classify conditions that have previously been listed according to their appearance. Limb hypertrophy and macrodactyly that is consequent upon tumor formation are examples (Fig. 25.22), as are the other tumorous conditions. All of these were previously classified either as a "failure of differentiation" (tumorous conditions) or purely as a descriptive term – "overgrowth" for macrodactyly or limb hypertrophy. There may be dissent as to whether these conditions are in fact malformations or deformations instead of dysplasias. Indeed, increasing knowledge may demand their future transfer to either group 1 or group 2. This system allows such adjustments.

This classification has the advantages of allowing inclusion of all groups within a logical framework; of utilizing a common terminology; and of indicating a site of anatomical insult in

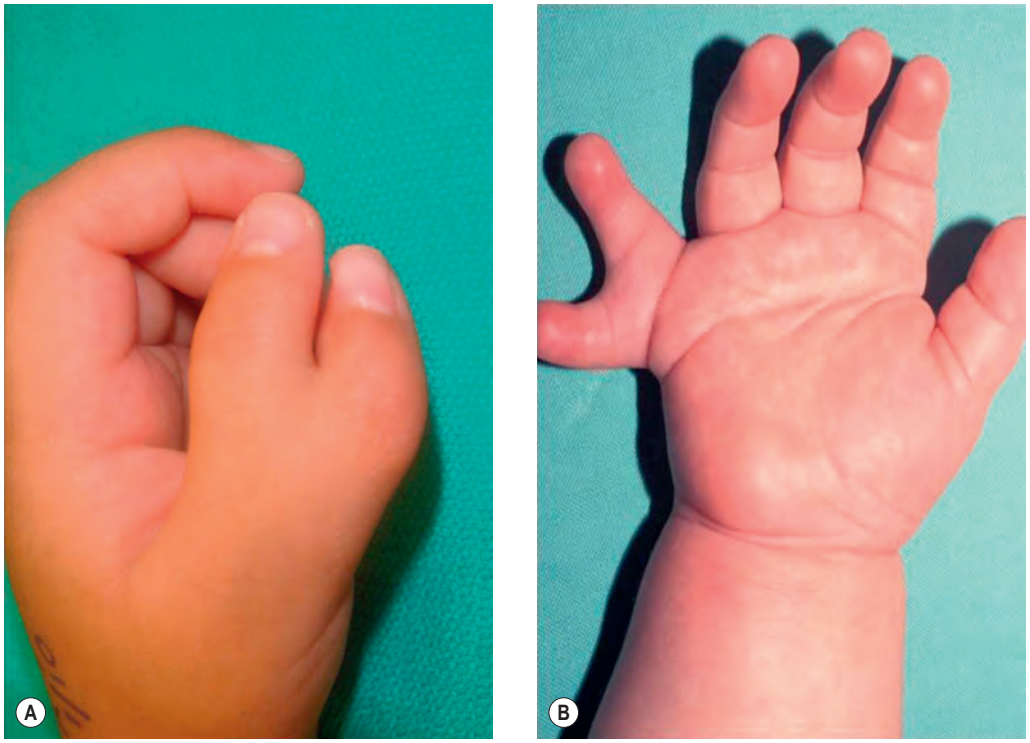

Fig. 25.18 (A,B) Radial and ulnar duplications demonstrate involvement of radial and ulnar axial abnormalities within the hand.

the developing or developed limb bud. The common descriptive terms, which are familiar to all surgeons, are placed within this framework. Each common descriptive diagnosis, such as radial longitudinal deficiency, retains its surgical subclassification, i.e., groups 0–4 for radial aplasia and Blauth groups 1–5 for thumb hypoplasia. These surgical subclassifications are discussed in subsequent chapters devoted to specific anomalies.

Fig. 25.21 Constriction ring syndrome with acrosyndactyly.

Fig. 25.22 Macrodactyly.

Although aberrations in some molecular pathways have been identified as causative of specific anomalies, it is not yet possible to develop a classification that relates cause and effect at the molecular level for all limb anomalies. Furthermore, the complex interaction between the various signaling centers and the cascades of molecular pathways that they control must be appreciated. Hence, any disruption of one signaling center or pathway will have consequences within other signaling centers and pathways, both upstream and downstream. However, many but not all of the current contradictions and flaws find solutions in this method of classification, which also allows adaptation based on evolving knowledge. Of importance is the necessity to utilize a system that allows recording of all anomalies present in any particular child. It is not a contradiction to document more than one diagnosis per child. If, for instance, polydactyly, clefting, and syndactyly occur together, then this is simply classified under "cleft hand complex". However, if a limb presents with apparently unassociated anomalies, such as syndactyly and clinodactyly, these are documented separately.

A further addition has been to list the common syndromes. This allows cross-reference with specific anomalies when the anomaly is part of a syndrome. For instance, Holt–Oram syndrome is documented and the limb anomaly – radial longitudinal deficiency (entire upper limb or hand plate alone) – is also documented.

In 2014, the IFSSH Scientific Committee for Congenital Conditions recommended adoption of the OMT classification system.[3] That committee accepted that no classification system is perfect, that the classification of some conditions remains controversial and, for these, the principle of "best fit" is utilized. The Committee recommended that, as the OMT system has the ability to be flexible and respond to new developments and additional conditions, there be reviews at 3-year intervals and modifications as appropriate following those reviews.

Assessment of the child and family

There are great rewards in treating children who are unfortunate enough to be born with hands we recognize as less than perfectly formed. Adaptive ability in the child is quite extraordinary, such that some question the wisdom of surgical interference for many presentations. Furthermore, initially, the hand is normal to the child. It is a growing awareness of the "normal" environment that alters the child's perception. However, it is the observation of many that the child reflects the attitudes of others. If parents, relatives, friends, doctors, or therapists consider the problem to be overwhelming, the child will be more likely to have a problem.

For the surgeon, the opportunity to observe the development of the child and hand function during growth and learning provides a satisfaction that cannot be underestimated. Decision-making must be precise and involve parents and child such that all develop a confidence that the treatment is both appropriate and in capable hands. Few surgical fields allow greater application of surgical principles to the management of deformity and loss of function. The aim is to achieve optimal hand function – prehensile grasp and dexterity of fingers and thumb for fine activity – whilst also striving for optimal appearance.

The involvement of family doctor and pediatrician, therapist, and psychologist in the overall management of child and family is necessary. The geneticist can assist in identifying inheritance factors and advise regarding risk of recurrence for subsequent children. Specialist medical care is often required, as involvement of systems other than the musculoskeletal system is common. Specifically, cardiac, hematological, neurological, gastroenterological, and urological systems must be investigated for abnormalities. Many syndromic patterns have been described and alert the surgeon and treating physicians to probable associations. Finally, support groups can be of significant benefit. Often parents and children find great solace and encouragement from discussing their problems with others with similar afflictions.

The clinic

A calm, private, and warm environment is conducive to optimal assessment. Parents, often young, may be overwhelmed by the medical and paramedical attention that has been directed towards them and their child. At the initial introduction, the child and parents should not be confronted by too many foreign faces, perhaps only the surgeon and one other. Minimally, the surgical congenital hand clinic should also have immediate access to experienced occupational therapists and physiotherapists. In developed societies, an assessment of all other systems has been completed or is in progress before consultation with the hand surgeon. However, it is vital that the treating surgeon has sufficient understanding of the processes of normal and abnormal limb development and is sensitive to the association of other system anomalies with specific hand and upper limb anomalies. The parents expect and should receive information from the surgeon regarding: the cause and mechanism of dysmorphogenesis; the likelihood of recurrence in subsequent children, and the likelihood of recurrence in future children of the presenting child; a description of the dysfunction the child is likely to confront in the future; and the possible methods and timing of procedures aimed at improving function and appearance. Photographs and models of pre- and postoperative example cases are beneficial in demonstrating expected outcomes. They also provide reassurance that surgery is not disfiguring.

History

Following introductions, a preliminary examination through observation alerts the surgeon to possible diagnoses and associations. A detailed history of the pregnancy, its duration and any untoward events, the lie of the child *in utero*, and the method of delivery and birth weight provide valuable information. The presence of a positive family history of limb anomalies in siblings, parents, and the relatives of parents is suggestive of an inherited disorder. The surgeon should always question as to whether there are anomalies in other systems and whether a general pediatric review has been performed. The need for further specific system review may become apparent during the assessment.

Examination

Observation of the child at play provides much information, which may be withheld if the surgeon approaches a direct physical examination of the child either too early in the assessment process or too brusquely.

An understanding of developmental milestones is integral to recognition of delayed or abnormal functional development (Table 25.3).[108] The child's upper limb movements are mainly reflexive at birth. There is a rudimentary grip via digit flexion. The thumb is clasped within the palm but exhibits reflex extension when startled.[109,110]

The development of prehension is well summarized by the work of Erhardt and Lindley.[111] These patterns are depicted in Fig. 25.23. They demonstrate the development from rudimentary grasp utilizing an ulnar power grip, to precision function radially incorporating the thumb. Fig. 25.24 demonstrates the

change in weight-bearing through the upper limbs over the first 5 months of life.

Determination of hand dominance is usually not possible in the first year or so but becomes apparent by age 5.[112–114]

A general examination includes observation of the facial appearance with specific attention to eyes, ears, mouth, and jaw, examination of the spine and lower limbs, observation and palpation of the chest wall and abdomen where appropriate, and examination of all four limbs.

It often allays the child's distrust for the surgeon to take the mother's hand, gently examine this and return it to its owner, before attempting the same with the child. The experienced examiner will note any deformity and size discrepancy, diminished passive and active ranges of motion in any particular joint, often in association with poorly developed or absent skin creases, and joint instability. Some changes are subtle. A close examination of a child with second-web syndactyly in the feet may reveal subtle webbing of the third webs in the hands. This may also be present in the hands of the parent(s). Obvious thumb hypoplasia in one hand may be accompanied by subtle changes in the other.

All findings must be precisely recorded. Tracings, measurements of girth, and clinical photographs provide objective data for comparison at subsequent assessments.

Investigations

The mainstay of investigation is radiological. Plain X-rays should be requested for the specific anomaly with which the child presents but should be extended to a broader skeletal survey as indicated. Of course, the immature skeleton will not reveal the complete picture. For instance, the Wassel classification of thumb duplication relies on relative skeletal maturity to distinguish a type 1 from a type 2. The bony connection present in the former may not be apparent at the base of the terminal phalanges in initial X-rays until ossification of a cartilaginous connection has occurred. In most instances, X-rays should be repeated immediately prior to surgical intervention as the skeletal appearance may have changed. It is helpful to have available in the clinic sample hand X-rays and charts that detail the timing of appearance of ossification centers and closure of growth plates (Fig. 25.25).[115,116] The method of Greulich and Pyle[117] and that of Tanner *et al.*[118] are the most commonly used for measurement of skeletal maturation. In the former, the patient's radiograph is matched with an atlas image of the appropriate age.[117] One must be careful to differentiate actual age and maturity. The Tanner and Whitehouse method is more complex and is based on the rate of development of 19 individual bones.[118] Both methods suffer from the problem of variation between races. Progress is delayed in European children in comparison with those from Africa and North America.[119] Poor nutrition results in slower maturation. Maturation in girls is more rapid than in boys by 2 years.

Fluoroscopy, tomography, and arthrography may all have a limited place in the assessment of the pediatric hand, often more for injury than for congenital anomaly. Computed tomography and magnetic resonance imaging have replaced many of these modalities but do require sedation or general anesthesia for the child. Ultrasonography has many characteristics that make it an ideal imaging modality in that there is no ionizing radiation, and it is painless and inexpensive. However, it is operator-dependent and differentiation between

tissues can be problematic. It is helpful in assessing cartilaginous contours prior to ossification.

Vascular studies, such as angiography, magnetic resonance angiography (MRA), or Doppler flow studies, may be considered prior to procedures involving vascularized tissue transfer, including toe transfers, particularly to parts with anomalous anatomical development. In particular, angiography and MRA, although uncommonly performed, may be indicated in some specific vascular reconstructions and for assessment of vascular tumors.

It is beyond the scope of this chapter to detail a complete investigation of all systems of the child with congenital limb anomalies. The incidence of associated anomalies is high. For instance, thrombocytopenic absent radius, Fanconi anemia, Holt–Oram syndrome and the VACTERLS association may accompany a longitudinal radial deficiency. A cardiac echogram, renal ultrasound, and blood examinations are routine.

Diagnosis

Following the assessment and investigations, a classifiable diagnosis is usually evident. The surgeon, with assistance from medical colleagues, will have determined whether the anomaly is isolated or syndromic; whether a genetic abnormality is present through either a spontaneous mutation or an inheritance pattern; and whether there has been an abnormal formation of tissue, a breakdown of normal tissue, or a lack of organization of cells into normal tissue.

Principles of surgical management

Indications

When considering surgery, the following question must always be asked: "Is reconstructive surgery likely to improve function and/or appearance with minimum risk?" That a part is incomplete or inadequate is not in itself an indication for surgical reconstruction.

Function

A stable shoulder, arm, elbow, and forearm enable appropriate positioning of the hand in space for function. The instability, deformity, and shortening of radial longitudinal deficiencies, for instance, severely compromise hand function. Hand function itself depends on the ability to use a mobile thumb ray against other parts of the hand, ulnar digits for grasp and radial digits for precision pinch. Adequate digit length, stability, and motion are necessary components of optimal hand use. Surgical decisions may be best guided by a simple assessment, asking whether the size and number of digits are appropriate, whether deformity requires correction, whether stability is a problem, and whether an improvement in mobility would benefit.

Some decisions regarding surgery are relatively easy. Most parents and children will request that an extra digit be removed, particularly if it gets in the way (Fig. 25.26). Occasionally social and/or religious mores will dictate otherwise. Removal of a type 3 hypoplastic thumb, with subsequent pollicization of the index finger, may prove to be less palatable for parents, as they fear a decision that results in four rather than five digits. As a principle, when confronted with the option of reconstruction or removal of a part, it is perhaps wiser to advise reconstruction if the part is incorporated into the child's activities, even if in an inefficient manner. The child and surgeon may benefit from the opinions of others who are experienced in this field of surgery. Advice from a knowledgeable colleague is particularly reassuring.

It is often not possible to restore normal function, even for what would appear to be a straightforward reconstruction of a Wassel type 1 thumb duplication, in which some joint instability and some compromise in interphalangeal joint motion may remain postoperatively. For complex duplications, full function and normal size are difficult to achieve,

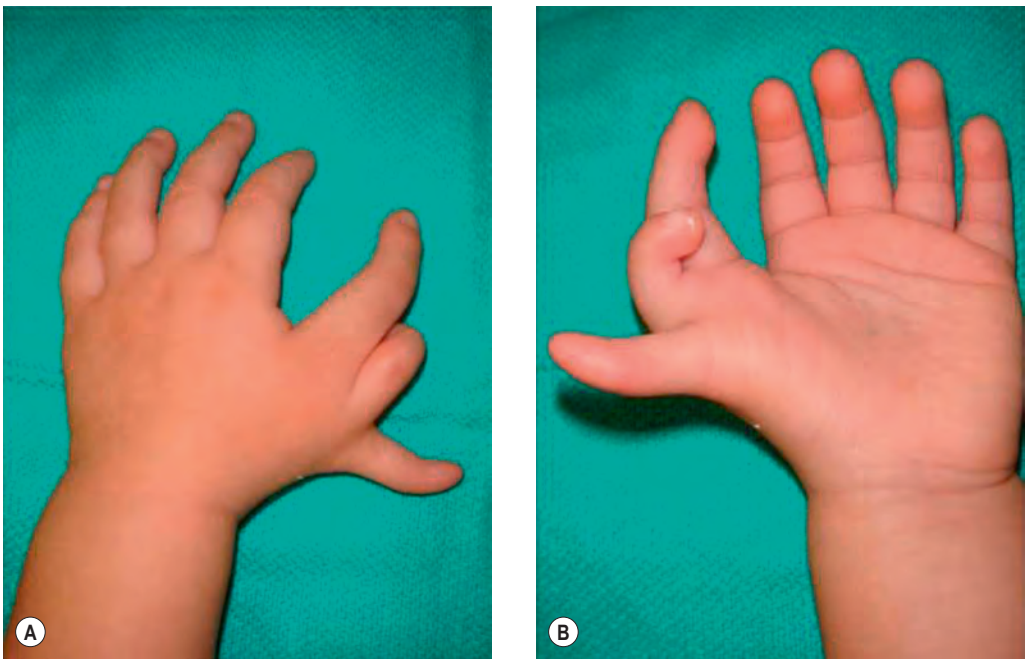

Fig. 25.26 The obvious deformity of thumb triplication.

and pollicization never creates a normal thumb. Trigger thumb release should result in normal use and appearance. Clinodactyly of the little finger may represent no functional deficit preoperatively. Surgical interference should be carefully considered. Surgery for camptodactyly may improve extension at the expense of full flexion.

Appearance

The stigmata associated with an abnormal appearance are obvious. The hands are expressive and communicative. Deformity of a part is often more obvious than its absence and its correction may clearly result in an improved appearance for all eyes (Fig. 25.27). However, for many severe deformities it is simply not possible to create a normal-looking hand. Surgery to improve appearance in these cases must be undertaken realistically. Whether the appearance is improved, remains the same, or is poorer following surgery is simply in the eye of the beholder. Toe transfer for symbrachydactyly is one procedure that excites argument, with some adamant that appearance is improved and some adamant that it is not and that appearance should not play a role in decision-making. Probably the argument is irrelevant. The hand remains different regardless of the surgical reconstruction and the surgeon should not impose his or her views regarding appearance. Postoperative questionnaires in which patients and parents state their belief in an improved appearance are often flawed, as many psychological factors are involved, including that of guilt in having given birth to a "less than normal" child and the responsibility of having made a decision to subject that child to surgical intervention.

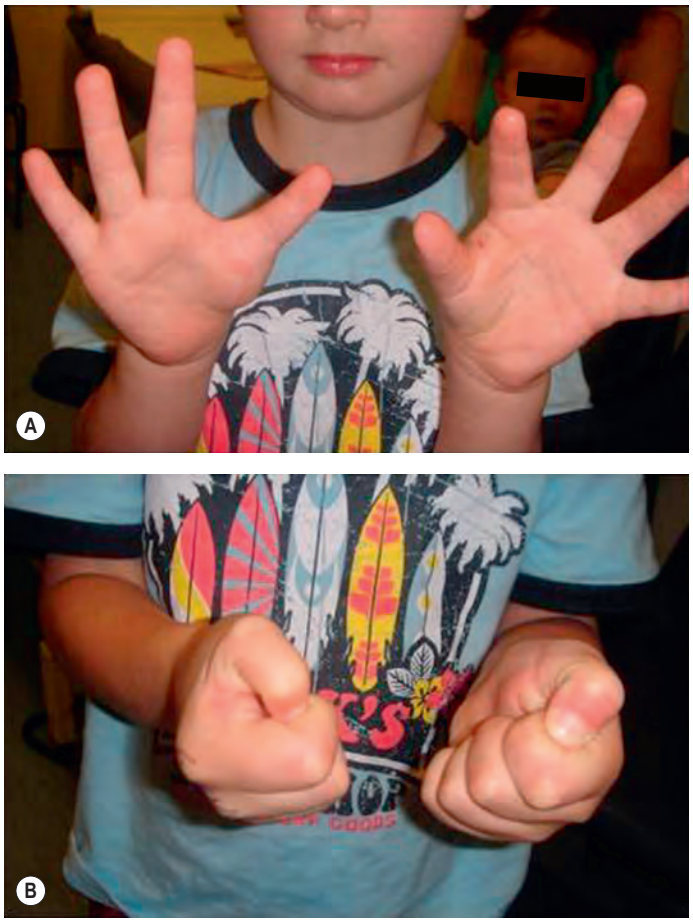

Fig. 25.27 (A,B) Pleasing appearance and function following pollicization.

It is the responsibility of the surgeon to provide advice based on training, experience, and a knowledge of the literature. However, should that advice be rejected, the doctor–patient/parent relationship must not become adversarial. Repeated assessments over a period of time will usually lead to an agreeable solution.

Timing

The question of timing is vexatious. Surgical results may be compromised by the technical difficulties of procedures on small structures in early life. This must be balanced against the principle of providing the child with a final result as early as possible, such that learned patterns of use do not compromise optimal function following appropriate surgical reconstructions. It is a reasonable approach to allow the child to adapt to the new hand as early as possible. However, cortical plasticity allows significant adaptation at older ages and, if the surgeon is doubtful that the surgery is indicated or the parents demand delay, it is preferable to wait. If functional improvement is unlikely and if the indication for surgery is one of a questionable improvement in appearance, perhaps the child should make this decision for him- or herself at an older age.

Parents may wish to defer surgery in the hope that there is something new on the horizon that will, if not cure, at least improve the outcome. It is the surgeon's responsibility to encourage hope but to discourage unrealistic expectations. Having failed to make a decision at the optimal time, these decisions rarely become easier with further passage of time. Web pages are full of information, some beneficial, some not. Some is simply advertising.

Table 25.4 details common practice as it relates to timing of specific surgical procedures, although it is recognized that more urgent treatment of life-threatening conditions will delay hand surgery.[120] It will be seen that many anomalies are treated within the first 2 years of life. In principle, the development of progressive deformity is an indication to operate earlier. An example is a syndactyly of the fourth web with terminal phalanx fusion (Fig. 25.28). Release of the first web, such as in an Apert hand, should be early. It is beneficial to complete most surgical procedures prior to school age, particularly in those instances in which appearance is significantly improved, such that teasing and ridicule by other schoolchildren are minimized. However, some procedures, such as minor revision surgery for the Apert hand or limb lengthening for the short forearm of a radial longitudinal deficiency, may be indicated at an older age (Fig. 25.29).

Finally, expectations of all involved must be realistic. Despite the rewards for surgeon, child, and family following surgery for congenital limb anomalies, an apparently successful and pleasing surgical result may be compromised by recurrent deformity, inadequate growth, uncontrolled growth, or the development of instability or immobility. At the time of operation the surgeon needs to be aware of the presence of factors that may, with time, subsequently alter the early result. In principle, these require correction at the initial surgery.

Table 25.4 Common practice relating to timing of specific surgical procedures

Condition	Procedure	Timing
Syndactyly		
Simple	Release	12 months
Unequal digits with bony tether	Release	6 months
Including thumb	Release	6 months
Apert's acrosyndactyly	Sequential simultaneous bilateral releases	Begin at 6 months
Constriction ring syndrome		
Digit at risk	Release	Immediate
Acrosyndactyly	Release	6 months
Floating digit(s)	Excision	3 months
Thumb duplication	Reconstruction	12 months
Postaxial or central polydactyly	Reconstruction	12 months
Absent or inadequate thumb	Pollicization	12–18 months
Thumb hypoplasia	Reconstruction	12–18 months
Central longitudinal deficiency	Reconstruction	12–18 months
Symbrachydactyly	Toe phalangeal transfer Vascularized toe transfer	12–24 months 2–3 years
Radial longitudinal deficiency	Distraction Stabilization	3–6 months 6–12 months
Clinodactyly	Physeolysis Osteotomy	4–6 years Late
Camptodactyly		
Fixed with joint changes	Joint and soft-tissue release	12–18 months
Soft tissue	Release and transfers	After 2 years
Trigger thumb	Release	After 12 months

(Reproduced from Tonkin MA. An introduction to congenital hand anomalies. *Handchirurgie*. 2004;36:75–84.)

Congenital trigger thumb

Although congenital trigger thumb does not fit well into any classification scheme for congenital hand anomalies, it is one of the most common pediatric hand problems in practice.

Etiology

Pediatric trigger thumb is a stenosing tenovaginitis of the flexor pollicis longus tendon within its fibro-osseous tunnel, with the obstruction to tendon glide occurring at the A1 pulley. Controversy continues as to whether this is a true congenital condition or whether it is an acquired condition. The distinction between the two would appear to rely on whether or not the condition is present at birth. Although many authors have described presence at birth, the majority of these studies depend upon a retrospective history from the parents. The presence of trigger thumb in twins, the frequent bilateral nature of trigger thumb, and the association of trigger thumb with trisomy 13 are factors that have been used to support the theory of a congenital cause.[121–125] However, several investigators have performed assessments within the early postnatal period, finding an absence of trigger thumbs in a combined number of 9000 neonates.[126–128] The study of Kikuchi and Ogino examined 1116 babies within 14 days of birth.[129] None presented with trigger thumbs. Of 601 children assessed by a questionnaire at 12 months of age, only two had developed trigger thumbs within that period, an incidence of 3.3 per 1000 live births. Three other children subsequently developed trigger thumbs, one bilateral, after the age of 12 months. Although response to the 12-month questionnaire was only obtained from 53% of patients and the true prevalence of trigger thumb after 12 months in this cohort of patients cannot be established, this study does tend to suggest that trigger thumb deformity is an acquired condition and is not present at birth. However, if the incidence of one patient per 2000 live births, as described by Ger *et al*., is accurate, the number of children required to establish an absence of trigger thumb at birth would need to be far greater than those examined in the study.[130]

Trauma has been incriminated as a possible cause of acquired trigger thumb. However, the absence of this history is more usual than not. Furthermore, the definition of what is a traumatic incident and what is not in a 2-year-old is unclear.

Notta described a node affecting the flexor tendons of digits that impeded their movement.[131] Notta's node is palpable proximal to the A1 pulley in children with a locked flexion deformity. If the deformity is correctable, either actively or by the examiner's passive extension of the digit, the node can be felt to click as it passes beneath the A1 pulley. Some consider the node to be primary, preventing passage of the tendon past the edge of the obstructing A1 pulley. Most believe that this is a secondary phenomenon consequent upon

Fig. 25.28 Deformity of ring finger secondary to a four–five syndactyly.

the bunching of the tendon as its passage is impeded. It seems to disappear following surgical release, which supports the latter theory.

Two other observations are interesting. The first is that there is a percentage of "trigger thumbs" that present with the digit locked in extension. In this instance, the failure to glide through the A1 pulley is from distal to proximal when Notta's node presumably abuts against the distal end of the A1 pulley. The literature does not provide us with an incidence of triggering in extension; indeed some may have interpreted this as a spontaneous resolution of triggering in a digit previously locked in flexion.

The second observation is that many children with a trigger thumb have hyperextensibility of the metacarpophalangeal joint. Ligamentous laxity is greater in children. No study has made a comparison of the incidence and degree of metacarpophalangeal joint hyperextension in children with and without trigger thumbs. However, it is logical to propose that the diameter of the A1 pulley, which is attached to the palmar plate of the metacarpophalangeal joint, decreases during hyperextension of the metacarpophalangeal joint, potentially restricting gliding of the tendon.

The current evidence suggests that the appearance of trigger thumb is more likely to be after birth. There is no real evidence of a primary pathological process other than a mismatch in size between the flexor tendon and the pulley.

Management

The rate of spontaneous resolution following observation and the rate of resolution following a combination of observation, manipulation and splinting, vary. Ger *et al*. found no cases of resolution in 53 thumbs diagnosed before the age of 6 months, following 40 months of nonoperative therapy.[130] Steenwerckx *et al*. reported similar findings in 57 thumbs after 6 months.[132] Other reports document high rates of spontaneous resolution,[132–138] up to 96% for those thumbs that trigger during active extension, with a lesser resolution rate for those with a fixed flexion posture.[133] Dinham and Meggitt observed a spontaneous recovery rate of 30% in those children presenting with trigger thumb prior to the age of 6 months and a rate of 12% for those presenting between 6 and 30 months.[124] They advised treatment guidelines accordingly, advising that trigger deformities present in the early postnatal period should be observed for 12 months; those presenting between the ages of 6 and 30 months should be observed for 6 months; and that operative treatment should be performed before the age of 4 years to prevent the creation of residual flexion deformities. Although there has been an occasional report of interphalangeal (IP) joint radial deviation and a rotational deformity of the IP joint in older children,[139] there are no reported instances of persistent deformity if the condition is corrected surgically by the age of 3 years, or even later, according to some authors.[140]

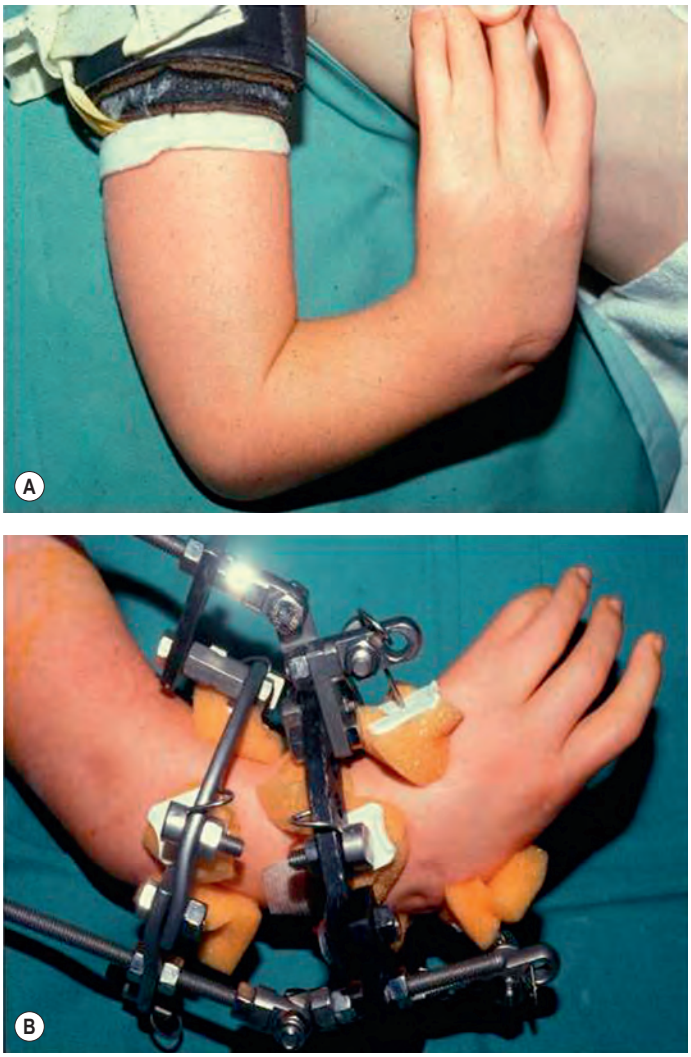

Fig. 25.29 (A,B) Correction of deformity and length for radial longitudinal deficiency at age 8.

Recently Baek *et al*. found a 63% rate of spontaneous resolution in 71 trigger thumbs.[141] No treatment was instituted in these children who were assessed 6-monthly for a minimum period of 2 years. They found that the flexion deformity can be expected to improve even in those patients who did not have complete resolution. The general trend in the literature pertaining to children of Asian descent is to recommend a prolonged period of observation with or without splinting and passive exercises.

From the above it can be seen that the necessity for and timing of surgery for pediatric trigger thumbs are open to debate. Most would advise surgery for persistent painful episodes of triggering. Intermittent, non-painful triggering may be safely observed for a prolonged period of time, with or without the addition of night splinting in extension, without fear of the complication of joint deformity. It is questionable as to whether or not treatment with night splints for an extended period of time (up to 5 years or longer) is a greater imposition on child and parents than a surgical procedure. It is the author's (MT) practice to offer the parents surgical release if there is a persistent flexion or extension contracture for longer than 3 months and/or if there is accurate documentation by the parents of an uncorrectable flexion contracture for 12 months. However, this advice is offered along with the information that spontaneous resolution may well occur, even in these circumstances.

Surgical procedure (Video 25.1 ▶)

The surgical procedure is performed as day-only surgery under general anesthesia and with an arm tourniquet. The incision is transverse at the base of the thumb (metacarpophalangeal joint level). This incision is not easily extensile and therefore its position is important if one is to obtain an optimal view of the A1 pulley. If Notta's node is easily palpable, an incision centered on this node provides very adequate access. Often, this leads the surgeon to an incision halfway between the two basal thumb creases that are present in most hands. The neurovascular bundles of the thumb lie more anteriorly than those of the digits. The A1 pulley should be visualized and palpated with the tip of forceps to identify its proximal and distal edges. The surgeon or assistant should not attempt to passively correct the flexion deformity manually prior to incision of the A1 pulley. Full and easy correction following pulley release provides evidence of a complete release. The incision should be made in the midline of the pulley or erring to its radial side. This avoids continuing the incision through the fibers of the oblique pulley, whose origin on the ulnar side abuts the distal end of the A1 pulley. Occasionally, there are further transverse fibers just distal to, but separate from, the A1 pulley, which deserve release.

With careful attention to detail, complications should be minimal to nil. Absorbable 6/0 Vicryl Rapide sutures avoid the necessity for suture removal. Bathing and massage can begin at about 7–10 days postoperatively. Although Michifuri *et al*.[142] reported a complication rate of 15%, including digital nerve injury, this is not the author's (MT) experience. There may be some inflammatory response during wound healing but this settles once the sutures have dissolved or are rubbed out with massage.

Congenital hand II: Longitudinal, central, and transverse deficiency

Scott Oishi and Lesley Butler

SYNOPSIS

- Clinical evaluation of the entire patient is essential as multiple associated findings may exist.
- It is important to remember that untreated patients function very well, so any surgery, needs to be assessed on an individual case basis and should only be performed if there is a realistic goal of increasing function.
- If a syndactyly exists but the finger tips are separated and no significant tethering exists, reconstruction should be delayed until the child is in the 2–3 year-old age range as to minimize possible effects of anesthesia as well as to allow the fingers to be bigger and easier to perform surgery on.

Introduction

Upper limb development occurs very early during fetal development, with ingrowth into the ectoderm by the mesoderm signaling the initiation of limb bud development.[1–3] This begins about 28 days after fertilization and is completed by about day 56. The development is regulated by a complex feedback mechanism that determines growth, orientation, and differentiation of the three axes: longitudinal, radioulnar, and ventral–dorsal. Critical areas include the apical ectodermal ridge (AER), zone of polarizing activity (ZPA), and the dorsal ectoderm, which are regulated by fibroblast growth factors (FGF), sonic hedgehog, and the Wingless-type (Wnt) pathway respectively[3] (Fig. 26.1). It should be noted, however, that these pathways do not act solely independently and instead rely on feedback mechanisms from each other for growth and differentiation of the upper limb. Abnormalities occurring during this crucial time period of development can lead to abnormalities of longitudinal, central, and transverse deficiencies. In a series of eloquent experiments, Ogino and his group were able to induce ulnar and radial longitudinal deficiencies in rats by administering busulfan at different points in early development of the upper limb (weeks 4 and 5 of fetal development). Greater doses of busulfan led to both a higher incidence and severity of ulnar or radial longitudinal deficiency.[4–5] Transverse deficiencies have not been reproduced in animal models; however, it is speculated that subclavian artery disruption at an early developmental stage may lead to the clinical findings associated with transverse deficiencies.[6]

Patients with longitudinal, central, and transverse deficiency can face significant societal issues as they grow and it is important for them to have support groups, child-life specialists, and child psychologists available, not only to them, but also to their parents. Counseling for the parents is also important at the first visit regarding potential etiologies of the underlying conditions as many of them have significant feelings of guilt and confusion. At Texas Scottish Rite Hospital for Children, we started a hand camp many years ago, which has been an integral part of treatment of these patients, as it allows them to interact and talk with other children with either the same or different congenital hand difference diagnosis.

Radial longitudinal deficiency

Basic science/disease process

Radial longitudinal deficiency (RLD) is the most common upper limb longitudinal deficiency, with an incidence that has been reported as between 1:5000–100 000 live births,[7–9] being bilateral in 38% to 58%.[9] It can range from involvement of the entire upper limb to thumb involvement alone. In 1976, the International Federation of the Societies for Surgery of the Hand (IFSSH) adopted the classification system of congenital hand differences proposed by Swanson.[10] In this classification, RLD is considered in the IB group (failure of formation – longitudinal arrest). Since its publication, many conditions have been found to not fit into this system. An expanded classification system, OMT (Oberg–Manske–Tonkin), has recently been introduced to more accurately categorize congenital hand differences.[11] (see Table 25.2 for

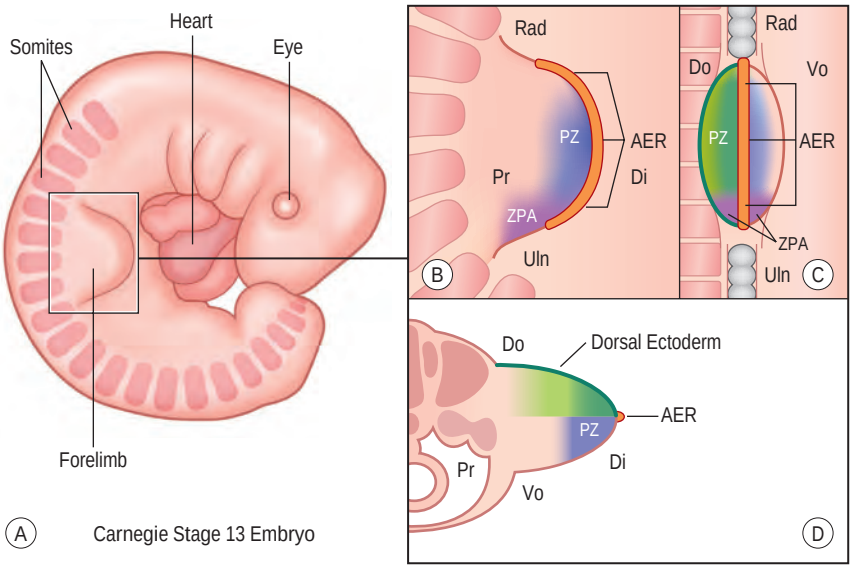

Fig. 26.1 Limb bud coordinate axes and signaling centers.[3] AER, Apical ectodermal ridge; Di, distal; Do, dorsal; Pr, proximal; Rad, radial; Uln, ulnar; Vo, volar; ZPA, zone of polarizing activity. *(Redrawn after Oberg KC, Feenstra JM, Manske PR, et al. Developmental biology and classification of congenital anomalies of the hand and upper extremity.* J Hand Surg Am. *2010; 35:2066–2076.)*

2015 version). In this system, RLD with thumb hypoplasia and forearm involvement would be I.A.2.i, and thumb hypoplasia without forearm involvement would be I.B.2.i. Although many cases occur as a sporadic mutation, some are related to an inherited condition. For example, Holt–Oram syndrome is an autosomal-dominant condition that has been mapped to a mutation on chromosome 12 at the location of the *TBX-5* gene.[12] In affected individuals, this presents as RLD along with cardiac abnormalities. Although the most common cardiac abnormality present is a septal defect, conduction abnormalities can also be the lone cardiac finding. Obviously this can be an important consideration for the patient undergoing surgery, and must be conveyed to the anesthesiologist. TAR (thrombocytopenia absent radius) syndrome is inherited in an autosomal-recessive fashion and can present with profound thrombocytopenia as a newborn. However, this usually improves/resolves over the first year of life and overall prognosis is good. These patients usually have bilateral involvement with thumbs that are present, albeit hypoplastic. Another autosomal-recessive condition is Fanconi's anemia and RLD. This anemia usually is not seen in routine blood counts done as a newborn, and is identified only by DEB (diepoxybutane) chromosome breaking testing. VACTERL (vertebral anomalies, anal atresia, cardiac abnormalities, tracheoesophageal fistula, esophageal atresia, renal agenesis, and limb anomalies) represents an association and is not an inherited disorder. A minimum of three of these clinical findings need to be present before the VACTERL diagnosis is made. Thalidomide was a medication which previously was given to pregnant women to treat nausea and morning sickness, but was unfortunately found to have a high incidence of RLD and other skeletal deficiencies in the newborn when given between days 38 and 45 of fetal growth.[13] In addition, maternal use of valproic acid, phenobarbital, and aminopterin, as well as fetal alcohol syndrome, have also been associated with RLD.[14–16]

Diagnosis/patient presentation

Bayne and Klug (1987) initially classified radial deficiency into four types[17]; however, this was later expanded by James *et al.*[18] to include types 0/N and also by Goldfarb *et al.* (2005) to include a more proximal variant (phocomelic), type V[19] (Table 26.1). A type 0 radius is of normal length (<2 mm short), with the 0/N modifier reflecting whether the carpus is normal (N) or abnormal (0); a type I radius is at least 2 mm short (measured between distal physis of radius and ulna); a type II radius is termed a "miniature radius" with proximal and distal physes present; a type III radius only has remnant of radius with absent distal physis; and type IV is an absent

Table 26.1 **Modified classification of radial longitudinal deficiency.**

Type	Thumb	Carpus	Distal radius	Proximal radius
N	Hypoplastic or absent	Normal	Normal	Normal
0	Hypoplastic or absent	Absence, hypoplasia, or coalition	Normal	Normal, radioulnar synostosis, or congenital dislocation of the radial head
1	Hypoplastic or absent	Absence, hypoplasia, or coalition	>2 mm shorter than ulna	Normal, radioulnar synostosis, or congenital dislocation of the radial head
2	Hypoplastic or absent	Absence, hypoplasia, or coalition	Hypoplasia	Hypoplasia
3	Hypoplastic or absent	Absence, hypoplasia, or coalition	Physis absent	Variable hypoplasia
4	Hypoplastic or absent	Absence, hypoplasia, or coalition	Absent	Absent

(Adapted from James M, McCarroll R, Manske PR. The spectrum of radial longitudinal deficiency: a modified classification. *J Hand Surg Am.* 1999;24:1145–55.)

radius. The type V radius reflects a more proximal involvement of the upper limb.

The hypoplastic thumb was classified as by Blauth (1967) into types I–V.[20] An important distinction was made by Manske (1995) who introduced a type IIIA and type IIIB, which has implications on the treatment offered to the patient and family.[21] Type I hypoplastic thumbs are a little smaller than normal thumbs but possess all the structures usually present in an unaffected thumb. As a result, they very rarely need any surgical treatment. In type II thumbs, the thenar musculature is poorly developed with associated adduction contracture of the first ray and variable amounts of metacarpal–phalangeal (MP) joint laxity. As hypoplasia progresses to type III, a loss of extrinsic musculotendinous units is noted. Type III has been further subdivided into an A or B depending on whether the carpometacarpal (CMC) joint is stable.[21] This has important ramifications on the type of reconstruction that is performed. Type IV is the *pouce flottant*, or floating thumb, and type V is an absent thumb.[22] (Fig. 26.2).

Patient selection

Because of the appearance of the upper limb, the hand surgeon may have early involvement in the care of the affected patient. It is imperative that a thorough history is taken, as well as a complete physical examination. This should include evaluation of the lower extremities, hips, back, head and neck area, as well as the upper extremities. In addition, because of the possible associated anomalies, it is important to make sure the patient has had a complete blood count (CBC), echocardiogram, and renal ultrasound. If a significant sacral dimple (+/– hairy patch) was noted on examination, a spinal ultrasound is warranted to rule-out tethered cord. Obtaining a DEB test at the time of initial evaluation is advocated by some, because infants with Fanconi's anemia have a normal CBC and may not display signs of aplastic anemia until 3–4 years of age or older.[22] In the past, low incidence and high cost of DEB testing argued against routinely obtaining it; however, the advent of more successful treatment of these patients by pediatric hematologists at earlier ages has made DEB testing more routine in our practice.

Clinical tips

RLD – evaluation for surgery

- Careful evaluation of the entire patient.
- Scoliosis screening.
- Complete blood count, renal ultrasound, echocardiogram.
- +/– DEB test.

Upper limb evaluation usually reveals some radial deviation at the level of the wrist with some degree of thumb hypoplasia. It is important to note that the severity of the radial hypoplasia does not necessarily correlate with degree of thumb hypoplasia (Fig. 26.3A,B). In other words, a patient with a type IV radius may have a type I hypoplastic thumb, and *vice versa*. The physical examination should note the motion at the shoulder, elbow, wrists, and fingers, with notation of the resting position of the radius and degree of passive correction. Degree of thumb hypoplasia as well as the nature of the fingers (supple or stiff) is also important to note in the

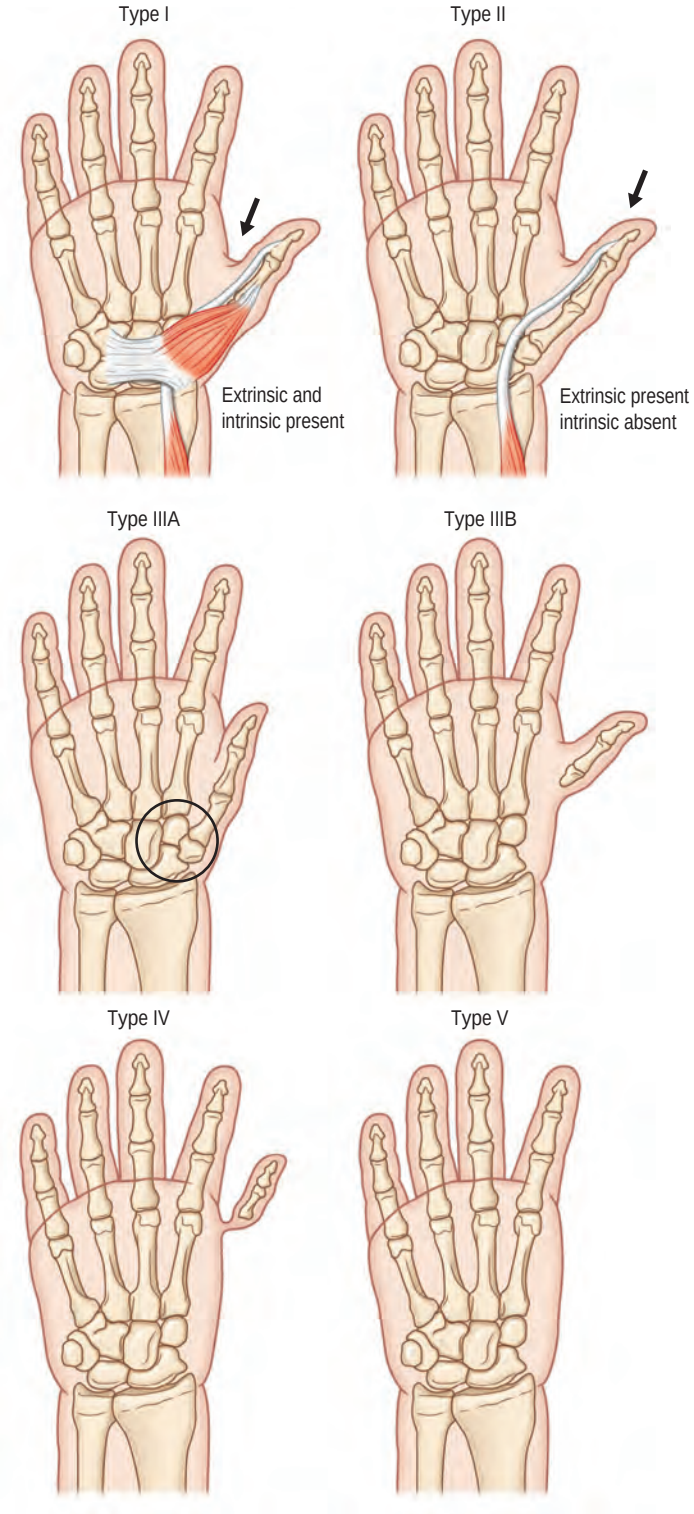

Fig. 26.2 Thumb hypoplasia, types I to V: type I, hypoplastic type; type II, + missing intrinsics; type IIIA, + missing extrinsics, stable carpometacarpal (CMC) joint (circle); type IIIB, + unstable/missing CMC; type IV, *pouce flottant*; type V, absent joint.[22] *(With permission from Herring JA, Tachdjian MO. initial evaluation. If the patient is a newborn, radiographs may not be of much use and can usually wait until they are seen at the 6–12 month-old time interval.

The role of the occupational therapist is crucial, as stretching of the wrist is begun when the newborn is first seen. When the child is of adequate size, a splint is fashioned to aid in the stretching of the wrist. On subsequent visits it is crucial to observe and document the use-pattern of the fingers. In other words, when the child grasps objects, is it between: thumb–index finger (if thumb present); index–middle finger; or ring–little finger? This becomes important when considering surgical intervention, not only for the thumb but also the wrist. If a child grasps primarily between the ring and little fingers, any attempt to formally centralize the wrist (discussed later) may actually worsen function as it may prevent the child from getting his/her hand to the mouth. Also, it has been shown in these patients that the average growth of the ulna in an untreated patient is 64% of normal, with centralized patients achieving only 48–58% of normal length, which can further limit access of the hand to the mouth.[23] Additionally, in a recent article, Ekblom (2014) reported that in RLD patients, grip strength, key pinch, forearm length, and elbow and digital motion are more important than radial angulation of the wrist for daily activity and participation.[24]

Surgical treatment and postoperative care

As the child reaches a year of age, he/she can be assessed for suitability for surgical intervention. As stated above, some patients actually benefit from having a radially deviated wrist and would be greatly impaired if it was placed in a straight, stiff position. Other important considerations include the generalized health of the patient. As many associated organ systems can be affected in these patients, no surgery should be contemplated until after medical clearance is obtained.

A common procedure for the wrist is distraction with some variation of centralization, whether it be centralization or radialization.[25–33] In general terms, this involves surgically placing the carpus on the distal end of the ulna. Centralization, without distraction, was described by Sayre in 1893 with multiple modifications being made over the years by other surgeons.[25] An important addition was by Kessler in 1989, who introduced the concept of pre-distraction of the soft tissues prior to centralization, as many surgeons noted difficulty performing centralization without it because of the severity of soft-tissue contractures.[28] The age that this is performed, as well as the speed of distraction, varies depending on the surgeon.[28,30,31,33] In the classic centralization procedure, a notch is made in the carpus to align the third metacarpal with the ulna. In the radialization procedure, described by Buck-Gramcko, the carpus is balanced on the ulna with the second metacarpal in alignment with the ulna.[32] Dorsoradial muscle mass is then transferred to the dorsoulnar side in an attempt to re-balance the forces across the wrist. The greatest problem with these procedures is that the wrist deformity tends to recur over time,[34] with potential for ulnar physeal injury and ultimately a shorter forearm.[23] Also, only one published study has shown functional benefit of the procedure,[35] with most reporting no significant improvement using validated outcome studies.[24,36] In addition, as stated above, in some patients elbow stiffness and/or ulnar prehension exists which makes wrist radial deviation an advantageous position for getting the hand to the mouth.

An alternative to centralization for severe cases (types III and IV) is the soft-tissue release and bilobed flap procedure[37] (Fig. 26.4). In this procedure the non-essential soft-tissue

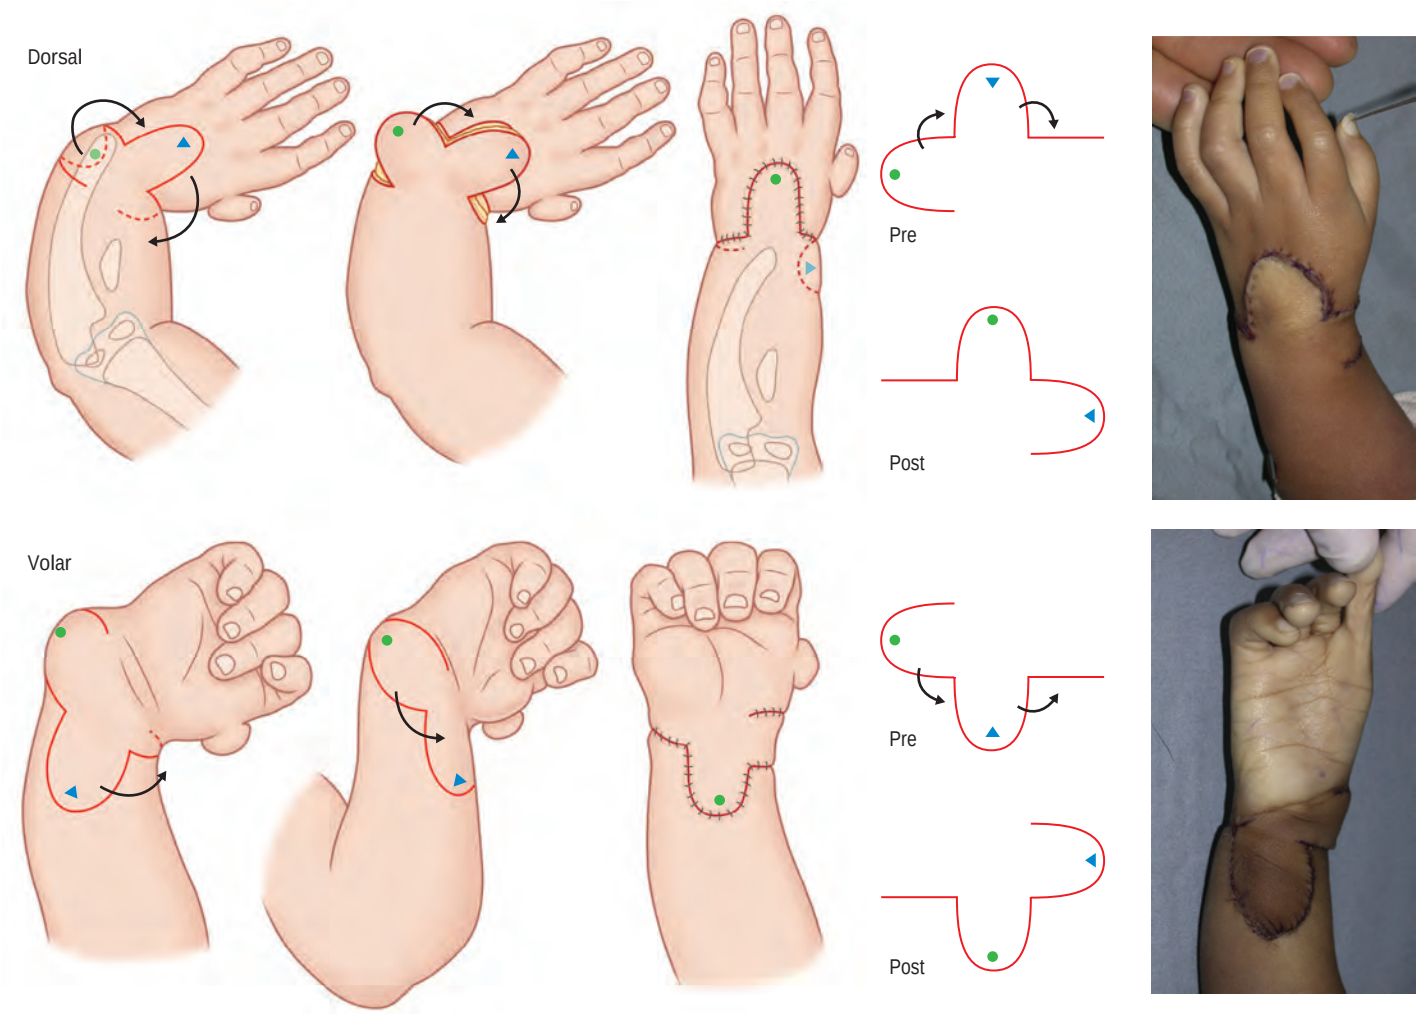

Fig. 26.4 Diagram of rotation for dorsal and volar bilobed flaps with corresponding clinical photographs.[37] *(Reproduced with permission from Vuillermin C, Wall L, Mills J, et al. Soft tissue release and bilobed flap for severe radial longitudinal deficiency.* J Hand Surg Am. *2015;40:894–9.)*

structures are released with use of a bilobed flap for skin closure. Our original procedure involved a dorsal approach, but we have now transitioned to a volar approach based on several factors: improved, less conspicuous scars and better exposure for identification and safe release of tight radial structures. Under tourniquet control, the skin flaps are incised and raised off the investing fascia. This dissection plane, in addition to wide flap bases, preserves maximal blood supply to the tips of the flaps. During dissection, the dorsal branch of the ulnar nerve as well as sensory branches of the radial nerve should be identified and preserved. At this point, all tight fascial bands along the radial wrist are released. It is important to not perform extensive dissection around the distal ulna as it may compromise physeal blood flow and lead to growth arrest. If a pure wrist flexor is identified inserting into the radial carpus, it can be released and transferred to the ulnar wrist. The median nerve and finger flexors can be in a very aberrant location and must be carefully identified and preserved. After this is performed, usually the wrist can be brought to a neutral position in both the radial/ulnar and extension/flexion axes. It is important to place a Kirschner wire for stabilization with the wrist in maximum correction which is directed obliquely from the distal ulnar metadiaphysis to the radial carpus to prevent motion during flap healing. This wire is carefully placed as to not cross the ulnar physis. At 4 weeks, the wire is removed and a custom static wrist orthosis is fashioned, with institution of range of motion exercises and stretching. The orthosis is continued full-time for 6 weeks, then transitioned to night-time use only.

It is understood that recurrence of some radial deviation at the wrist is the anticipated outcome; however, it preserves motion of the wrist with an improved resting position. In addition, there is no potential for ulnar physeal injury, thereby allowing the ulna to grow to its full potential, which, as stated above, is approximately two-thirds of normal. In patients with TAR syndrome, a significant elbow flexion contracture can be present and can be effectively treated by releasing the so-called brachiocarpalis muscle, which has been previously described.[38] This muscle has a high origin on the humerus and inserts on the radial carpus, thereby causing a significant elbow flexion contracture along with deformity at the wrist. At a later time, if the patient and family desire a straighter wrist position, a Vilkki procedure can be offered as an alternative.[39] (Fig. 26.5A,B) In this procedure, a distractor is placed and the hand is gradually brought out, if not overcorrected, over a period of 6 weeks. This can be a very difficult distraction as the

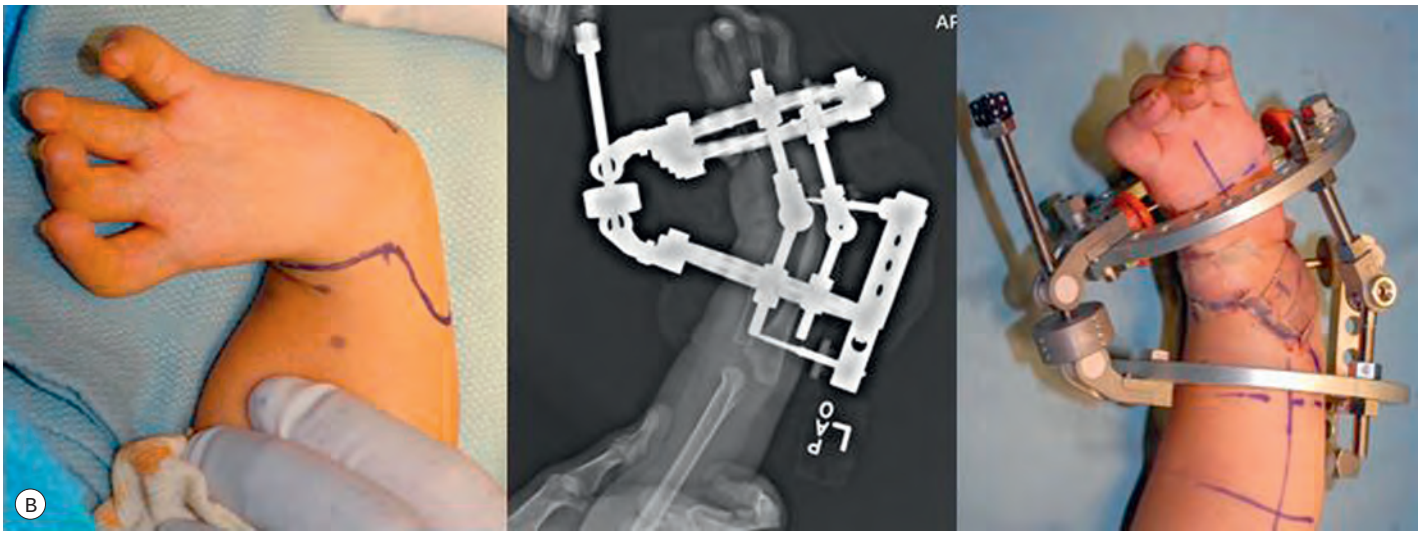

Fig. 26.5 **(A)** A 5½-year-old male with RLD. **(B)** Initial surgery with bilobed flap/soft-tissue release and distractor placement.

deformity is not only radial but also volar. At this point, a vascularized second metatarsal–phalangeal toe joint is transferred to the radial side of the distal forearm. (Fig. 26.6A,B) The distraction device is left on another 6 weeks and then removed. This results in a straighter wrist while preserving wrist motion. However, we have found that most patients/parents are satisfied with the soft-tissue release alone and do not want to proceed with the toe joint transfer.

Surgical treatment options for the thumb

Type I hypoplastic thumbs have all the structures and thus do not usually need reconstruction. Type II hypoplastic thumbs usually can benefit from an opponensplasty +/− MP joint ligament reconstruction if significant instability is present. I prefer a flexor digitorum superficialis (FDS) ring transfer; however, a Huber transfer (abductor digiti minimi) has also been used to reconstruct opposition. (Fig. 26.7A–C) In addition, many of these patients also benefit from a four-flap Z-plasty of the first webspace. This is performed by first elevating the flaps for the four-flap Z-plasty in the first web and exposing the ulnar base of the proximal phalanx as well as the metacarpal neck. Next, an incision is made along the radial side of the thumb, exposing the radial metacarpal neck. A bone tunnel is then made through the metacarpal neck/head area to allow the FDS ring finger tendon to be passed through it. Next, an incision is made over the A1 pulley of the ring finger, and the FDS tendon is isolated and transected distally. An incision is then made over the volar–ulnar wrist or the transverse carpal ligament, depending on which pulley is to be utilized. The FDS tendon is then retracted proximally and re-directed around the desired pulley to the radial incision that had already been made. If only the MP (metacarpal–phalangeal) ulnar collateral ligament (UCL) is to be reconstructed, then the entire tendon is passed through the bone tunnel and across the joint to the ulnar base of the proximal phalanx. A suture anchor or bone tunnel can be used, but it is obviously essential to be distal to the proximal phalanx physis. If the radial collateral ligament (RCL) also needs to be reconstructed, then the tendon can be split: half passed through the bone tunnel, while the other half is passed across the radial side of the MP joint to reconstruct the RCL. The Z-plasty flaps are

Fig. 26.6 **(A)** 6 weeks post-distraction. **(B)** After graft incorporation (note the open physes of the toe transfer).

rotated and sutured in place. A pin is placed across the MP joint with the patient in cast immobilization for 4 weeks. After the 4-week period, the patient is then placed in a basic opponens splint, and range-of-motion (ROM) exercises instituted with the splint gradually being weaned over a 4-week period.

Clinical tips

RLD – considerations for thumb surgery

- Observe patient to ensure he/she attempts use of thumb for pinch (i.e., does not bypass it), otherwise pollicization may be the better procedure.
- Metacarpal must be large enough to allow bone tunnel to be made.
- Patient must be able to participate in postoperative rehabilitation.
- Avoid injury to the proximal phalanx physis when decided on insertion point for FDS tendon.

In general, type IIIA thumbs benefit from reconstruction as stated above; however, type IIIB thumbs require index finger pollicization because of the gross instability of the CMC joint. Type IV and V thumb hypoplasia is treated with an index pollicization if warranted clinically. Prior to performing a pollicization, it is important to observe the child's prehensile grasp. If he/she preferentially pinches between the index and middle finger, then a pollicization is indicated (Fig. 26.8A–D). If, however, the index finger is stiff and pinch is between the ring and little finger, then pollicization will not likely improve function. In some countries, because of cultural considerations, a toe transfer is preferred over a pollicization.[40] Extensive details for thumb reconstruction can be found in Chapter 27.

Outcomes, prognosis, and complications

In summary, early treatment for patients with RLD includes stretching and splinting of the wrist if significant radial deviation is present. A thorough evaluation of the patient is warranted due to the many medical conditions that may also be present. As the child approaches the age range of 12–18 months, consideration for surgery on the wrist can be undertaken, if warranted, as long as underlying medical issues do not preclude it. At about 2 years of age, index pollicization can be performed if this is indicated. Tendon transfers/MP stabilization procedures usually are not performed until the child is older, in the range of 4–6 years old, as structures are larger and rehabilitation easier and more effective. Genetic counseling can be important for parents because of the many associated syndromes and the varying inheritance patterns that exist.

Ulnar longitudinal deficiency

Basic science/disease process

The incidence of ulnar longitudinal deficiency (ULD) is much less than that of radial longitudinal deficiency, approximately one-quarter, and usually is unilateral. In the Swanson classification, this represents a IB, and in the OMT classification it is I.A.2.ii (upper limb including hand) or 2.ii (hand only).[11] In contradistinction to RLD, most cases of ULD are sporadic and rarely have associated heart and hematopoietic abnormalities. In addition, ULD patients can have musculoskeletal anomalies such as fibular and tibial ray deficiency, proximal femoral focal deficiency, scoliosis, clubfeet, and absent patellae, which are not usually seen in RLD patients. Interestingly, radial hand abnormalities are not infrequent. This is thought to be due to an insult in the ZPA, which resides on the ulnar side of the developing hand. Depending on the severity of the insult, this can affect the development and growth of both ulnar and radial hand structures.

Diagnosis/patient presentation

Bayne (1982) classified the forearm/elbow into four types based on the length and size of the ulna. Type I is a hypoplastic

Fig. 26.7 **(A)** Preoperative photographs of a type IIIA hypoplastic thumb. **(B)** Intraoperative photograph of design of opponensplasty. **(C)** Postoperative opposition and metacarpal–phalangeal joint stability.

ulna with proximal and distal ulnar epiphyses present.[41] Minimal deformity or shortening is noted. Type II is absent distal or middle third of ulna with possible fibrous anlage and consequential radial bowing. However, the elbow is stable. Type III is a total absence of the ulna with an unstable elbow. Type IV is an absent ulna with radiohumeral synostosis. In addition, there is possible progressive ulnar deviation at the wrist secondary to a fibrous anlage, although this is controversial.[41] As in RLD, a type 0 has been added, to represent patients who display hand plate abnormalities only.[42] Also, as in RLD, a type V has been added, to represent more proximal involvement (phocomelic)[19] (Fig. 26.9). Cole and Manske (1997) classified the hand based on the appearance of the thumb and first webspace as this is critical for hand function[43] (Fig. 26.10). In type A, the thumb and first webspace are normal. In type B, the thumb is mildly deficient with a narrow first webspace. Opposition is present with intact extrinsic tendons. In type C, there is a more severe first webspace deficiency with varying degrees of thumb involvement, including possible syndactyly to the index finger and malrotation of the thumb into the plane of the palm. Opposition function is lost and dysfunction of the extrinsic tendons is present. Type D represents an absent thumb. As in RLD, there is no correlation between the severity of ulna and hand involvement.

Patient selection

As in any child with an upper limb anomaly, it is important to perform a thorough examination from head to toe. As stated above, lower extremity abnormalities can be present in ULD and must be documented and appropriate referrals made if present. In the upper limb, the hand can be in a variety of positions, including facing backwards in some cases of type IV ULD, but a significantly short extremity is usually present. The elbow can be stable or unstable depending on ulna involvement, with restricted or absent forearm pronation/supination. The wrist may have some ulna deviation but is usually stable. Oligodactyly in the hand with varying degrees of deficiency in the fingers/thumb that are present is the usual clinical scenario. This can include underlying possible bony anomalies such as metacarpal synostosis or aberrant bony anatomy of the hand/fingers, which may represent further deforming forces. Syndactyly may also be present to varying degrees in the fingers.

Fig. 26.8 **(A)** Preoperative photograph and radiograph for pollicization (note the pronated position of the index finger). **(B)** Intraoperative photograph of design of incisions along with photograph of final closure. **(C)** Postoperative function. **(D)** Postoperative radiograph showing good stability at the base and open physes of the pollicized digit.

These children are usually of normal to above-normal intelligence and function very well. At times, adaptive devices can be very helpful with activities of daily living, and it is imperative that therapists are involved with the care of these patients. It should be noted that since these children are usually extremely functional, any surgery that is contemplated must have a specific goal to increase use/function prior to proceeding.

Clinical tips

ULD – evaluation for surgery

- Assess the child for proximal femoral focal deficiency, fibular and tibial deficiency, scoliosis, clubfeet, and absent patellae.
- Anomalies of the heart and hematopoietic systems are rare.
- The deficit in the hand can include ulnar, radial, or both sides of the hand.
- Carefully assess the function of the hand as well as radiographs since variable anatomy may be present and separation of digits may not be warranted.

Surgical treatment and postoperative care

While most ULD children are able to bring the hand to the mouth, some type IV children (radiohumeral synostosis) have his/her elbows fused in a position with the hand facing backwards. These children can benefit from a flexion osteotomy to put the hand in a position to reach the mouth. Importantly, this is usually not a rotational osteotomy as clinically it is apparent that most times the deformity is one of hyperextension, not rotation, based on the thumb position. The osteotomy is usually performed in the supracondylar region of the humerus. It is important to Doppler out and mark the course of the brachial artery prior to surgery. Also, removal of 1–2 cm of bone usually allows the osteotomy to be

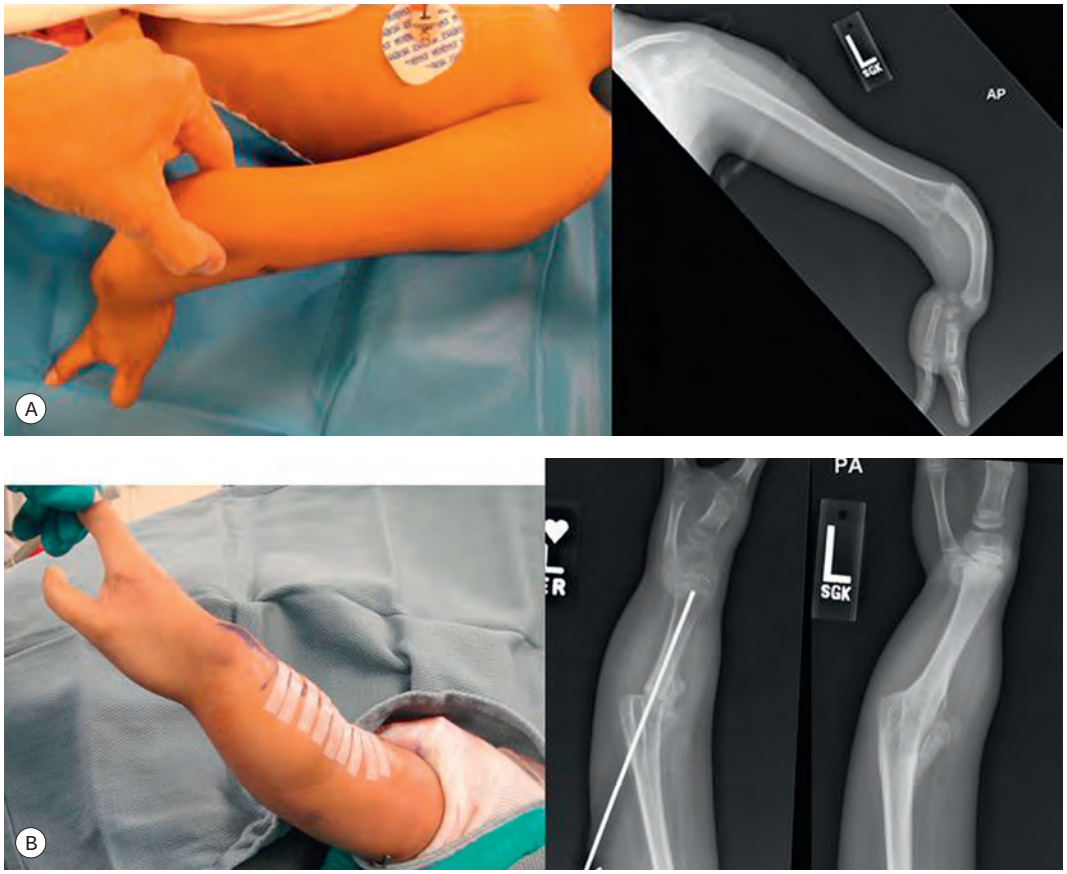

Fig. 26.11 **(A)** Preoperative photograph and radiograph of ULD with hand facing backwards. **(B)** Immediate postoperative photograph, immediate postoperative radiograph, and final follow-up radiograph.

performed without undue tension on the neurovascular structures, which is a potential serious complication. This osteotomy can usually be stabilized with K-wires +/− intraosseous wire. It is then held immobilized until radiographic evidence of union is noted (Fig. 26.11A,B). As expected, this will usually improve function in these children as it enables them to reach the hand to the mouth.

In some patients, release of the ulnar anlage can be beneficial as it acts as a tether that can cause increasing deformity, radial bowing, and ulnar wrist deviation as the child grows (usually type II or IV). Interestingly, histology of this structure has shown it to be hyaline cartilage proximally and fibrocartilage more distally. Serial X-rays and clinical examinations will determine the appropriate patients and timing for the surgery as not all ULD patients will benefit from this. Of note, this should be done when the patient still has significant radial growth potential remaining, as release of the tether will allow correction of much of the angular deformity over time. To do this, an incision is made over the ulnar border of the forearm/wrist with careful identification of the ulnar neurovascular bundle, if present, as the flexor carpi ulnaris is usually not present. It is essential to completely dissect out and release the distal portion of the anlage which attaches to the carpus and sometimes the radius. After this is performed, the "tether" effect should be alleviated and passive motion should be markedly improved. If severe bowing is present or not much growth remains in the radius, then an osteotomy can be performed at the same setting. The extremity is then casted until wound healing has taken place (bone healing if osteotomy was performed) (Fig. 26.12A–C). Stretching and splinting is instituted along with serial follow-up radiographs.

The majority of surgical procedures in ULD patients are usually focused on the hand. Depending on the type of hand deformity present, surgery can involve first webspace reconstruction, syndactyly reconstruction, and/or thumb reconstruction (Fig. 26.13A,B). It is imperative that a thorough clinical and radiographic examination be performed prior to contemplating any surgical reconstruction. Because of the unusual anatomy that can exist, no syndactyly reconstruction is warranted and/or feasible at times (Fig. 26.14A,B). Also, when syndactyly reconstruction is undertaken, careful exploration of the neurovascular and tendinous structures is warranted since at times separation is not technically feasible. First webspace reconstruction is accomplished either through standard webspace deepening techniques or flap reconstruction in severe cases. A difficult situation exists when the thumb is in the plane of the palm. Since opposition function is so crucial in these patients, performing a rotational osteotomy through the metacarpal can be helpful. However, significant memory in the periosteum and other deforming forces can exist and can cause recurrence of the deformity. To address these, the periosteum should be scored circumferentially as well as a release and re-insertion of the adductor and thenars, if present. At times, opposition transfer is also required to provide enhanced function of the thumb.

Outcomes, prognosis, and complications

ULD is less common than RLD and is distinguished from it in several important ways. As opposed to RLD, patients with ULD usually do not have associated cardiac, renal, gastrointestinal, or hematopoietic abnormalities. Instead, they can have associated musculoskeletal abnormalities and, therefore, a thorough lower extremity exam is warranted. Surgical treatment is usually centered on issues present in the hand including webspace insufficiency, syndactyly, and/or thumb (if present) position.

Central deficiency

Basic science/disease process

The etiology of central deficiency is thought to be a defect in the AER, which has been reproduced in the chick embryo by removing the central portion.[44] Of note, complex polysyndactyly and central deficiency are two phenotypes that can result from the same teratogen, and are thus related. This has been shown in eloquent experiments by Ogino (1990), who gave busulfan to a litter of rats, which resulted in both phenotypes (Fig. 26.15). A logical explanation for the sequence of this exists in his paper and is beyond the scope of this chapter.[45]

Autosomal-dominant inheritance pattern is present in many patients, and has been localized to chromosomes 3, 7, and 10. However, *de novo* mutations are also quite common. An interesting inherited central deficiency is EEC (ectrodactyly ectodermal dysplasia, cleft lip/palate), which has been localized to 7q11.2–q21.3. In this syndrome, central deficiencies can be present in all four limbs as well as cleft lip/palate, sparse and brittle hair, external ear abnormalities, hearing loss, ophthalmologic abnormalities, and genitourinary problems, although phenotypic expression is highly variable. Split-hand/split-foot syndrome also has an autosomal-dominant inheritance pattern with variable penetrance.

Diagnosis/patient presentation

In the original IFSSH classification, this was I.B.3. In the OMT classification, cleft hand is 3.11.c. Manske (1995) published a classification that is useful in guiding treatment in these patients.[46] His classification is based on the first webspace: type 1, normal web; type 2A, thumb web mildly narrowed; type 2B, thumb web severely narrowed; type 3, syndactylized web; type 4, thumb web merged with cleft with index finger suppressed; and type 5, absent thumb and web suppressed with ulna ray remaining.[46]

Patient selection

Because of the phenotypic variability, it is imperative to examine the entire patient. Classically, the cleft deformity in the hands and feet has been described as "V" shaped; but in the monodactylous form, only the ulnar digit may be present. Syndactyly between digits adjacent to the cleft is common, as is variable metacarpal and phalangeal anatomy. Evaluation of ectodermal-derived structures is also important because of possible EEC syndrome. Radiographs yield important information regarding underlying bony abnormality as well as possible presence of aberrant osseous structures.

As in other patients with congenital hand differences, therapists are essential members of the team as they provide teaching as well as assistive devices if necessary.

Surgical treatment and postoperative care

Adrian Flatt commented that these patients are "a functional triumph and social disaster", meaning that these patients are very functional and any considerations for surgery should take this into account, especially when deciding to operate on

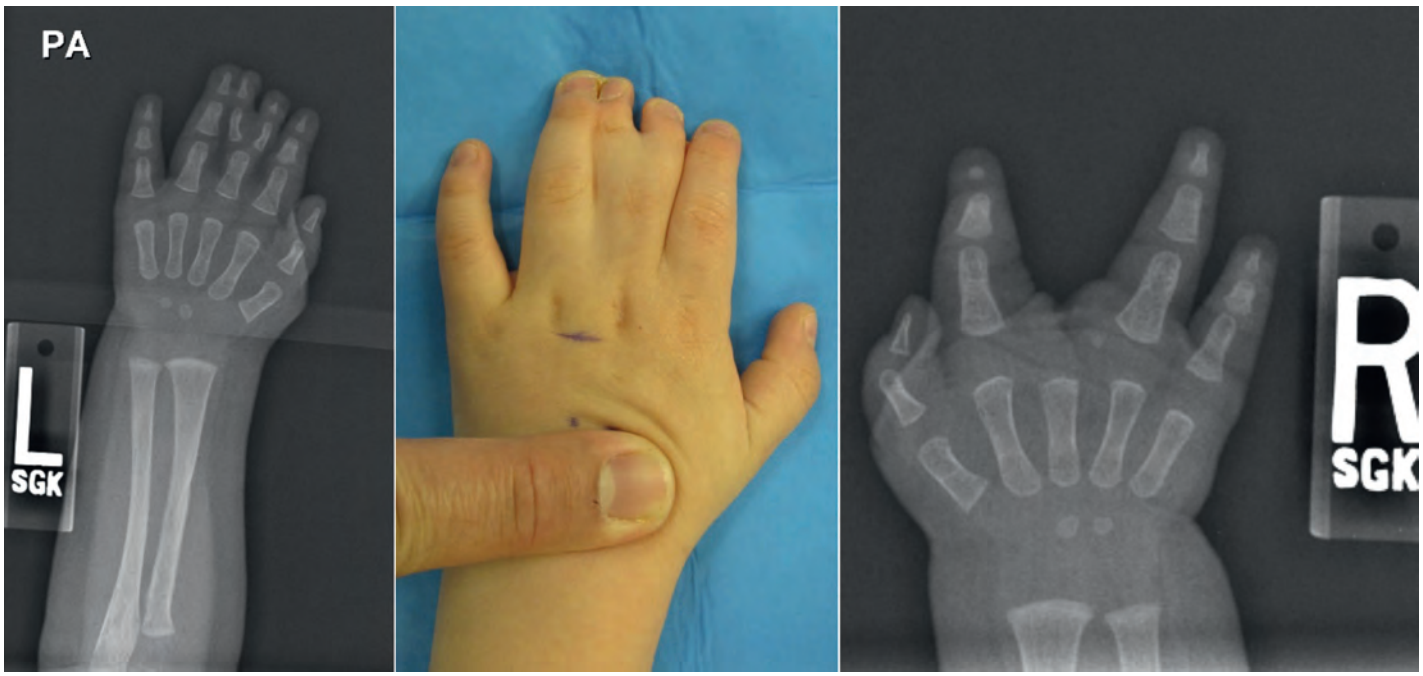

Fig. 26.15 Cleft hand and central synpolydactyly hand in same patient.

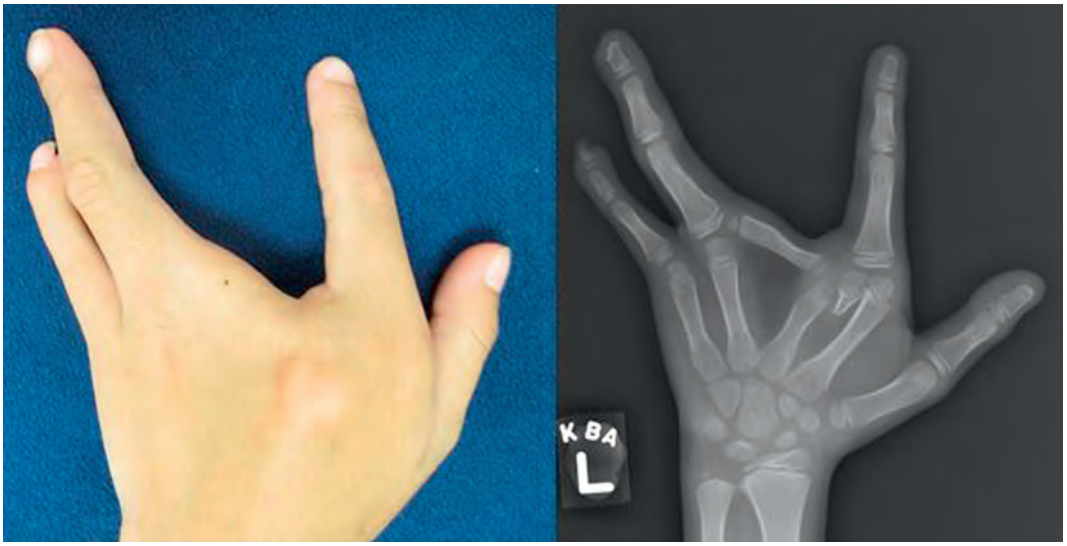

Fig. 26.16 Cleft hand with transverse element.

a cleft solely for cosmetic reasons.[47] Certainly Manske's classification offers generalized principals for treatment based on the importance of the first webspace for grasp. Creating an adequate first webspace certainly provides increased grasp and is of significant benefit to the patient. Depending on underlying anatomy, the thumb–index fingers may be better left together, based on clinical examination and radiographic appearance.

At times there can be a transverse bone present in cleft hands and, if not addressed, this can be a significant deforming force as the child grows (Fig. 26.16). Excision at the base of the transverse bone should ensure removal of potential physis of the transverse bone to decrease risk of recurrence. In addition, underlying structures such as the collateral ligaments may need to be repaired/reconstructed after removal of the transverse bone.

If thumb–index finger release is to be performed along with cleft closure (types 2B and 3), many techniques have been described. Popular skin incision designs that are utilized include Snow–Littler,[48] Miura–Komada,[49] and more recently Upton.[50] I prefer a slightly modified version of Upton, as the design is much simpler and the risk of wound problems is much less than that seen in the Snow–Littler and Miura–Komada procedures (Fig. 26.17A–C). After the skin incisions are made, meticulous technique must be utilized to preserve vascularity of the skin flaps, as partial or moderate skin flap loss can be a frequent complication. No matter which incision is used, it is imperative that thorough exploration of the neurovascular structures is performed to assure the anatomy will allow transposition and closure of the cleft without undue risk to the digit. Also, assessment of the adductor muscle insertion is essential and re-positioning performed, if warranted, as it sometimes is attached to the index finger. Fascia and other aberrant muscle may also need to be released in order to adequately release the first web. After this is performed, transposition of the index metacarpal to the middle metacarpal is performed if technically feasible. The origin of the adductor muscle off the middle metacarpal is carefully identified and preserved, with the index metacarpal being transposed just distal to this point after adjusting for appropriate length. This can be stabilized with K-wires, interosseous wires, or a combination of both. If a third metacarpal is not present, an osteotomy at the base of the index metacarpal can help with re-positioning the finger in the plane of the ring and little finger. In either case, reconstruction of an intermetacarpal ligament is performed using bone tunnels and local tissue such as A1 pulleys, free tendon graft, or a combination of these.

In cases of central clefts with a normal thumb–index web, closure can be performed with local flaps producing good results in terms of function and aesthetic appearance. Usually transposition of the metacarpal is warranted as well as reconstruction of the intermetacarpal ligament using localized tissue or graft.

In some cases, no separation/closure should be performed since the function is good and any attempts at separation and transposition may actually make the digits unstable.

In cases of four-limb involvement, where the pediatric orthopedists are planning Symes amputation, consideration should be given to use of toes as a potential transfer to the hand, if indicated, to improve overall function, especially if a type 5 cleft (absent thumb) is present.

Outcomes, prognosis, and complications

In summary, it is imperative that every patient be evaluated separately and decisions regarding surgical intervention be made on a case-by-case basis. Surgery should be reserved for patients in whom improved function and cosmetic appearance can be achieved with minimal potential morbidity. If patients are not selected appropriately, poor outcomes along with significant scarring can occur.

Transverse deficiencies

Basic science/disease process

As mentioned earlier, this condition is thought to be caused by disruption of the subclavian vascular axis as described by Bavinck and Weaver.[6] They hypothesize that occlusions occur at specific locations around the sixth week of embryonic

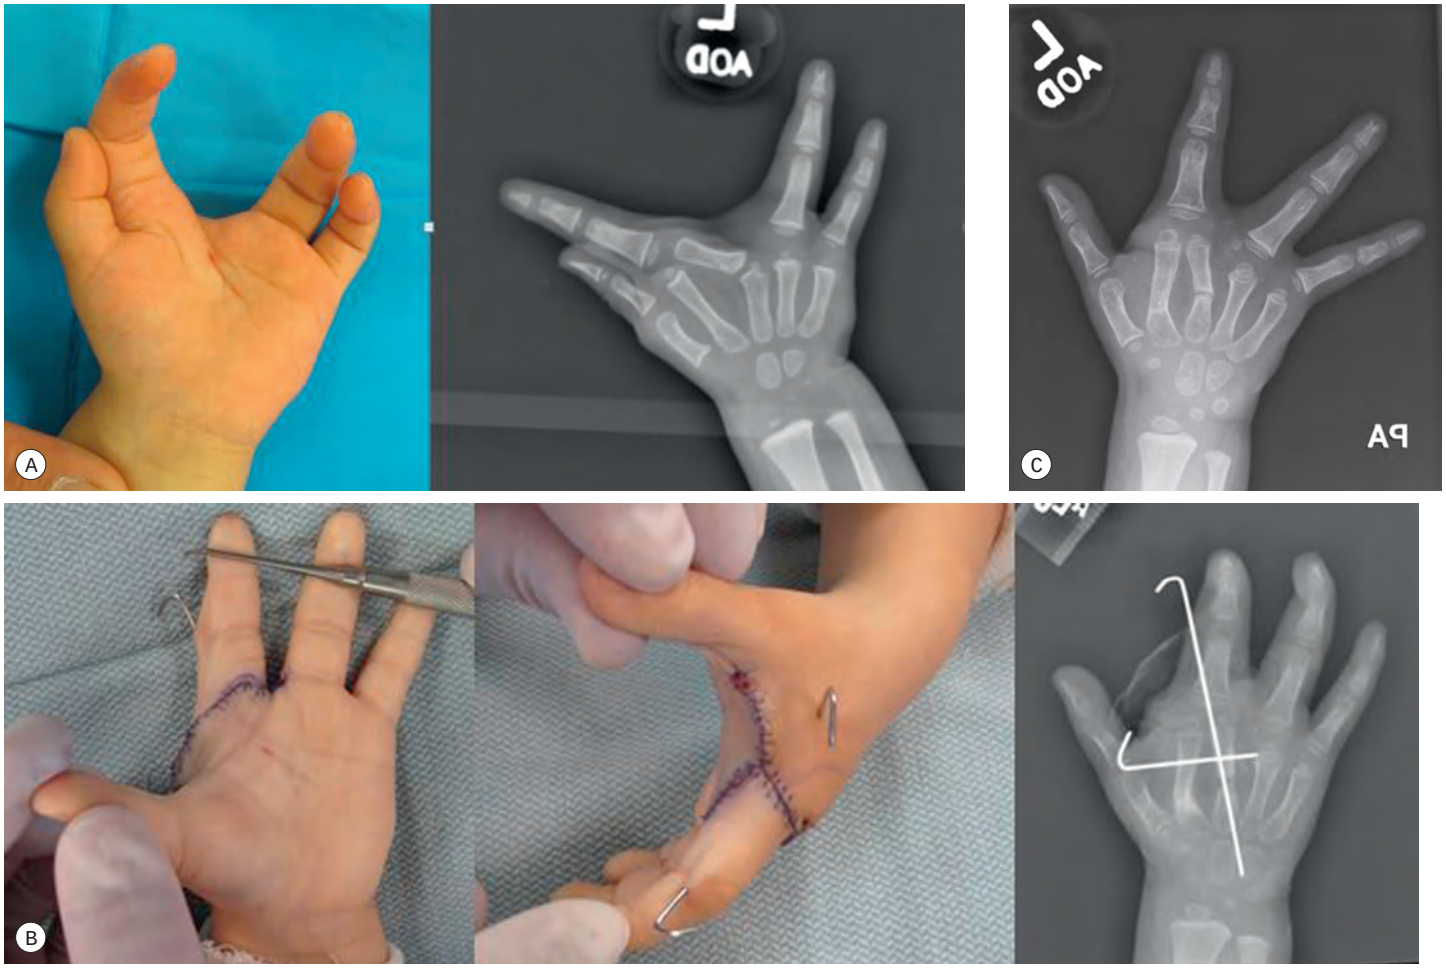

Fig. 26.17 **(A)** Preoperative photograph and radiograph of a cleft hand. **(B)** Intraoperative photographs and follow-up radiograph. **(C)** Final follow-up radiograph.

development. Depending on the timing and location of the insult, different phenotypes may arise. In addition, there may be associated findings of Poland's (varying amounts of pectoralis muscle absence), Moebius syndrome, Klippel–Feil, and even Sprengel deformity.[6]

No animal model has been developed that re-creates this deformity. This is usually a sporadic occurrence that presents unilaterally. Four-limb transverse deficiency associated with aplasia cutis congenita is the exception (Adams–Oliver) and can have either an autosomal-dominant or recessive inheritance pattern.

An interesting transverse deficiency has been reported from our institution that we feel has a different etiology than symbrachydactyly.[51] The phenotypical presentation is that of a transverse deficiency with no ectodermal elements in affected digits. Instead, fleshy bulbous soft-tissue sleeves are present, and the severity seems to be most on the ulnar side of the hand (Fig. 26.18). Because of the lack of ectodermal elements and involvement pattern, we feel that this represents a different etiology than the more commonly occurring symbrachydactyly (subclavian artery supply disruption sequence).

Diagnosis/patient presentation

This is one of the diagnoses that did not clearly fit into any of the categories that Swanson described in his classification system. In the OMT system, this is I.A.1.ii(a,b) for whole limb or I.B.1.ii for hand plate alone without forearm/arm involvement.[11] The diagnostic phenotype shows great diversity, including short-finger type, monodactylous type, atypical type, and peromelic type. As opposed to patients with central deficiency which have a "V" deformity, these patients display a "U" deformity along with nubbins (remnants of ectoderm). Interestingly, Poland's is usually seen more commonly with the short-finger variant than with the peromelic type.

Patient selection

Examination of these patients should begin in the head and neck region to assess for possible Moebius syndrome. Next, a careful examination of the neck and trunk for clinical evidence of Klippel–Feil, Sprengel's, and/or Poland's is warranted. In children with Poland's, the findings can be solely a lack of the sternal head of the pectoralis major or be the entire muscle with involvement of the chest wall with involvement of the pectoralis minor and latissimus dorsi muscles. In infants, it can be very difficult to identify the very mild cases of Poland's and reassessment at a later date is necessary. The findings in the upper extremity can be divided into four types: (1) short-finger type, (2) monodactylous type, (3) atypical cleft type, and (4) peromelic type (Fig. 26.19A–D). In patients with the peromelic type, the level of truncation can be the hand, carpus,

Fig. 26.18 Hypodactylia (note the lack of ectodermal elements).

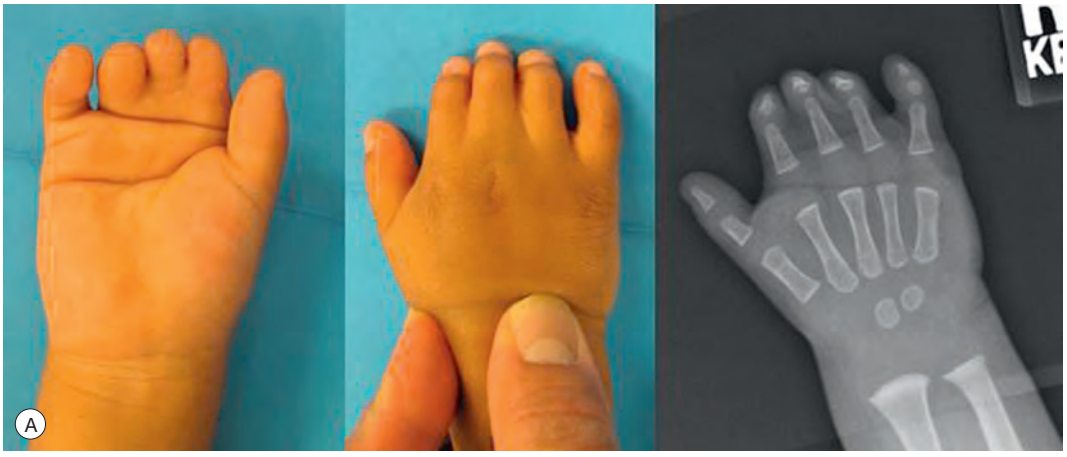

Fig. 26.19 **(A)** Short finger symbrachydactyly. **(B)** Monodactylous symbrachydactyly. **(C)** Atypical symbrachydactyly. **(D)** Peromelic symbrachydactyly.

Fig. 26.20 Adaptive devices for activities.

or forearm, with nubbins being present distally. Ogino (1989) reported the order of radiographic findings found in the progression of symbrachydactyly. The most common finding in all types was hypoplasia of the central rays followed by progressive brachymesophalangia leading to absence of middle phalanges then more proximally to include metacarpals.[52] Many times, the middle phalanx hypoplasia can be significant enough to affect joint motion at the proximal interphalangeal and distal interphalangeal joints. Even in severe forms of symbrachydactyly (peromelic), nubbins consisting of nail and underlying distal phalanx are present as these are derived from ectodermal tissue.

Clinical tips

Transverse deficiencies – evaluation for surgery

- Clinical evaluation of the entire patient is necessary as multiple associated findings may exist.
- It is important to remember that untreated patients function very well, so any surgery, except syndactyly reconstruction, needs to be assessed on an individual case basis and should only be performed if there is a realistic goal of increasing function.
- If a syndactyly exists but the finger tips are separated and no significant tethering exists, reconstruction should be delayed until the child is 2–3 years of age as to minimize possible effects of anesthesia as well as to allow the fingers to be bigger and easier to perform surgery on.

Surprisingly, these patients usually have very few limitations, even with the most severe form. Most do not benefit from prostheses as they are most commonly passive, insensate devices and actually impair function in these children. For patients and parents that are interested, reports of 3D-printer prostheses have emerged and initial data is promising as a cheaper alternative to myoelectric devices, which can be very costly.[53] Prostheses made to aid with specific activities, however, can be very useful. These are usually custom-made to suit the needs of the child and enable them to more easily perform activities such as jumping rope, riding bikes, and sports (Fig. 26.20).

Surgical treatment and postoperative care

Parents of patients with the peromelic type of symbrachydactyly can occasionally desire removal of the nubbins for cosmetic reasons or because they frequently get traumatized. In my experience, this is a rare occurrence and most parents prefer to leave the nubbins and let the child make their own decision when they are older regarding excision. At that time it is extremely rare that they desire any surgery for this.

Short-finger type symbrachydactyly patients often have webspaces that can benefit from deepening. The timing of this depends on the severity and webspaces involved. In general, because of the new reports of potential harm from general anesthesia in young patients, we try not to perform this surgery until after 2 years of age.[54] Exceptions would be if significant tethering of digits is present and/or significant first webspace narrowing, in which case surgery would be performed at an earlier age. If the middle phalanges are severely hypoplastic, it is important to discuss with the parents that even after separation the fingers may not have full range of motion, so that they have realistic expectations.

Non-vascularized toe phalanx transfer has been advocated by some in certain forms of symbrachydactyly to provide more length to the fingers.[55] In this procedure, portions of toe phalanges, including periosteum, are transferred to soft-tissue sleeves in the hand to provide more length. This must be performed at a very young age for optimal results. Despite some encouraging results, long-term studies show variable amounts of reabsorption along with significant donor site morbidity[56] (Fig. 26.21). Due to our own experience, and that of others, we are not advocates of this procedure.

Free vascularized toe transfers can be extremely beneficial to patients with the monodactylous form of symbrachydactyly, as it adds an ulnar digit which can provide increased grasp capabilities (Fig. 26.22). In this procedure, usually the second toe is harvested and transferred using standard

Fig. 26.21 Patient who underwent non-vascularized toe transfer to the right hand (left) with bone graft resorption and poor donor site (right).

microvascular techniques to the ulnar side of the hand in a position that allows tip-to-tip pinch with the thumb. Flexor function of the transferred digit can be very difficult to achieve as the recipient flexor tendons tend to be coalesced together in the distal wrist/carpal tunnel region. As stated above, these patients are usually very functional with very few limitations and they (along with parents) usually do not desire to pursue this procedure.

Patients with Poland's present a very difficult problem for the reconstructive surgeon. Some patients do not like the lack of fullness in the anterior axillary fold as they feel it draws unwanted attention and also limits what can be worn due to the asymmetry. In these children, I assess them for presence of ipsilateral latissimus dorsi muscle and, if present, discuss potential rotational flap to address this. In the young child, this can be performed with very limited incisions, thereby having limited morbidity. In my experience, this has yielded excellent results and happy patients/parents. In patients/parents that are interested, I perform this procedure at the age of 8–10 years. Girls present a very difficult reconstruction, as not only do they require breast reconstruction, but also the

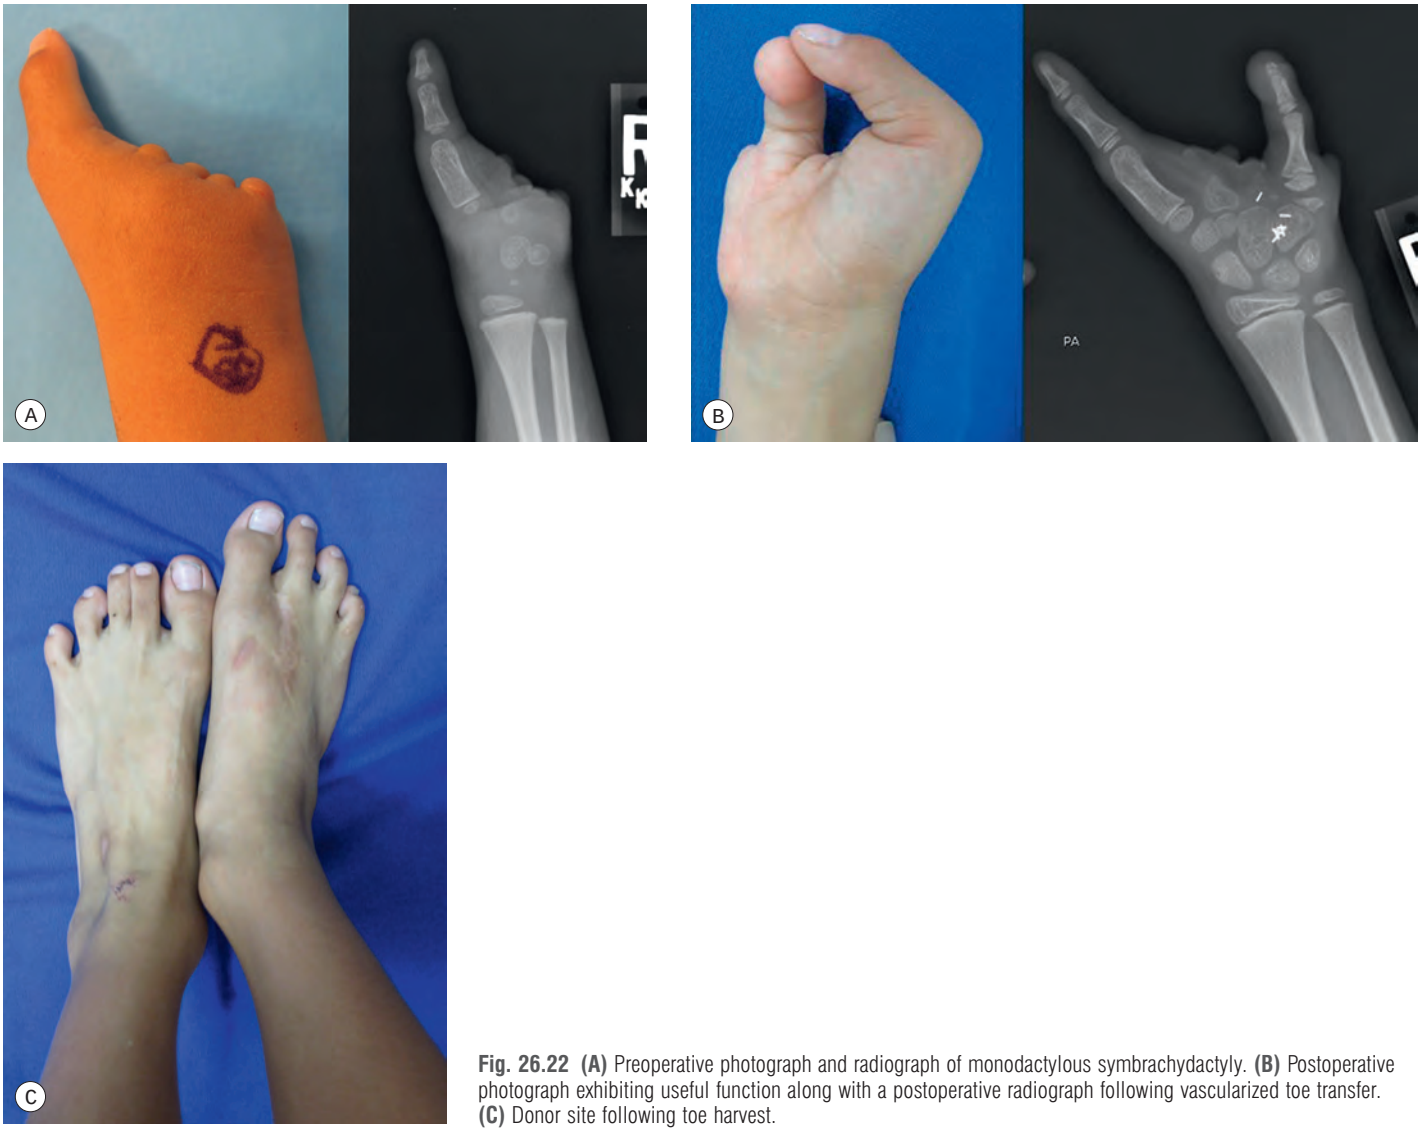

Fig. 26.22 **(A)** Preoperative photograph and radiograph of monodactylous symbrachydactyly. **(B)** Postoperative photograph exhibiting useful function along with a postoperative radiograph following vascularized toe transfer. **(C)** Donor site following toe harvest.

nipple is usually severely hypoplastic and in an aberrant location. In early teenage years, an expander can be placed with serial expansion until adulthood, at which point replacement with a permanent implant is performed along with nipple repositioning/reconstruction.

Outcomes, prognosis, and complications

Phenotypic variation is common in patients with transverse deficiency. Treatment depends on what, if any, deformity is present and can range from syndactyly reconstruction to free vascularized toe transfer. These patients usually are very functional and have an excellent long-term prognosis.

Future directions

For now, even though many RLD patients have genetic mutations that can be identified, it is hard to believe that any genetic manipulation is on the horizon that can alter the phenotypical presentation, as upper extremity development occurs very early in gestation. Likely alternative procedures that provide stability and position of the wrist with retained motion long term are possibly in our near future. Perhaps this will include a variation of the procedure Innocenti[57] uses for reconstruction after tumor excision in the distal radius. He utilizes a vascularized fibular head, which provides potential benefits of good stability of the wrist, retained motion, and growth potential, which is likely similar to that of the ulna. In addition, a portion of the biceps tendon can be taken with the fibular head to be used for ligamentous reconstruction in the wrist. At this point, the potential complication of peroneal nerve injury has limited its use. However, with improved dissection techniques and anatomical studies, this risk is likely to be decreased in the future. It is important to remember, however, that untreated patients are very functional, so any surgical intervention is largely cosmetic in nature and must not inhibit or worsen function.

As stated earlier, prosthetic hands/arms in the past have been of very little functional use for congenital upper extremity-absence patients, as they have been insensate and non-functional. Recently there have been significant advances in the development of functional myoelectric prostheses following traumatic amputation that may be of some value to selected congenital absence patients in the future.[58,59] However, these tend to be very costly, and recently there have been reports of 3D printing being a cheaper alternative.[53]

Although vascularized composite allografting (VCA) has become more accepted, its significant morbidities make it unlikely to become commonplace treatment for these patients. Perhaps tissue engineering for generation/regeneration of fingers/limbs may be a possible alternative if cell expansion can be perfected to the point of making it a viable option; however, this is likely many years away.[60]

Longitudinal, central, and transverse deficiencies are diagnoses that are treated often by the pediatric hand surgeon. It is imperative that the surgeon treating these conditions is knowledgeable regarding the proper work-up that should be performed for each condition, as well as appropriate referrals and genetic counseling that should be obtained. These patients are usually seen and treated from infancy until adulthood and thus go through many stages of physical and psychological development, which must be addressed. In fact, some of the social issues far outweigh any decision-making regarding surgery. These patients are usually very functional, so careful consideration before proceeding with surgery is warranted. Lastly, it is imperative to have a multidisciplinary team to properly evaluate and treat these children as their needs are certainly not static or identical in nature.

Congenital hand III: Thumb hypoplasia

Amir Taghinia and Joseph Upton III

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- The thumb ray is the prime ray of the hand – its size, position, mobility, independence, and relations to the other digits are critical to function.
- The thumb is considered hypoplastic if any portion of the ray, skeletal or soft tissue, is deficient or absent.
- Growth and function of the thumb in the first year of life follows a predictable pattern.
- Although new procedures have expanded options for reconstruction, standard procedures such as first webspace deepening, tendon transfers, and collateral ligament reconstruction remain the best options for treatment.
- Pollicization continues to be the treatment of choice for severe hypoplasia with a non-functional carpometacarpal joint, the floating thumb, or the absent thumb.
- Associated conditions of thumb hyperplasia include VACTERL, Fanconi anemia and other hematologic abnormalities, Holt–Oram syndrome, and thrombocytopenia absent radius (TAR) syndrome.

Introduction

The hypoplastic thumb represents a wide spectrum of functional and aesthetic differences. Before classification and management of the deficient thumb, a careful surgeon must assess its: (1) size; (2) position; (3) relation to other fingers of the hand; (4) osseous components; (5) joint integrity and stability; (6) intrinsic and extrinsic musculotendinous units; (7) first webspace depth and width; (8) associated malformations of the hand and elsewhere; and (9) functional consequences for the child. A thumb should be considered hypoplastic when there is a deficiency of any one or all structures that contribute to the "normal" thumb. In the past, all definitions were restricted to the radiographic appearance alone; however, presently, we understand that soft-tissue deficiencies also contribute to the overall diagnosis.

For the first 3 months of life, the thumb is adducted and flexed within the palm and serves primarily as a pacifier. However, by 9 months of age, this first ray gains its independence and mobility from the palm, and at 1 year of age, it has become a crucial portion of the hand.[15] In the normal hand, the strength and mobility needed for a wide variety of pinch and grasp functions rapidly develop, and by the time the baby is ambulatory, the thumb is used creatively and independently to manipulate the environment.

As relied upon in the past, a complete evaluation of the osteoarticular column will require plain radiographs. Normal primary ossification centers of the phalanges and metacarpal of the thumb appear in the second to fourth fetal months, but abnormalities of the skeleton of the thumb (e.g., triangular or trapezoidal bones) may not be seen radiographically until well into the first or second year of life. Secondary ossification centers within the epiphyses of the thumb normally appear between 13 months to 4 years of age.[16] The delayed appearance of both primary and secondary ossification centers in the hypoplastic thumb is highly relevant to the diagnostic process because their appearance is often delayed in proportion to the degree of hypoplasia.

Basic science/disease process

Incidence

The true incidence of thumb hypoplasia is difficult to determine due to the large number of congenital malformations within which a hypoplastic thumb is a component part. All reported reviews are subject to study of the genetic composition of the patient population as well as any discrepancies of nomenclature and sampling. Entin[17,18] reported a 16%

Historical perspective

The history of thumb reconstruction mirrors the development of hand surgery as a subspecialty. As such, advances in diagnosis, classification, and treatment of these conditions are relatively new – having occurred in the past 6 decades. Because many children with thumb anomalies have more serious conditions, advances in anesthesia also had to take place to make surgery safer and more predictable.

In terms of diagnosis and classification, Flatt stressed function potential and designated the digits as "adequate" or "inadequate"[1,2]; Bayne relied upon localized positions of deficiencies[3]; and three generations of German authors referred to the degree of skeletal hypoplasia.[4–6] The system proposed by Blauth recognizes the progressive degree of hypoplasia from a slight size discrepancy, with all normal structures present, to total aplasia of the thumb. In time, this system has been amended by others,[7,8] who subdivided type III (severe hypoplasia) into two groups – those with an intact carpometacarpal (CMC) joint (IIIA) and those without (IIIB) – and is very important in terms of management. Recently, Tonkin wrote a thorough summary of the grading systems, clarifying the definitions of grades of thumb hypoplasia, and proposing a modification of the Blauth classification.[9]

Progress in the treatment of thumb hypoplasia mirrored advances in diagnosis and classification. Working independently in Europe, Gosset[10] and Hilgenfeldt[11] developed the procedure of digital transposition for post-traumatic thumb losses. In the decades following World War II, Bunnell described similar digital transpositions.[12] Littler[13] refined their techniques and applied them to congenital differences. Following the thalidomide crisis in Europe, Buck-Gramcko[14] amassed a large clinical experience and set present day standards for pollicization.

incidence of thumb hypoplasia in his Canadian patients, while Flatt published an 11.2% incidence of thumb abnormalities and a 3.6% incidence of thumb hypoplasia or aplasia from his clinic in Iowa.[2] We have seen a 37% incidence within our entire registry, which includes many additional categories.[19] The majority of the children treated surgically are those with radial dysplasia – with and without a partial or complete absence of the radius. We have also seen a high incidence in syndromic patients, such as those with the Apert syndrome, who are commonly referred to large children's hospitals for treatment of their multiple malformations. Other populations include those with constriction ring syndrome (CRS), cleft hands, and symbrachydactyly hands, all of whom may have some degree of thumb hypoplasia.

Etiology

Because radial or preaxial longitudinal deficiencies occur in many conditions with a wide variety of etiologies, the causes for these malformations span the entire spectrum of genetic, environmental, teratogenic, and other factors (Table 27.1).[20] Therefore, consultation with a genetic specialist is strongly recommended, and referral to standard genetic textbooks or the Online Mendelian Inheritance in Man (OMIM) website (http://www.ncbi.nlm.nih.gov/omim) is a must for any pediatric hand surgeon.

Associated conditions

The many potential associations with thumb and radial hypoplasias and aplasia may involve any organ system within the body. Most significant are those with cardiovascular, gastrointestinal, and genitourinary involvement. Associated hematologic problems, specifically Fanconi anemia, can be detected early but usually become clinically apparent later in childhood. The most common of these associated conditions is outlined herein.

VACTERL

These children may have a wide spectrum of anomalies, including: **V**ertebral malformations; **A**nal atresia or hypoplasias; **C**ardiovascular anomalies; all degrees of **T**racheoesophageal fistuli; **E**sophageal atresia; **R**enal malformations, and **L**imb abnormalities – which in the upper extremity involve all degrees of radial dysplasia. A patient does not need to fulfill every category on this list to be considered VACTERL.

Fanconi anemia and other hematologic abnormalities[21]

Children with Fanconi anemia (FA) develop different degrees of pancytopenia, the most extreme of which can be life threatening.[22,23] Most of these children are small with growth restriction. Although many other organ systems may be abnormal, deficiencies of the thumb and, to a lesser extent, the entire radial ray are the most common and are present at birth in over half of these cases. Although in the past FA children were rarely diagnosed early in life, this condition can be diagnosed any time with a diepoxybutane (DEB) test.[22,24] Recently, Webb, *et al*.[25] looked at the incidence of Fanconi anemia in children with congenital thumb anomalies referred for DEB testing in a tertiary care pediatric center, and found that of 81 patients with thumb anomalies who underwent testing, six had a positive test (7%). The authors noted that patients with thumb hypoplasia *and* other associated conditions such as café-au-lait spots and short stature appear to be at increased risk of FA. Treatment of FA children with oxymetholone and prednisone therapy has a 70% response rate, and non-responders can be treated with bone marrow transplantation.[22] In 40

Saethre–Chotzen syndrome	

[a,b,c,d]Refers to the hypoplasia/aplasia associations of the listed syndromes. For example, Aase syndrome has both thumb and radial hypoplasia but Nager syndrome has just thumb hypoplasia.
(Data from Jones KL. *Smith's Recognizable Patterns of Human Malformations*, 5th edn. Philadelphia, PA: WB Saunders; 1997; and Rayan G, Upton J. *Congenital Hand Anomalies and Associated Syndromes*. Berlin: Springer-Verlag; 2014.)

years, the senior author has treated four children who died prematurely as a result of Fanconi anemia – children who could have potentially benefited from life-saving bone marrow transplant if the diagnosis was made early.

Clinical tips

Fanconi anemia

The low incidence of Fanconi anemia should be balanced against the life-threatening consequences of a missed diagnosis to guide testing in the current healthcare environment. The DEB tests costs between $1000 and $1200. The hematologists at our center have noted that all patients with Fanconi anemia have high mean corpuscular volume (MCV) on routine blood testing. Accordingly, one could consider DEB testing only in those patients with thumb hypoplasia who have high MCV and another clinical finding on examination (as noted above). Additional data is needed to lend credence to this consideration.

Holt–Oram syndrome

Two pediatricians, Dr. Holt in Philadelphia and Dr. Oram in London, independently described the association of congenital heart disease and radial longitudinal defects of the upper limb, and their names have subsequently been associated with all degrees of congenital cardiovascular malformations and radial dysplasia. Interestingly, there is no correlation between the severity of the anatomic deficiency in one system relative to the other. Common to the upper limbs are a stiff hypoplastic thumb joined to a stiff index digit by a complete simple syndactyly, radial deficiencies, and proximal radioulnar synostoses. Often, hypoplasia of the glenohumeral joint is not diagnosed until adolescence when shoulder abduction is diminished.

Thrombocytopenia absent radius syndrome (TAR)

This unique group of children may be born with normal hematologic parameters, but they usually have a low platelet count, which may decrease rapidly during the first year of life. They are easily distinguished from children with other types of radial dysplasia due to the presence of a thumb despite all degrees of radial deficiencies. The thumb is hypoplastic, and extrinsic flexion and extension vary tremendously. Thenar intrinsic muscles are usually present and provide some palmar abduction by age 2 years of age. The low platelet count commonly reaches normal levels by ages 4–5 years, and the clinical results from centralization are among the best.

Diagnosis and patient presentation

Classification

The varying degrees of differences between hypoplastic thumbs have been classified in a number of ways that have few common characteristics. Nevertheless, a well-accepted classification system has emerged that guides treatment. The five designated types of thumb hypoplasia–aplasia are shown in Fig. 27.1. These anomalies are commonly associated with radial (preaxial) dysplasia, and the majority of congenital hand surgeons consider most types of thumb hypoplasia with a normal radius as part of this spectrum. It is well recognized that there are concomitant soft-tissue anomalies that accompany the skeletal abnormalities. Since the correlation of soft-tissue and skeletal deficiencies has been so well defined, this refined system works very well for clinical decision-making.

Fig. 27.1 Thumb hypoplasia. Molds of the right hand in six children with the five classic types of thumb hypoplasia are displayed. Type III has been subclassified into two categories: one with an intact carpometacarpal (CMC) joint (IIIA) and one without an intact CMC joint (IIIB). The type IV is often called the *pouce flottant* or floating thumb.

The classification system proposed by Blauth[5] continues to be the most commonly used. The modification proposed by Manske[8] subdivides the type III thumb into those with stable carpometacarpal (CMC) joints and those with unstable CMC joints. This subdivision has significant implications for treatment, as the best reconstructive operation for the unstable CMC joint is index finger pollicization.

Hypoplasia of the thumb is associated with many other congenital differences, specifically central and transverse deficiencies. Because the anatomical make-up of the thumb does not always allow for easy categorization under the current system, we have included five additional categories,[19] which include the constriction ring syndrome, central deficiencies, radial duplication, the five-fingered hand, and short skeletal rays. In these conditions, the thumb ray usually has characteristic deficiencies that would fall into the German type II and III hypoplasia categories[5,26] and the anatomical abnormalities relevant to clinical decision-making will be presented here.

Clinical presentation (types of hypoplasia)

In the past, routine radiographs were the sole tool used for diagnosis of the hypoplastic thumb. However, this mode of assessment did not reveal any detail about the normal and abnormal soft-tissue structures of individual hands. Therefore, surgeons today use a more complete analysis of intrinsic muscles, webspace size, intrinsic muscles, extrinsic tendons, joint stability, and function – all of which impact directly upon treatment. It is difficult to adequately classify a hypoplastic thumb in a newborn infant. The authors have found it best to wait until the child is about 1 year of age, at which time physical characteristics and functional use are the main determinants of classification.

Clinical tips

Evaluating MP joint laxity

It is often quite difficult to differentiate between a normal and a lax metacarpophalangeal joint in an infant with thumb hypoplasia. Whereas absence of thenar musculature and a diminutive webspace are usually obvious, the MP joint is quite elastic and floppy in many normal infants. The authors have found that it is best to wait until the child is older to fully evaluate the MP joint. Functional observation of the older child can be as valuable a tool as physical examination. An older infant or younger toddler who can grasp a large object (such as a flashlight) in one hand using the thumb likely has a stable MP joint. Another who uses the thumb metacarpal head to stabilize the object likely has too much laxity and will need reconstruction.

Type I: mild hypoplasia

In this most mild type of hypoplasia, the thumb is slender and slightly shorter than a normally configured first ray (Fig. 27.2). The phalanges and metacarpal can be slightly thinner than usual, but the trapezium and scaphoid are present and the distal radius and styloid process are not affected. The interphalangeal (IP), metacarpophalangeal (MP), and CMC joints are stable and exhibit normal passive and active motion. While there may be a slight hypoplasia and weakness of the abductor pollicis brevis (AbPB), opponens pollicis (OP), and lateral head of the flexor pollicis brevis (FPB) muscles, all intrinsic muscles are present.[26] The joints, ligament and capsules, tendons, nerves, and vascular structures are all normal, and there may be minimal narrowing of the first webspace.

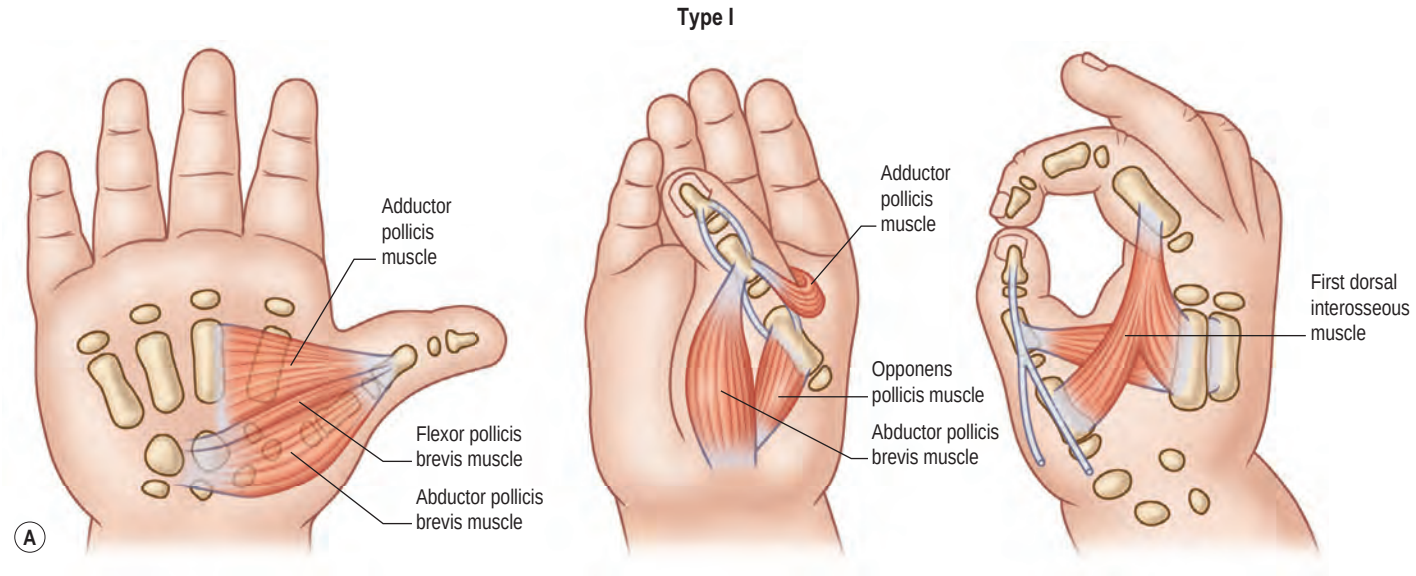

Fig. 27.2 Type I thumb hypoplasia – mild. **(A)** The skeletal ray is well segmented and may be short. All intrinsic muscles and extrinsic tendons are intact. First webspace narrowing is minimal to moderate. **(B)** Clinical appearance and **(C)** radiograph of a child who did not require any surgical correction. Although his thenar muscles are weak, there were no significant functional problems.

Type II: moderate hypoplasia

The metacarpal and phalanges are all present but small, and the trapezium, trapezoid, scaphoid, and – to a lesser extent – lunate may be hypoplastic. The first webspace is short with the thumb adducted, the ulnar collateral ligament at the MP joint lax, and median innervated thenar muscles underdeveloped or occasionally absent (Fig. 27.3).[27] Normally, the flexor pollicis brevis (FPB) and opponens pollicis (OP) are innervated by the median nerve, but the FPB varies, reported to be 40% median, 48% ulnar, and 12% both median and ulnar.[28] The ulnar innervated intrinsics, particularly the adductor pollicis (AddP), pull the metacarpal into adduction and narrow the first webspace, which, when explored surgically, has tight fibrous bands between muscle groups. Type II thumbs contain two neurovascular bundles, and the recurrent motor branch of the median nerve is consistently found.

Many different muscle and tendon anomalies seen on the radial side of the hand have been identified in conjunction with the type II and IIIA thumbs. In fact, the clinical designation of a given thumb may vary greatly due to this large spectrum of soft-tissue abnormalities. The absence of IP or MP flexion or extension creases in a slender thumb is the best clinical indicator of flexor and/or extensor abnormalities. Within this designation, many variations of the long flexor to the thumb (flexor pollicis longus; FPL) may be found. Both

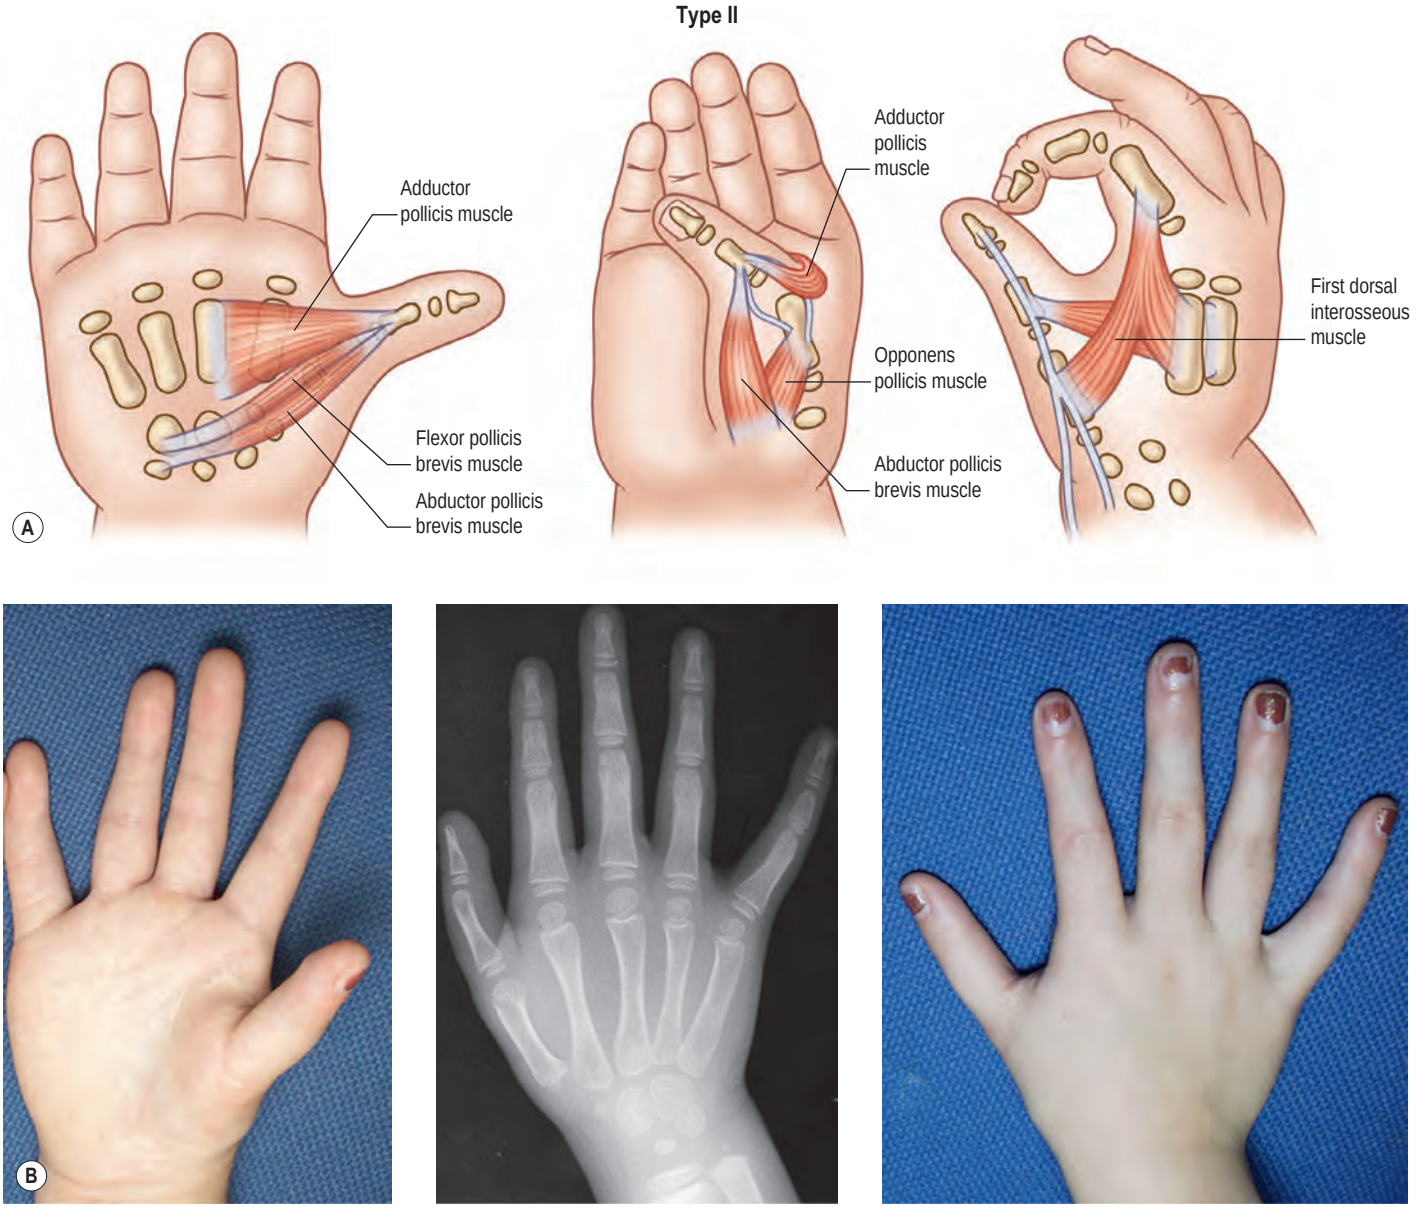

Fig. 27.3 Type II thumb hypoplasia – moderate. **(A)** There is minimal to moderate shortening of the skeletal ray. All bones are present and ligaments at the metacarpophalangeal (MP) joint may be lax. The ulnar innervated intrinsic muscles, adductor pollicis and first dorsal interosseous (second metacarpal origin) are strong, and the median innervated intrinsics are very weak. Anomalous anatomy is common. Adduction contractures from fibrous structures and MP joint instability accompany a deficient first webspace. **(B)** Clinical appearance and radiograph of a child with a type II hypoplasia of the right hand. The thenar intrinsic muscles are hypoplastic, the first webspace tight, and the thumb much narrower than normal. Key pinch was weak, and the patient could not hold heavy objects between the thumb and digits. In addition, the ulnar collateral ligament was weak at the MP joint.

the tendon and the muscle belly of the FPL may be abnormal,[29] may have proximal duplications,[30–34] and may have a more radial distal insertion.[31] In some patients, one can observe this muscle originating from the index profundus tendon,[31] the transverse carpal ligament, or the fascia of the thenar intrinsics and inserting into the flexor sheath[30] and/or the extensor mechanism.[35] In other cases, this muscle may be absent entirely.[36–40] Some of these anomalies may represent abnormal radial wrist extensors or short thumb abductors instead of malformed or malpositioned terminal thumb flexors.[41] Occasionally, a small abnormal "musculus lumbricalis pollicis" muscle may extend from the thumb origin across the first webspace and attach to the flexor system of the index finger.[42] We have seen this peculiar (atavistic) muscle extending across the first webspace in children with the Freeman–Sheldon syndrome and in complex thumb duplications at the metacarpal level.

The extrinsic extensors may have abnormal insertions,[43,44] extend over the MP joint in a non-centralized position, and reveal abnormal connections with the extrinsic flexor.[33,35,42,45] These abnormal insertions of both flexor and extensors, combined with their deviated course, conspire to make both tendons act primarily as radial deviators and not primary flexors or extensors. This deviation is further accentuated by the lax ulnar collateral ligament at the MP joint, resulting in more deviation. Tupper[45] has called this "pollex abductus" and noted that when these muscles contract, there is no IP flexion or extension, only abduction or radial deviation of the thumb. Many anatomical variations of this structure exist, but the functional result is the same (Fig. 27.4). A recent paper by Graham *et al*.[33] has summarized the large list of muscle and tendon abnormalities that often originate in the forearm. Although type II thumbs may present with these intratendinous connections, the abducted posture and wide degree of muscle and tendon anomalies are primarily seen with type IIIA thumbs (see Fig. 27.4). When followed proximally to the wrist and forearm level, many of these tendons have abnormal origins and long muscle bellies that extend well beyond the wrist into the metacarpal region.

Type III: severe hypoplasia

In these cases, the degree of skeletal shortening and narrowing is much more pronounced, particularly at the metacarpal level (Figs. 27.5 & 27.6). The hand and wrist may be radially deviated due to hypoplastic/aplastic carpal bones. The trapezium is usually very small, and frequently the scaphoid is absent. The distal radius is smaller in size and the styloid process absent, giving the radius a blunted appearance.[46] The extreme amount of anatomic variation within this group prompted Manske and colleagues to subdivide this group into type IIIA with a full-length metacarpal and an intact CMC joint and type IIIB with a tapered first metacarpal and no CMC joint.[8] Buck-Gramcko has included an additional variation called type IIIC thumb, which possesses only the metacarpal.[47] There are no tendons or muscles in this variant, and the skin bridge is much wider than that seen in type IV. In the B and C variants, a fibrous band may connect the hypoplastic metacarpal to a cartilaginous nubbin that represents either a trapezium or metacarpal base. Often, a small abductor pollicis tendon attaches to this remnant.

Median innervated intrinsic muscles are either severely hypoplastic or absent entirely; however, if they are present, they may actively flex the MP joint. The ulnar innervated AddP pulls the metacarpal medially. The MP joint is lax on both radial and ulnar sides and anatomically either collateral ligament and the volar plate may be severely hypoplastic or missing. The small thumb with a short webspace is abducted at the MP joint due to the frequent pollex abductus deformity. The radial origin of the first dorsal interosseous from the thumb metacarpal is more severely affected than that from the index metacarpal. In the forearm, radial head is usually hypoplastic and commonly subluxed, occasionally dislocated.

Abnormal anatomy is the rule. The many intrinsic and extrinsic anatomical variations described within the type II group may exist with greater degrees of hypoplasia. Usually, the extrinsic flexor and extensor are present and weak, but in some cases they may be missing.[36,40,43] The flexor retinaculum is poorly developed with either attenuation or absence of the major pulleys. In some patients, the motor branch of the median nerve is absent, and there may only be one neurovascular bundle.[31] The radial origin of the first dorsal interosseous to the index finger is severely hypoplastic, and the first webspace is severely restricted. Pollex abductus anomalies are common and must be recognized and corrected if IP flexion and/or extension is to be achieved.

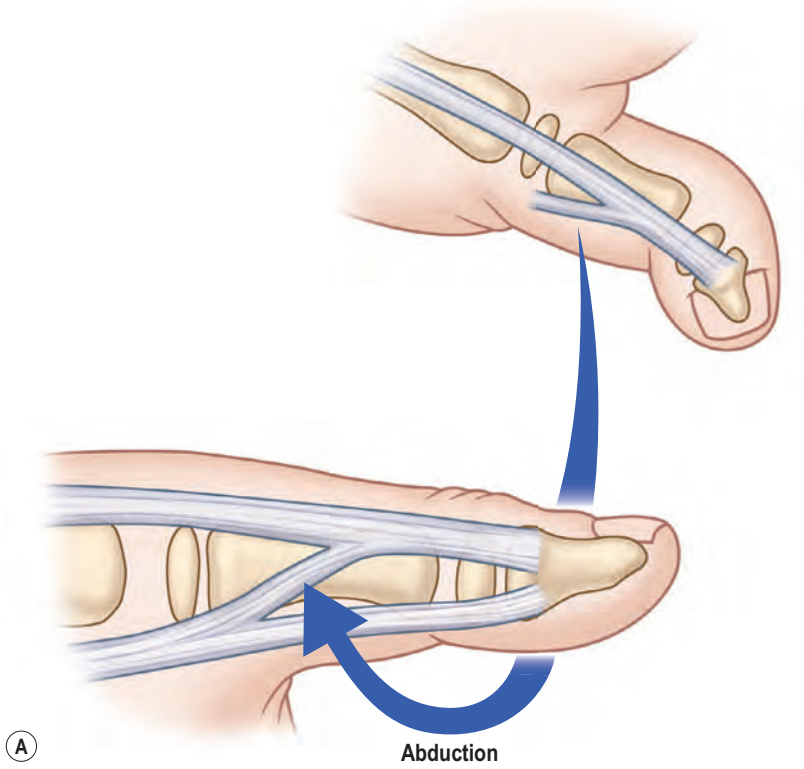
Type IV: floating thumb

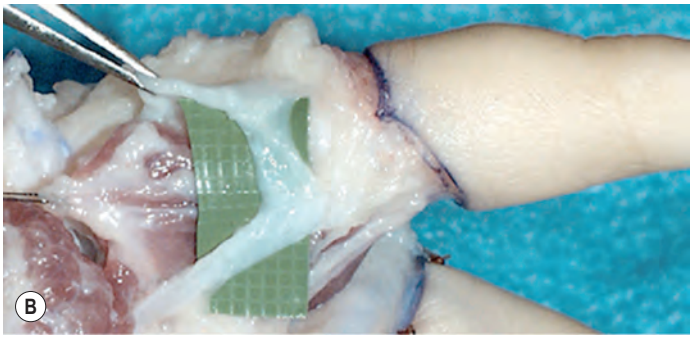
These thumbs (*pouce flottant*, French; *pendeldaumen*, German) arise distally from the palm and usually lie along the radial midaxial border (Fig. 27.7). They are attached only by a soft-tissue pedicle, which has been described by Littler as "Nature's own neurovascular pedicle", due to the presence of a digital artery, two vena comitantes, and one or two nerves within the skin bridge.[48,49] There may be anomalous vascular or neural rings, involving neurovascular structures[15] that could affect the outcome of a pollicization. There is no metacarpal, and two small phalanges tend to be present within the soft-tissue envelope, which contains a nail. It is important to note that a diminutive nail represents the presence of a distal phalanx. Intrinsic muscles do not insert onto these bones. A first dorsal interosseous muscle (abductor indicis) may be detected by abduction of the index finger. At the carpal level, the trapezium and less often the scaphoid are missing. The radial styloid may be absent, but the distal end of the radius is normal in most of these children.

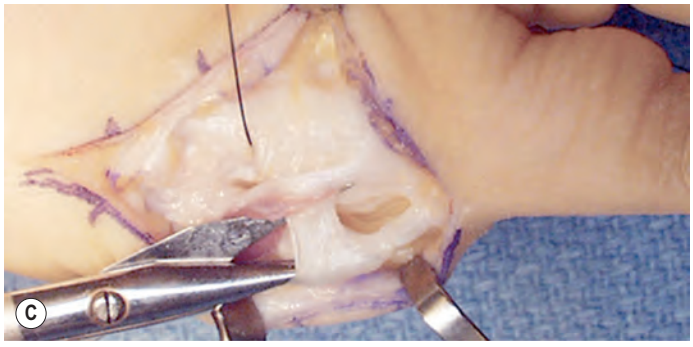
Clinical tips

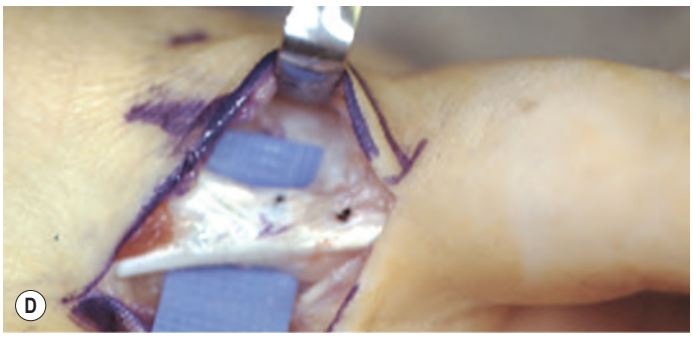
Aesthetic augmentation

The *pouce flottant* in type IV or the ablated thumb in type IIIB thumbs can be used for additional bulk in the thenar area. The technique is easy and improves appearance in these deficient hands. The part is stripped of skin, nail, and skeletal elements and rendered a vascularized adipofascial flap based on its original blood supply. It is then transposed into the thenar area at the conclusion of the procedure for additional bulk.[49]









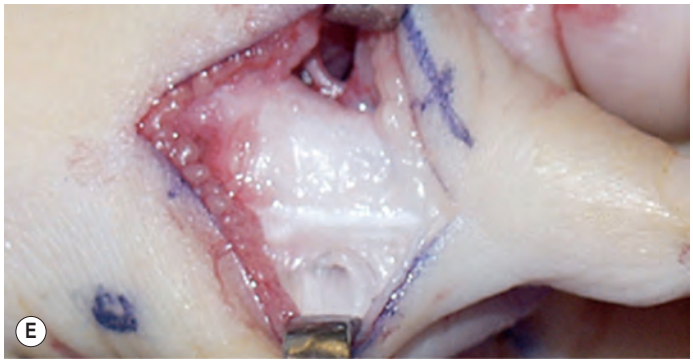


Fig. 27.4 Pollex abductus. **(A)** In severe type II and many type III thumbs, there may be very little, if any, interphalangeal joint flexion and there may be a radial deviation of the thumb at the metacarpophalangeal (MP) joint. This is due to the abduction force created by the combined action of the extrinsic flexor and extensor tendons joined by intertendinous connections, the "pollex abductus". **(B–E)** Within types II and III thumb hypoplasias (and proximal thumb polydactylies), a very wide spectrum of intratendinous connections may vary between a wide, loose, almost areolar band (top) to a complete coalition the flexor and extensor into a single tendon. With excursion from either the flexor or extensor side, the resultant movement in all these thumbs is abduction of the MP joint.

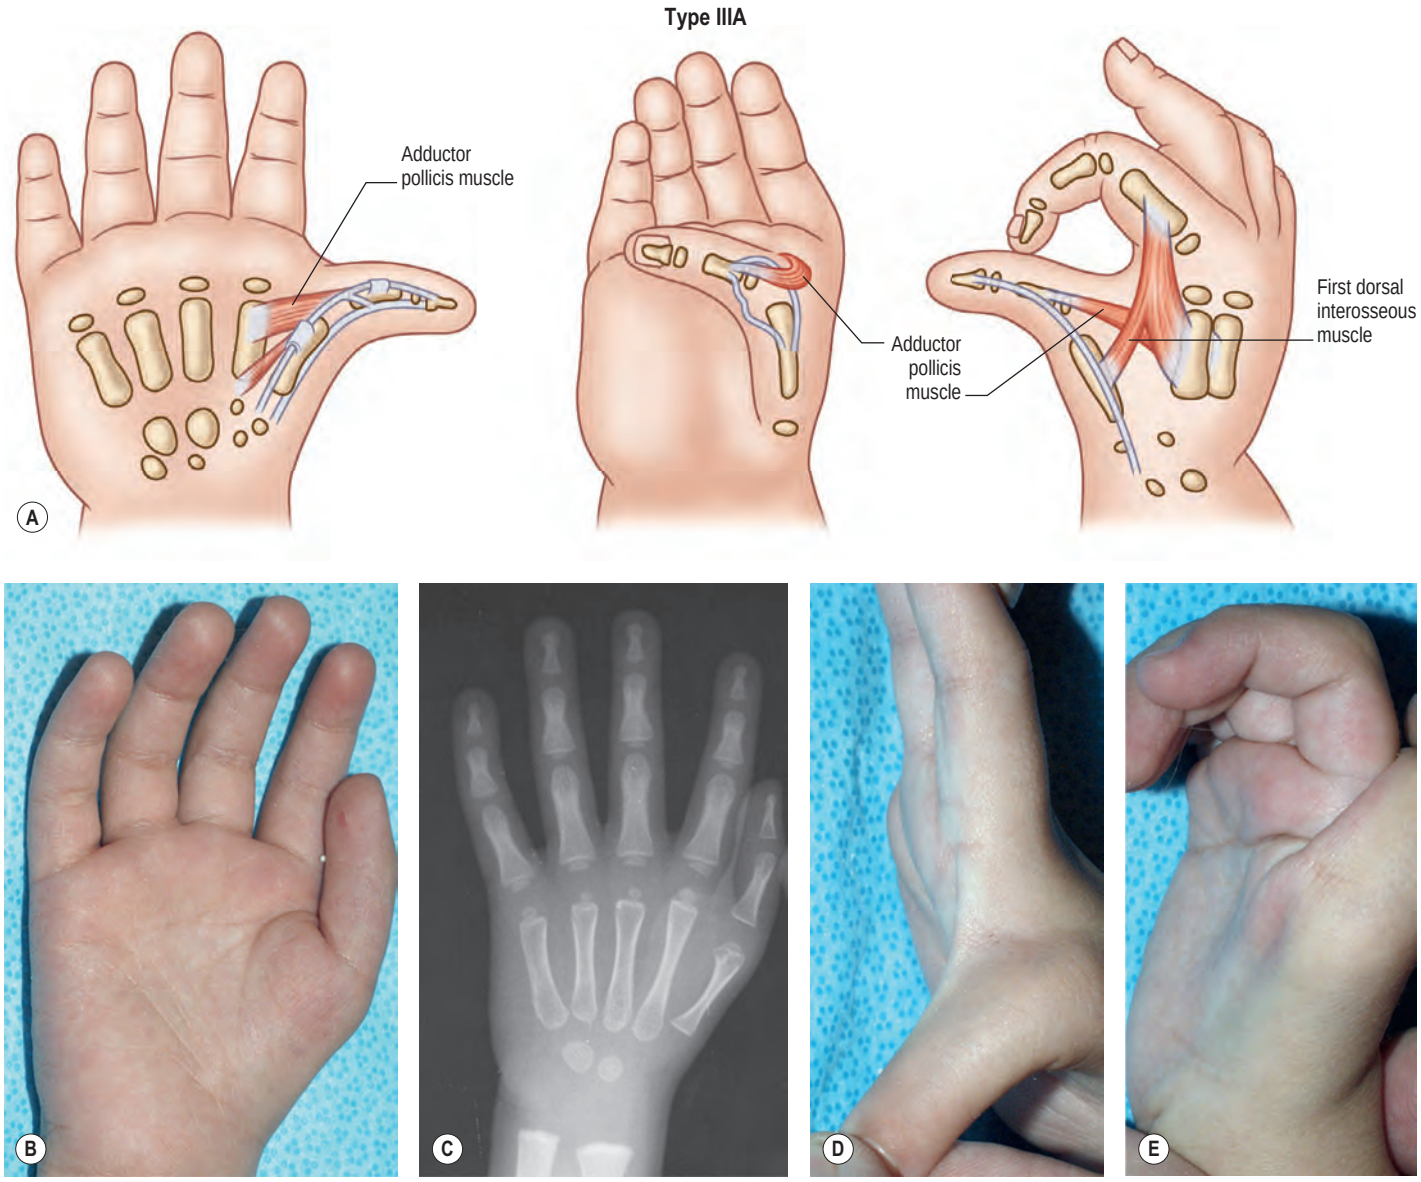

Fig. 27.5 Type IIIA thumb hypoplasia – severe. **(A)** These thumbs exhibit more severe skeletal hypoplasia, including the carpal bones. Median nerve innervated thumb intrinsic muscles are severely hypoplastic or absent, and the ulnar-innervated muscles are present but weak. Extrinsic tendons are abnormal, the "pollex abductus" deformity is frequent, the first webspace is small, and the metacarpophalangeal (MP) joint is unstable (more on the ulnar than the radial sides). The carpometacarpal (CMC) joint and thumb metacarpal are intact in IIIA thumbs. **(B–E)** The clinical appearance and radiograph show a short slender metacarpal, an intact CMC joint, severe hypoplasia of the thenar eminence, and a lax MP joint. The absent interphalangeal flexion crease is indicative of a deficient or absent flexor pollicis longus.

Type V: aplasia

The thumb is completely absent in this category (Fig. 27.8). In half of our patients[50] and half those reported by Flatt,[51] there is an associated deficiency of the radius. When the radius is normal, the index digit is normal and has strong abduction at the MP joint due to the presence of a strong first dorsal interosseous muscle (e.g., abductor indicis muscle). Many of these children with a normal radius will demonstrate "autopollicization".[50] The pulp of the index finger widens and the digit pronates and sits in a more abducted position resulting in a widening of the intermetacarpal space and attenuation of the intermetacarpal ligament. At best, this posture is a poor substitute for normal key pinch. In the case of a deficient radius, the index ray is stiffer, shorter, and often joined by a simple syndactyly to the long digit. There is a direct correlation between the degree of radial hypoplasia and the index finger deficiencies; the index ray is never normal when there are significant associated radial deficiencies. In these hands, the degree of stiffness decreases from the radial to the ulnar digits and the fifth finger is always the best on the hand.

Type VI: central deficiencies – cleft hand and symbrachydactyly thumb

Cleft hand (typical)

Cleft hand is characterized by hypoplasia or aplasia of the central ray(s) of the hand thus forming a "V" or funnel-shaped cleft (Fig. 27.9 ◍). All degrees of simple syndactyly of the first

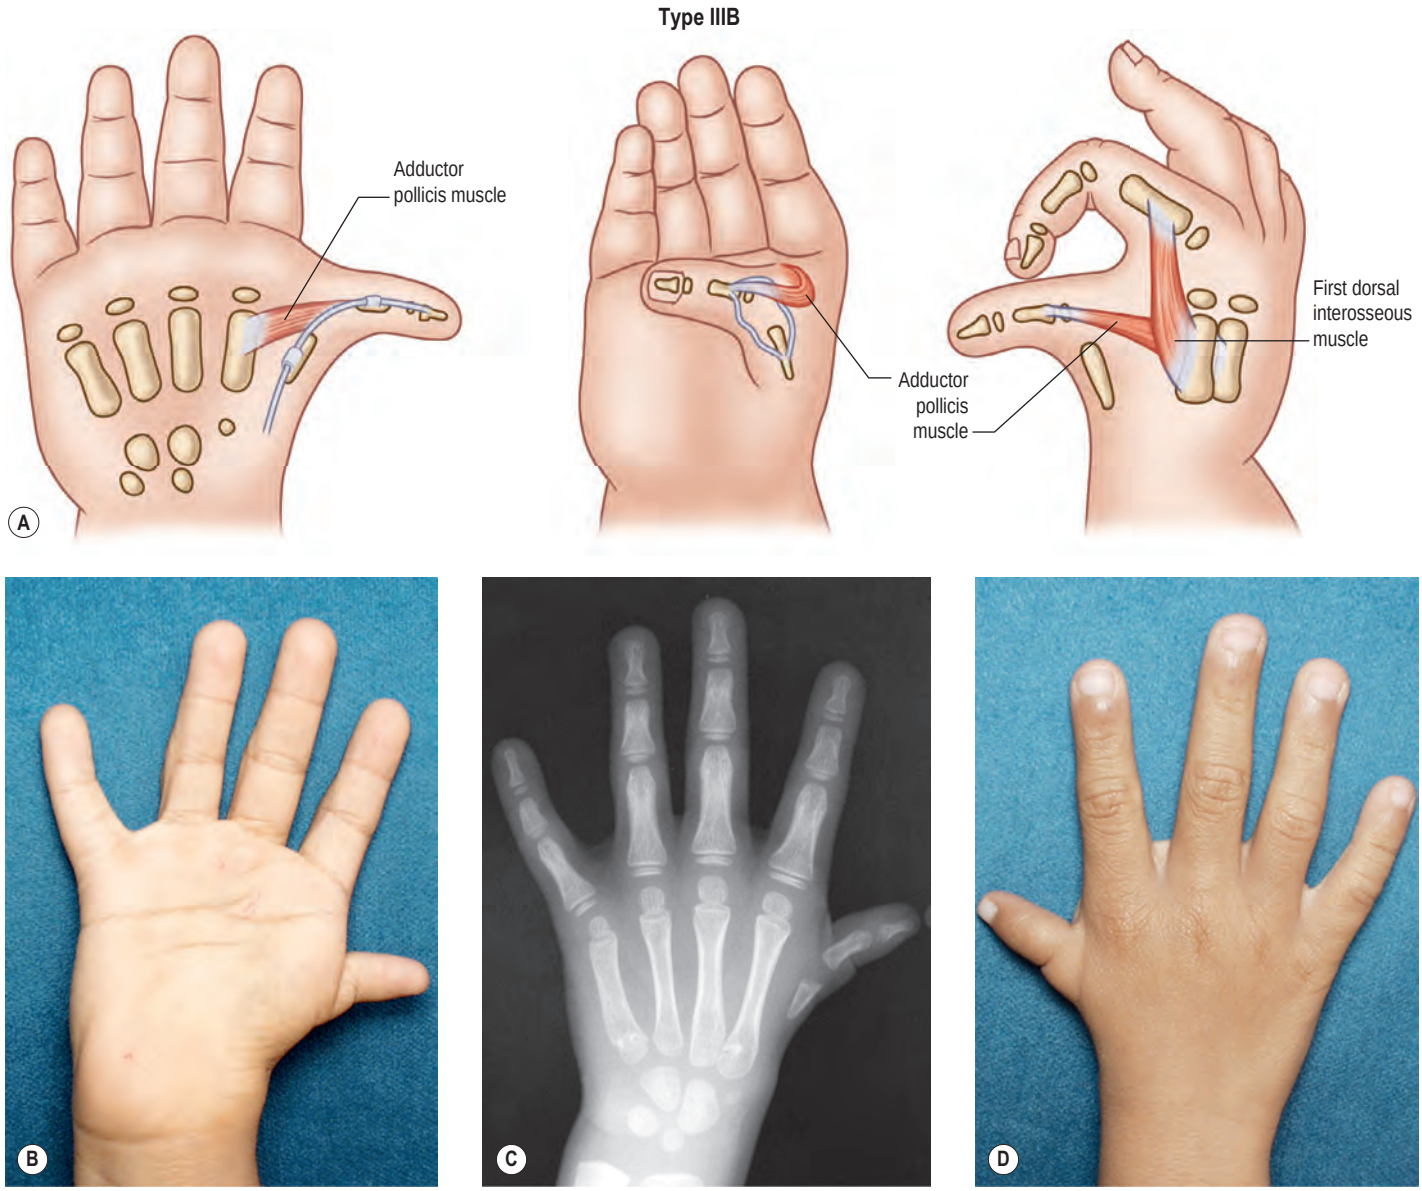

Fig. 27.6 Type IIIB thumb hypoplasia – severe. **(A)** The median-innervated thenar intrinsic muscles are absent entirely. There is severe hypoplasia of the adductor pollicis muscle, flexor pollicis brevis – lateral head, and the ulnar origin of the first dorsal interosseous. The carpometacarpal joint articulation of the proximal metacarpal is absent. The metacarpophalangeal joint is very lax or absent on both radial and ulnar sides. Flexor and extensor extrinsic tendons are severely hypoplastic or absent. **(B,D)** Clinical appearance and **(C)** radiograph shows a 4-year-old patient with a well formed but functionless floppy thumb. There is no skeletal stability or extrinsic flexion or extension. Very small flexor or extensor tendons may be present and can result in some movement.

web are seen, resulting in moderate to severe deficiencies of the first webspace. In addition, all degrees of hypoplasia, extending to aplasia of the central two rays, may exist.[7,8] The ulnar two digits in the ring and fifth positions are commonly webbed with simple syndactylies. The thumb in the cleft hand anomaly is usually slightly small with all components of the osteoarticular skeleton present. A Blauth type II thumb classification would be appropriate for the strict constructionist.[26] The wrist and forearm bones are normal, and the median innervated thenar intrinsics are present. The major deficiency of the thumb in this form of hypoplasia is that the ulnar innervated intrinsic muscles are severely hypoplastic or absent. In particular, the ulnar innervated adductor pollicis is usually severely hypoplastic or absent, and the first dorsal interosseous is moderately hypoplastic and contracted. The presence or absence of the third metacarpal is often an excellent indicator of the status of the AddP muscle. Finally, the extrinsic flexor and extensor musculotendinous units to the thumb tend to be unaffected. Fig. 27.9 appears online only.

In another variation of typical cleft hand, thumb polydactylies at all levels may be observed. The more distal type I and II polydactylies[52] are often associated with the absence of index phalanges that have an intact metacarpal. Super digits and transversely oriented tubular bones at the distal metacarpal level with complete absence of the index (and long) digits are often seen in this variation.[53] With more proximal type III,

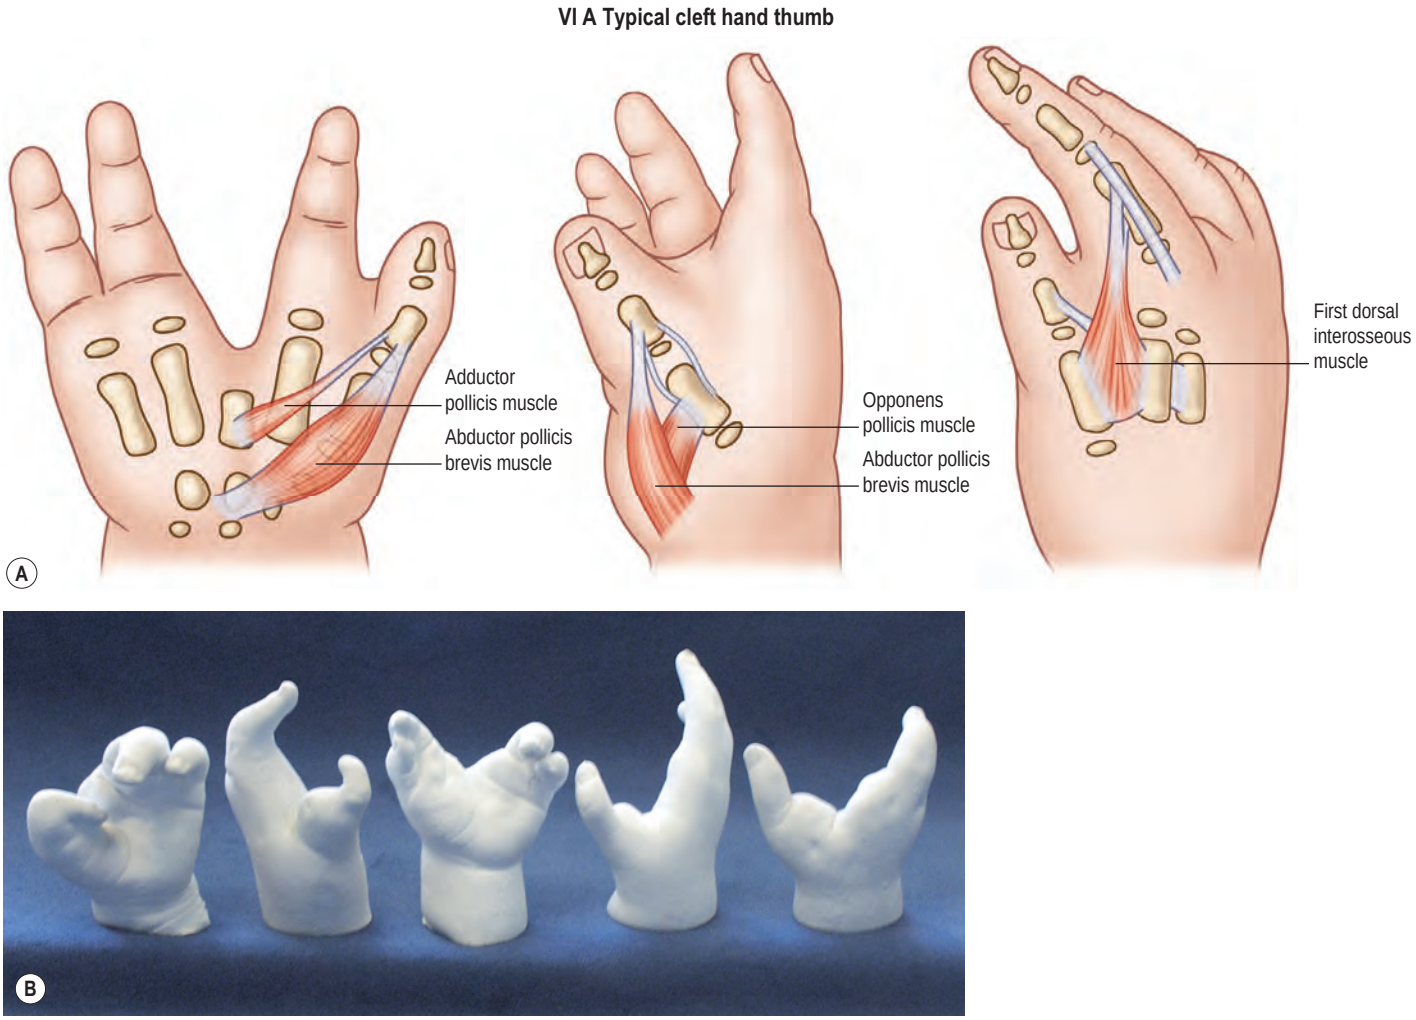

Fig. 27.9 Thumb in typical cleft hand. **(A)** Three layers of median innervated intrinsic muscles are present in most typical cleft hands. Commonly, the index ray is joined to the thumb by a simple syndactyly. All degrees of absence of the long rays may present. The first dorsal interosseous is present and tight, and the degree of adductor pollicis hypoplasia is proportional to the amount of the third metacarpal present. A very small adductor pollicis is illustrated here. **(B)** A sampling of molds shows the wide variation in the size and depth of the central clefting. The thumbs are smaller than normal, and the longer thumbs with flexion contractures are triphalangeal.

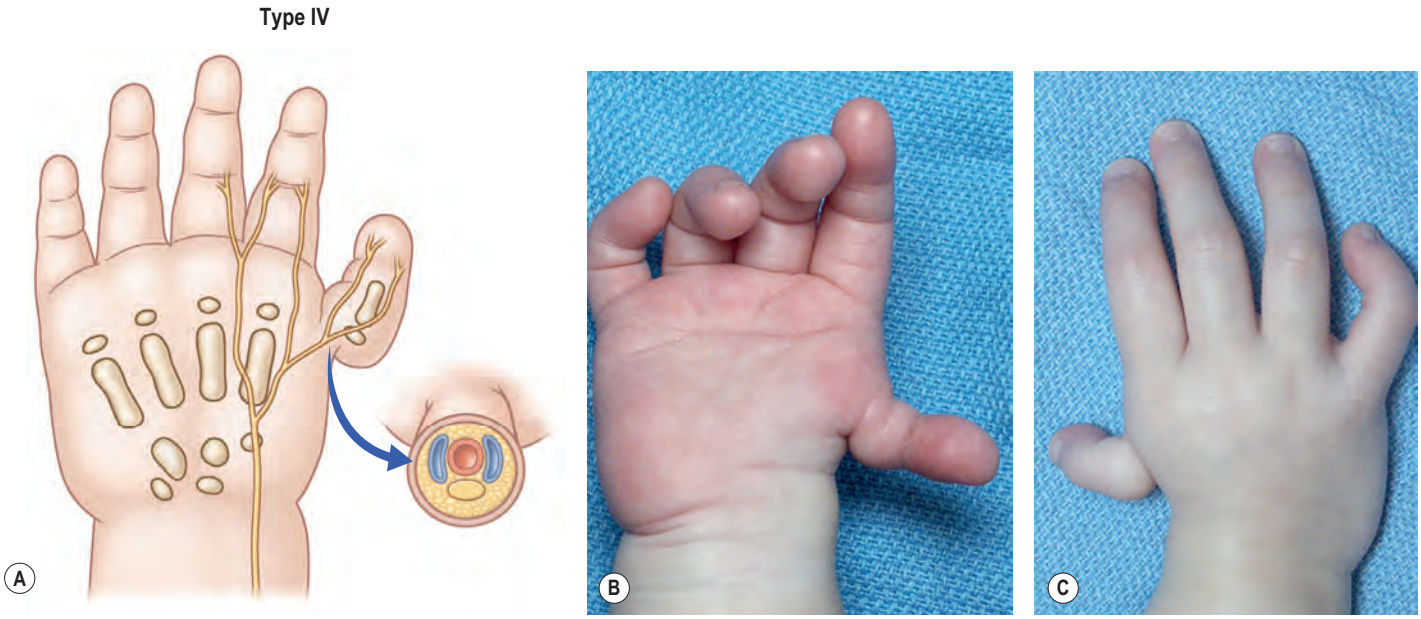

Fig. 27.7 Type IV thumb hypoplasia – floating thumb. **(A)** The hypoplastic thumb is attached to the hand only by a soft-tissue bridge, which contains neurovascular structures and rarely hypoplastic tendons and fascia. There is no skeletal connection. **(B,C)** The attached thumb is small with diminutive phalanges and a nail. There is no active flexion or extension. The radial deviation of the wrist and hand is due to hypoplasia of the trapezium, scaphoid and lunate.

IV and V polydactylies, the central (third) ray is often severely hypoplastic or absent.[54,55] Triphalangeal rays may also be encountered with the proximal duplications at the metacarpal level.

Symbrachydactyly thumb

Most refer to these atypical cleft hands as symbrachydactyly (Fig. 27.10 ◍). This form of deficiency is always unilateral, with varying degrees of hypoplasia of the central three rays of the hand. Nubbins with minute nail complexes may be present on the distal border of the palm, representing the index, long, and ring fingers, but commonly these central three digits are completely absent with varying degrees of hypoplasia of the central three metacarpals. Fig. 27.10 appears online only.

All degrees of variation exist, and no two hands are identical. The thumb in this condition is invariably smaller with severe hypoplasia or aplasia of the phalangeal components. Occasionally, a metacarpal and distal phalanx are present with a flail thumb at the MP joint level. With an intact third metacarpal, a functional adductor pollicis muscle is often present. Most of these thumbs have very weak adduction power. Usually, the median innervated thenar intrinsic muscles are intact and range from small to normal in size. The thumb CMC joint is well segmented and mobile, and the IP joint of the thumb may exhibit decreased passive and active motion due to weak extrinsic flexor and extensors. Upon exploration, the FPL tendon often courses to a hypoplastic or absent muscle belly in the distal forearm. In the severely hypoplastic thumb, there is marked limitation of MP and CMC motion, an absent IP flexion crease, and only a rudimentary FPL tendon. The anomalies seen with the extrinsic flexors and extensors are similar to those described for the types II and IIIA hypoplastic thumbs. The fifth ray is usually the best in the hand with intact intrinsic and extrinsic musculotendinous units. Frequently, this digit has a radial clinodactyly and a completely unstable MP joint, and the entire hand is hypoplastic. Radius and ulna are present and of equal length but may be small in comparison to the opposite limb.

Type VII: constriction ring syndrome

Constriction ring syndrome (amniotic band sequence, Streeter's dysplasia, fenestrated syndactyly, acrosyndactyly) is a condition that can affect one or all limbs and less commonly the face. As defined by Patterson,[56] limb involvement can result in any of the following deformities: (1) simple constriction rings, which may be partial or circumferential; (2) constriction rings with distal deformity, with or without concomitant lymphedema; (3) acrosyndactyly (distal fusion, fenestrated syndactyly); or (5) amputation(s) (Fig. 27.11 ◍). Fig. 27.11 appears online only.

Hypoplasia of the thumb is seen in this condition when there is a deficiency in the length of the thumb, which may have a transverse failure of formation at any level. Occasionally, the existing skeletal and soft-tissue components of the first ray may be hypoplastic. The hallmark of the amniotic band sequence is that the anatomy proximal to the level of amputation or level of congenital amputation is normal. Superficial or deep rings around the thumb can be associated with hypoplasia or lymphedema of the distal segment of the digit that contains hypoplastic nail remnants and slender, truncated phalanges. Acrosyndactyly (*acros*: peak, Greek) usually involves the central three rays of the hand but can also involve the thumb and fifth digit. Thumb amputation may occur at any level. The most practical way to classify these losses is at one of three levels: (1) distal to IP joint; (2) proximal phalanx, and (3) metacarpal (see Fig. 27.11). Motion of the IP joint is usually severely affected – even with amputations or deep constriction rings distal to it.

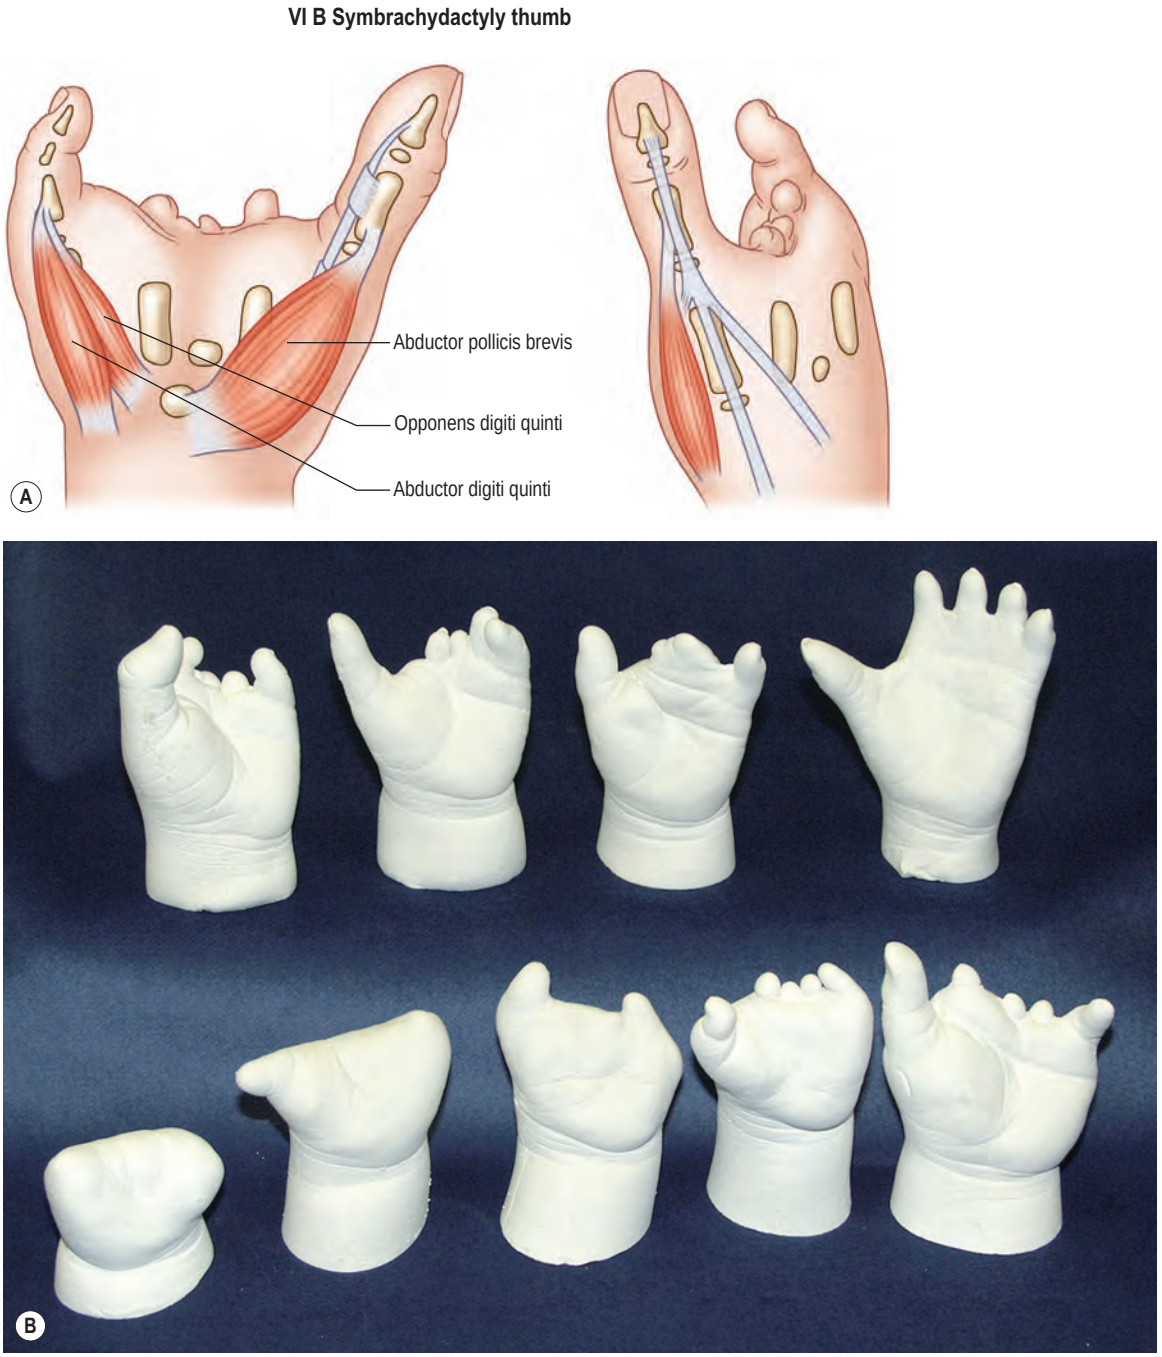

Fig. 27.10 Symbrachydactyly thumb (atypical cleft). **(A)** The border thumb and fifth rays are the most complete in the hand. Thenar and hypothenar muscles are present and often small. Central digits are represented by hypoplastic nubbins. There are all degrees of metacarpal hypoplasia within the central three rays of the hand. Extrinsic flexors and extensors are present but abnormal. **(B)** A very wide range of variation is present in these hands.

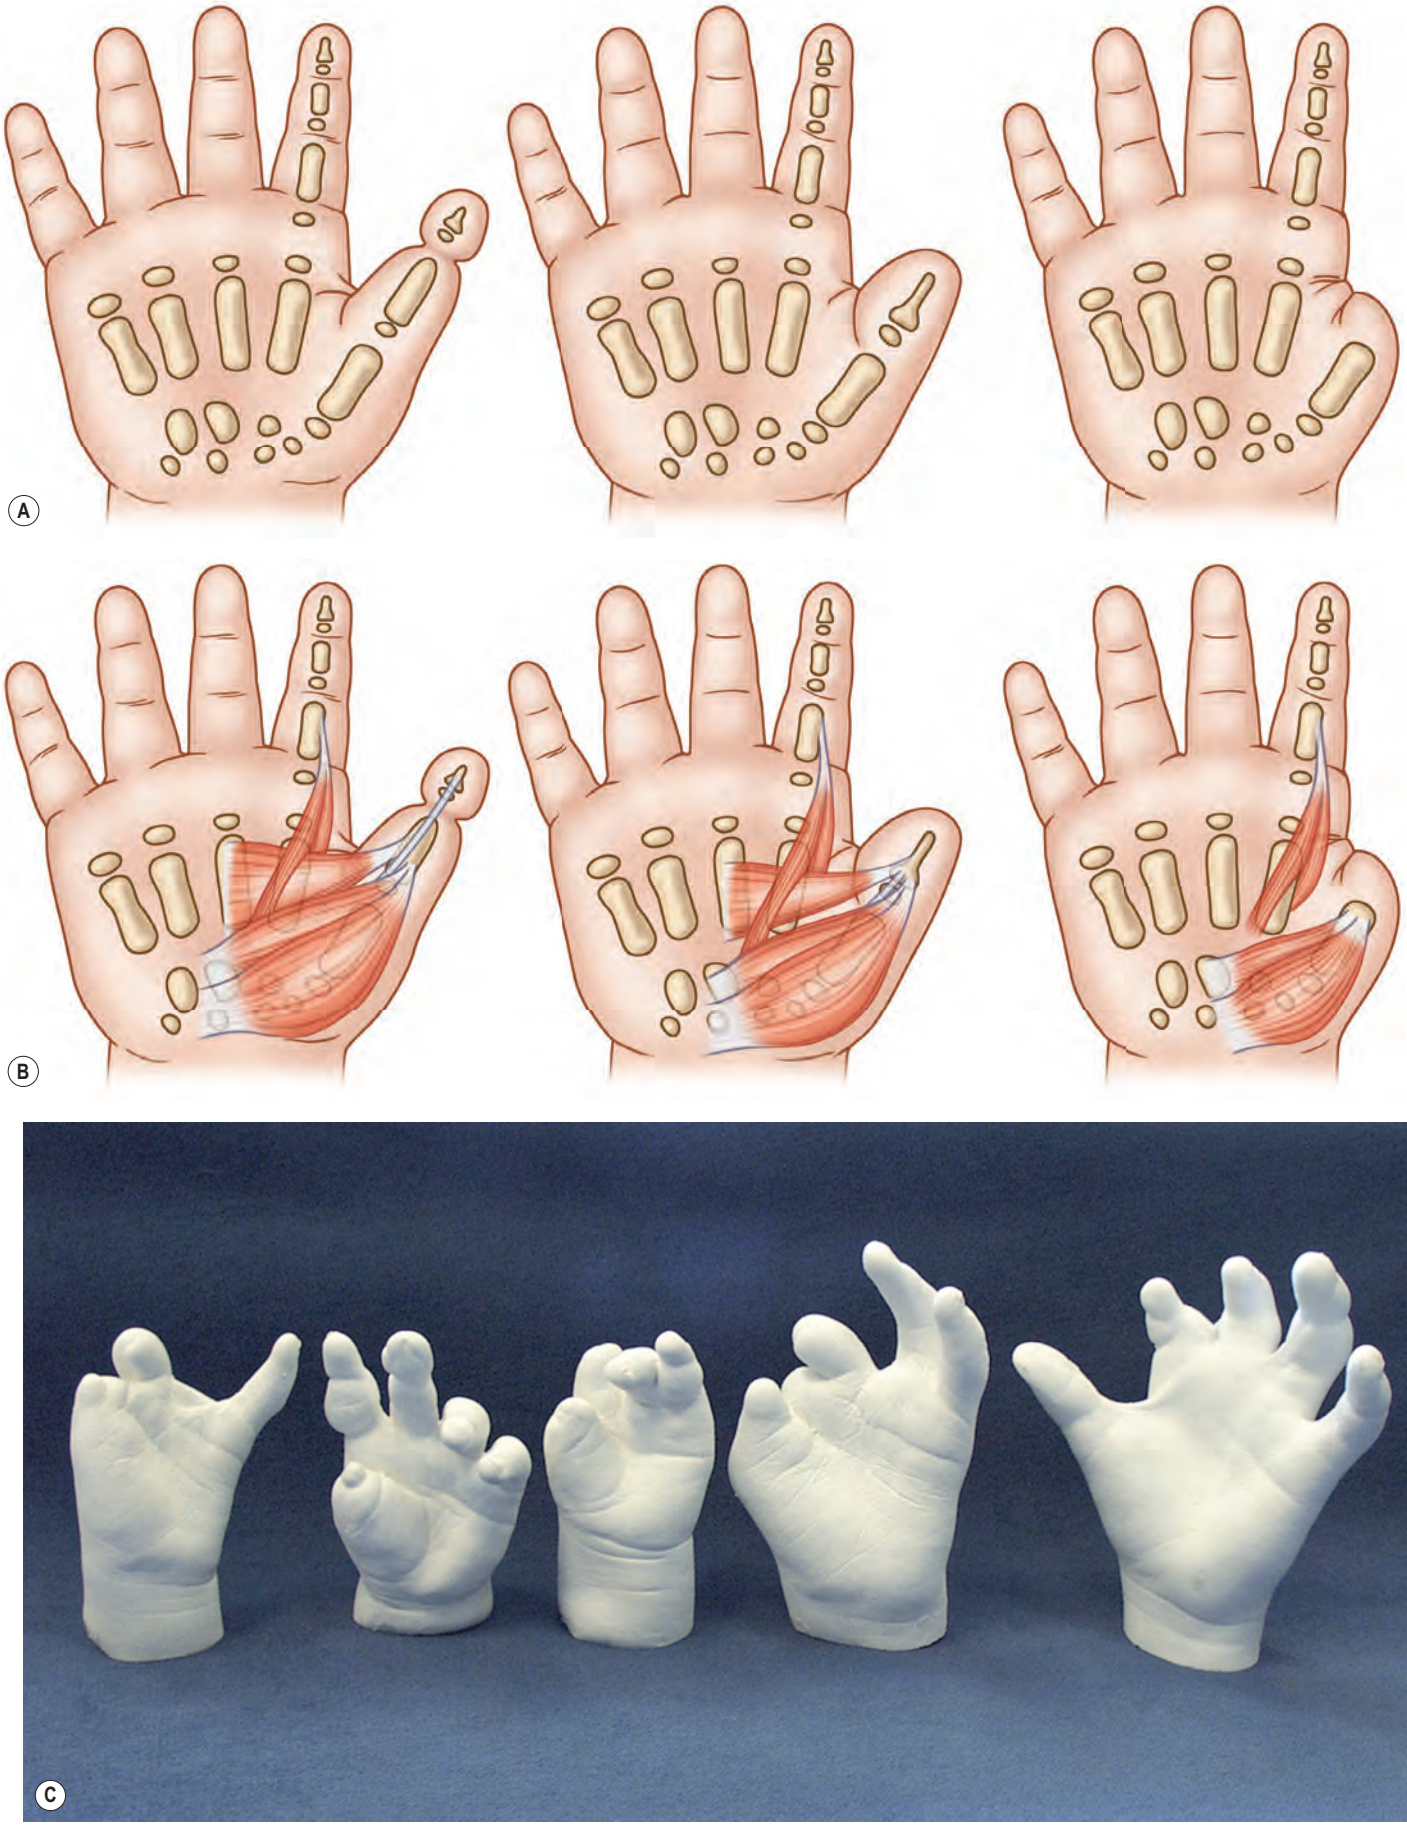

Fig. 27.11 Constriction ring syndrome thumbs. **(A)** The thumb in these hands may present with a shallow or deep constriction ring or an amputation at any level along the skeletal ray. The phalanges at the level of loss are characteristically narrow and taper to the distal stump. **(B)** The intrinsic muscles are all present up to the level of the amputation. The proximal anatomy in this condition is normal. **(C)** The thumb is absent on the left and shows increasing length in these molds. No two hands are identical. There is great variation in the depth and location of constriction rings along the digits.

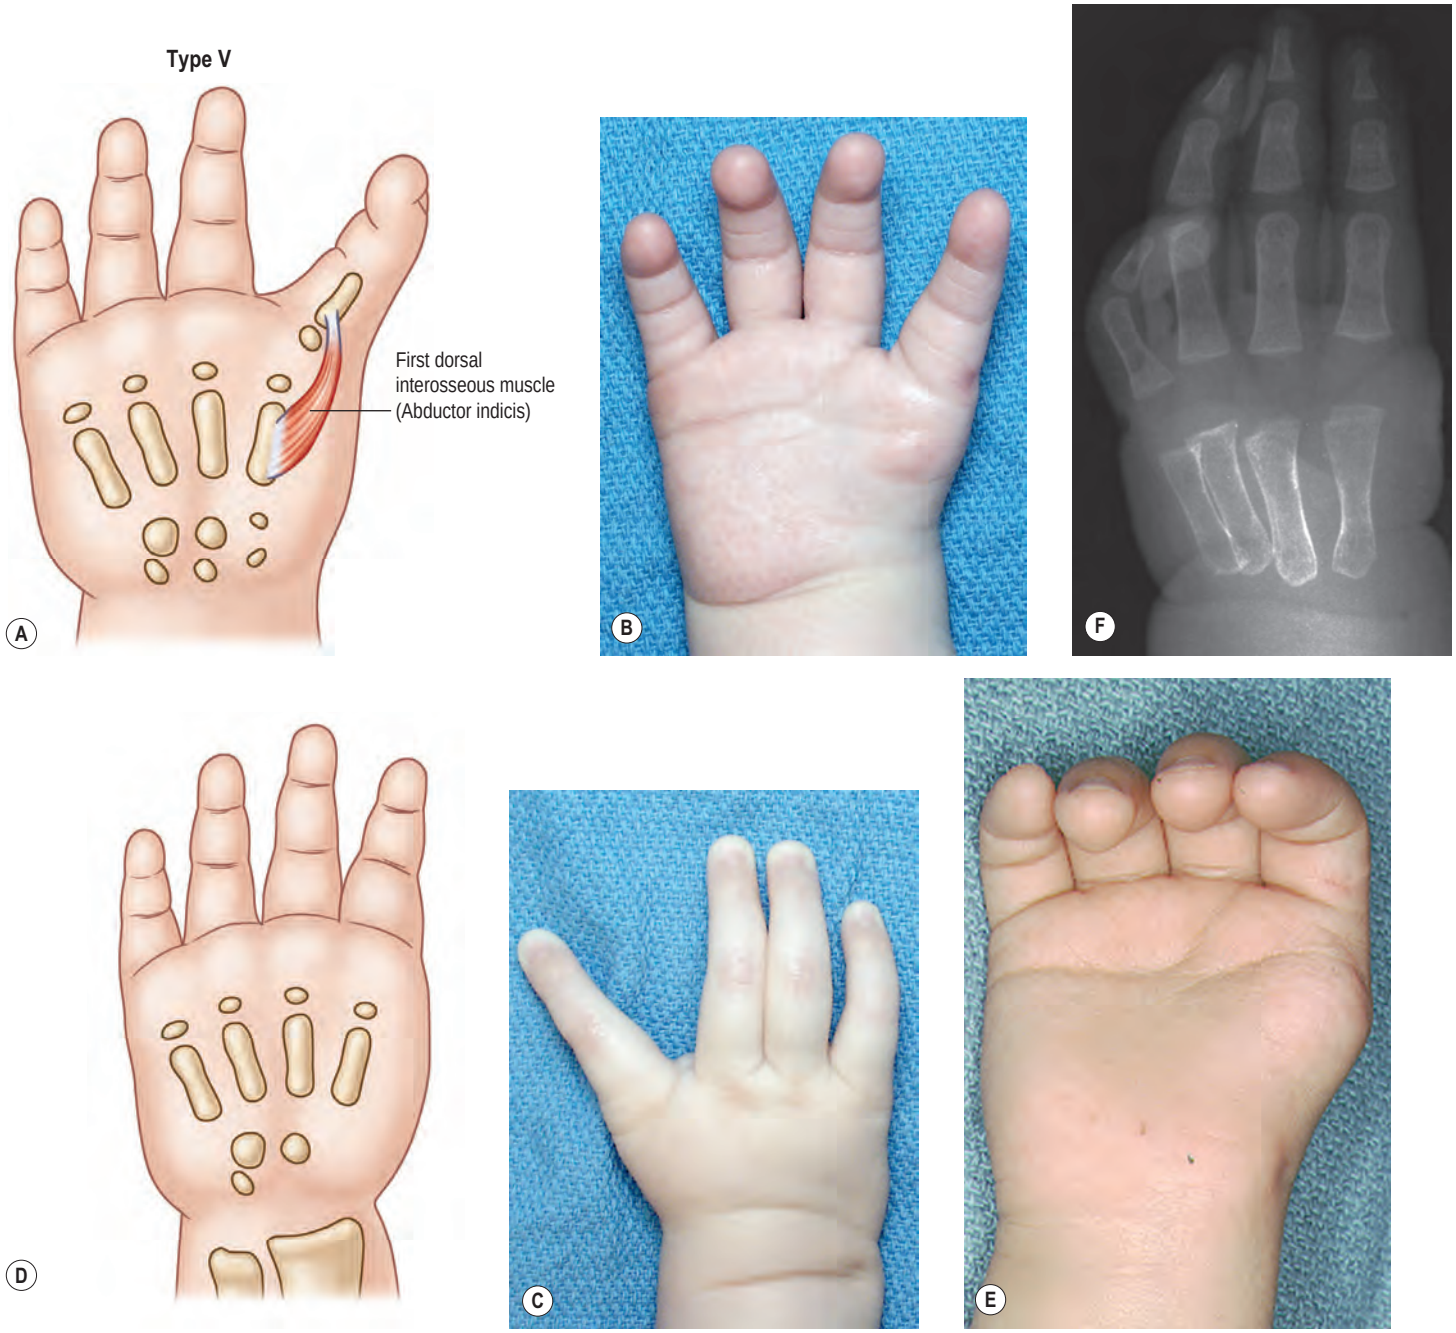

Fig. 27.8 Type V thumb hypoplasia/aplasia. **(A–C)** With complete aplasia, no thumb structures are present. In approximately half of these patients, the radius is normal. The trapezium, trapezoid, and scaphoid are often hypoplastic and a strong first dorsal interosseous (abductor indicis) pulls the index digit in abduction and in as much pronation as the intermetacarpal ligament will allow. **(D–F)** Index digits, which are not abducted, are often stiff at the interphalangeal joints and are commonly associated with some degree of radial hypoplasia or aplasia. The amount of stiffness decreases from radial to ulnar digits. Accordingly, the ring and small fingers are always the most functional components of these hands.

Type VIII: five-fingered hand

In this type of hypoplasia, the thumb is smaller in width and longer in length and has the characteristics of a finger. As the radial border digit, it lies in the same plane as the ulnar four digits and is non-opposable. It is usually the same length as the adjacent index finger. The digit is slender and may be joined to the index finger in an incomplete simple syndactyly. A severe deficiency or nonexistent first web is often present, and some type of transverse metacarpal ligament is also present. The skeletal anatomy is similar to that of the index ray: a metacarpal with a distal growth center and three phalanges with proximal growth centers. The scaphoid is usually absent or hypoplastic. The thenar musculature (AbPB, FPB, OP muscles) are also absent as is the AddP. Instead, the usual digital intrinsics are present – namely, a lumbrical, palmar, and dorsal interosseous (Fig. 27.12 ◍). The extrinsic flexors and extensors mimic those of the normal fingers. Because the radial digit lies in the same plane as the other fingers in the hand, manipulation of objects is usually performed by

utilizing lateral scissoring between the first two digits – or between the second and third if a first web syndactyly is present. Left untreated, those patients without a first web syndactyly tend to attenuate the transverse metacarpal ligament and "auto-pollicize" into an abducted and slightly pronated posture. Fig. 27.12 appears online only.

We have seen variants of this condition in which hypoplastic thenar muscles are present with a metacarpal that has a proximal physis. These thumbs are triphalangeal and also contain a lumbrical muscle that originates from the flexor digitorum profundus (FDP) tendon.

Type IX: radial polydactyly

Despite the level of arborization, each partner thumb is hypoplastic to varying degrees, with the radial duplicate usually being the most severely affected. Rarely are Wassel type II, III, and IV partner thumbs of equal side and conformity. The complexity of the deformity and, therefore, the surgical correction increases as the level of the duplication progresses proximally. Associated triphalangia of the ulnar partner further complicates any surgical reconstruction. Specific abnormalities in each thumb are seen in the nail plate, the osteoarticular column, and both the intrinsic and extrinsic musculotendinous units. The nail plate of each partner is always more narrow than that of the unaffected thumb, and the entire skeletal ray is hypoplastic in all polydactylies proximal to the MP joint.

Musculotendinous abnormalities are common with the extrinsic extensor almost universally shared. Indeed, nearly half of the patients presented in papers on pollex abductus involve duplicate thumbs.[42,45] Deviation of the partners toward each other indicates abnormal insertions of the extrinsic tendons into the distal phalanges, and connections between the extrinsic flexors and extensors are not unusual. These tendinous interconnections will limit function and cause digital angulations. The first web is usually unaffected in polydactylies involving the distal phalanx, but as the level of arborization lies more proximally, the first webspace becomes increasingly deficient and tight.

Type X: syndromic short skeletal thumb ray

Deficiencies of the osteoarticular column of the thumb may result in a short, hypoplastic thumb (Fig. 27.13 ◉). Bony abnormalities can occur as isolated bone (brachymetacarpia, brachyphalangia), all bones in combination, or as part of a generalized syndrome, such as the acrocephalosyndactyly (e.g., Apert, Pfeiffer, Carpenter, etc.) syndromes or the Rubinstein–Taybi syndrome. Joint function is usually impaired on either side of the abnormal bone(s). In patients with anomalies of a single bone, brachymetacarpia, or brachyphalangia, the remaining components of the thumb tend to be unaffected, and in patients with generalized syndromes, other abnormalities of the thumb components are common. In the acrocephalosyndactyly (ACS) syndromes, delta phalanges are common. They usually involve the proximal phalanx with a longitudinal epiphyseal bracket on the radial side. This abnormal growth plate checks longitudinal growth on the radial side and results in radial clinodactyly of the thumb ("hitch hiker's thumb") – which becomes more severe over time. The metacarpal is usually short and the distal phalanx is short and broad. Incidentally, many feel that the abnormal proximal phalanx and broad distal phalanx are variations of a polydactyly. Musculotendinous anomalies are associated with poor joint function but are not as common as those with type IIIA thumbs. Deficiencies of the first web are most common, occurring along a spectrum of mild adduction contracture to complex syndactyly involving the first two rays. Fig. 27.13 appears online only.

The whole spectrum of patients with metabolic bone diseases, skeletal dysplasias, benign skeletal tumors, and many syndromes may include thumb hypoplasia. In general, very little surgical correction is required for these youngsters. The need for surgical improvement is determined by very critical observation of these children at play.[20]

Patient selection

General considerations

The child with thumb hypoplasia may present many unique problems with both pinch (precision, pulp, key) and grasp (precision, span, power), despite his/her ability to adapt remarkably to the functional deficiency.[57] The ideal prerequisites for reconstruction of a functional thumb include [19,58]:

1. A mobile, stable CMC joint with an intact metacarpal
2. A scar-free first webspace of adequate width and depth lined with full-thickness skin
3. Mobility in at least two of its three joints (CMC, MP, IP)
4. MP joint stability, particularly of the ulnar collateral ligament
5. Adequate motors for strong MP or IP flexion and extension
6. Capacity to be placed in a palmar abducted (i.e., opposition) position for pinch and grasp maneuvers.

All six of these components should be considered in any detailed analysis of the thumb.

Timing

As researchers and clinicians struggle with the possibilities of fetal surgery, many surgeons wonder if they should wait rather than performing reconstructive procedures of the congenitally different hand as soon as possible (Fig. 27.14). Early reconstruction of the hypoplastic or absent thumb is certainly attractive in an effort to allow the infant to adapt more rapidly with optimal cortical representation. This ideal needs to be tempered with the knowledge that a congenital hand difference is, in itself, not a life-threatening condition (but may be associated with one), and the surgeon can use time to allow the affected part to grow, to observe development, and to assess the functional needs. The construction of the thumb with a stable osteoarticular column of adequate length, mobile joints, growth potential, scar-free first web, and gliding muscle tendon units is not easily accomplished in very small hands – despite refined microvascular instruments and skills.

However, the arguments that are forwarded by the proponents of the early surgery persist. The most powerful arguments include anatomic, cognitive, and psychological factors. Anatomically, the release of tethered musculotendinous units

IX Five-fingered hand

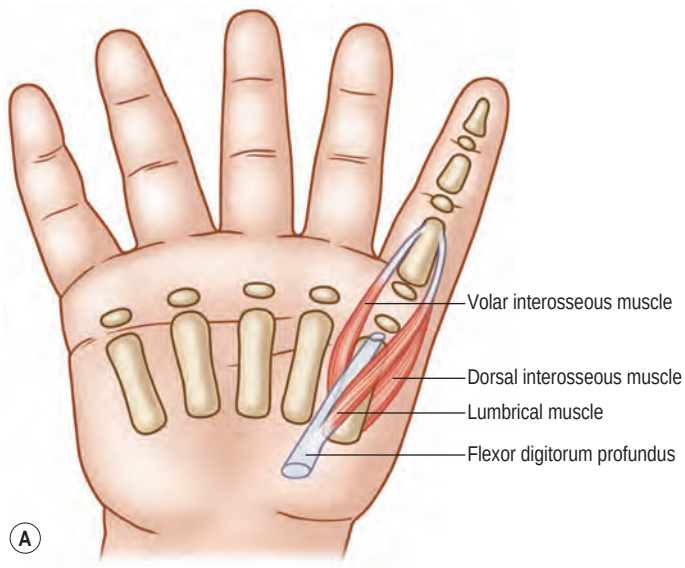

Fig. 27.12 Five-fingered hand. **(A)** In the five-fingered hand, the normal complement of median innervated thenar intrinsic muscles are absent. First dorsal interosseous, volar interosseous, and lumbrical muscles are present in this ray, which anatomically is a digit, not a thumb. **(B)** The clinical appearance (preoperative) on the left shows that the patient has tried to flex and auto-pronate this ray to become a thumb.

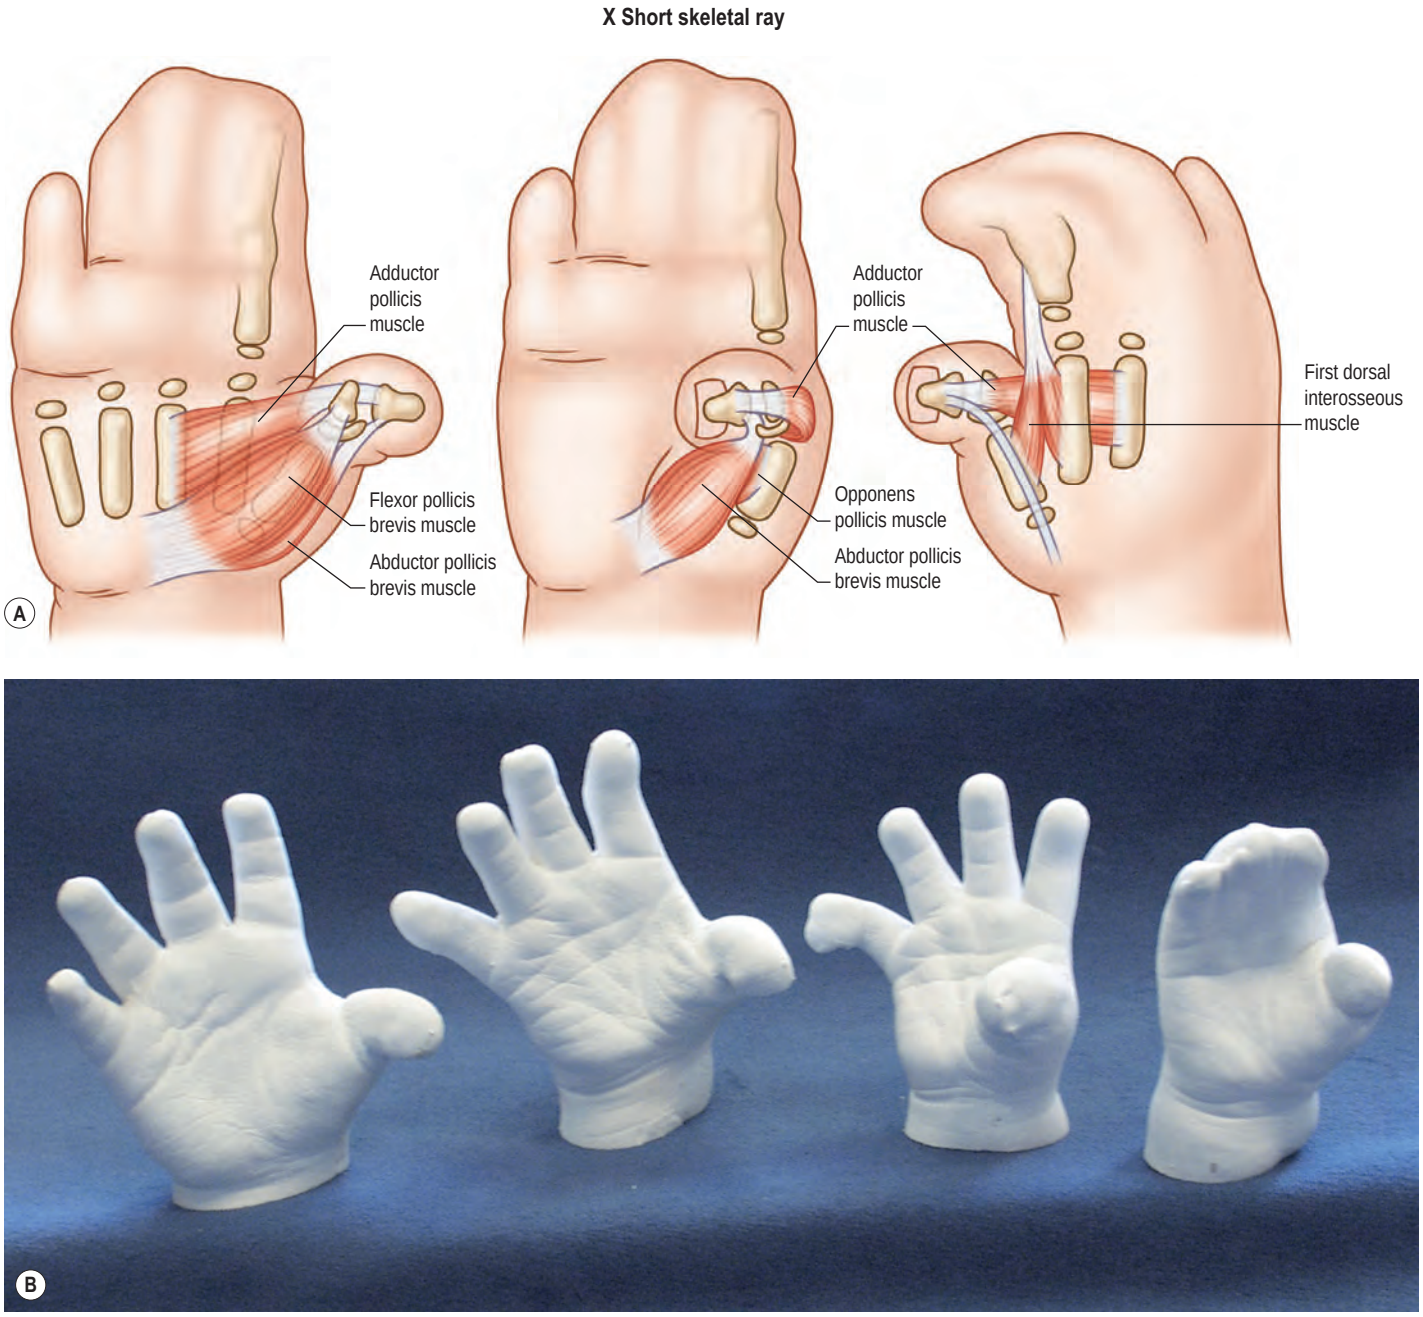

Fig. 27.13 Type X short skeletal ray. **(A)** A short thumb with or without radial clinodactyly is seen in many syndromes. The primary osseous abnormalities are usually seen at the proximal phalangeal joint level. The median and ulnar innervated intrinsic muscles are all present and very hypertrophied. Extrinsic and intrinsic flexors and extensors are normal up to the phalangeal level. **(B)** The left thumbs of children with four different syndromes all look similar: (from left to right) Rubinstein–Taybi; Pfeiffer; Greig cephalopolysyndactyly; Apert acrocephalosyndactyly.

Fig. 27.14 Timing – plaster molds made of patients with type V hypoplasia made at ages (left to right): 32 weeks' gestation, 12 months and 8 years of age demonstrate the tremendous growth difference. Despite their discrepant sizes, the anatomy of these hands was remarkably similar with normal index active and passive range of motion. Any surgery on the hand on the left would be quite challenging.

and joint contractures will allow unrestricted growth, and physiological adaptation of the reconstructed thumb will occur secondary to growth and functional use. On a cognitive level, early surgery will allow the development of the child with a reconstructed thumb to occur prior to thumb cortical-ization, which takes place at around 18 months of age. Psychologically, correction will alleviate anxiety in the parents and, therefore, in the child.

These purported advantages should be weighed against risks that include: (1) growth-related complications; (2) functional need assessment, and (3) patient cooperation. Another risk that has been on the forefront of pediatric surgery recently remains the long-term cognitive effects of general anesthesia in early childhood and infancy. Although answers are not yet known, multi-center trials are in progress.

In slightly older patients, the affected thumb is larger so potential problems with osteotomies, alteration of growth, skeletal fixation, joint reconstruction, and potential for compromise of blood supply are reduced.[59] Also with an older patient, the surgeon is better able to accurately assess the functional needs of the child according to his or her interests, current adaptations, and lifestyle. Finally, an older child is potentially a more cooperative patient.

Surgical correction of the hypoplastic or absent thumb must be individualized. As these children may have other congenital anomalies, an early assessment of the upper limb deficiencies and a coordinated management plan can be formulated and instituted.

In the absence of other organ system complications, we try to perform pollicization when the child is between 12 and 18 months of age. Pollicization is often preceded by centralization of the hand and wrist between 5 and 8 months of age in those with radial longitudinal deficiency. The timing for correction of type IIIB deformities may be problematic. Though pollicization is the procedure of choice, some parents and families simply will not allow it. We agree with other surgeons that the alternatives involve difficult reconstructions, often including one or more stages, and are wisely deferred until the child is aged 4–5 years, a time when the hand is larger and the patient may be more cooperative with the postoperative therapy regimen.[33,60]

For thumbs that need reconstruction alone without pollicization, the authors feel that ligament reconstruction of a lax metacarpophalangeal joint should be deferred until the child is large enough so that bone tunnels can be made safely. This timing typically coincides to between 2 and 3 years of age.

Treatment

This section on treatment is divided into two parts: in the first part, treatment considerations will be outlined for each type of thumb hypoplasia, and in the second part, surgical techniques will be outlined in detail for each particular clinical problem.

Treatment considerations for thumb hypoplasia (types I–V)

Type I: mild hypoplasia

These children are not usually functionally impaired (see Fig. 27.2). In fact, many type I thumb hypoplasia patients, along with their parents, do not recognize anything abnormal about these hands. These thumbs are commonly found in patients who have a more severe radial dysplasia in the opposite upper limb. However, in this stronger limb, they have very little or no difficulty with key pinch, pulp-to-pulp pinch, opposition and grasping activities. Since functional problems are rare, surgical correction is not often needed. Occasionally, a child with a type I hypoplastic thumb will require a release of a mildly contracted web (see type II management). All web releases involve more than simple skin incisions. Careful attention[61] must be directed to tight fascial bands within the webspace, anomalous tendon and muscle anatomy, and joint ankylosis. Of all the methods available, the four-flap Z-plasty provides the best contour and appearance (Fig. 27.15). Dorsal transposition flaps from the index finger[36,62] and rotation flaps[61] are effective but require skin grafting on the visible dorsal surface of the hand. Of course, any method must be carefully individualized to the patient.

Type II: moderate hypoplasia

Five specific problems in the type II thumbs must be addressed individually: (1) narrowed first webspace; (2) instability of the MP joint; (3) poor palmar abduction (opposition) for pinching and grasping; (4) lack of IP joint flexion, and (5) abduction posturing of the thumb ("pollex abductus") (see Figs. 27.3 & 27.4). In this type of hypoplasia, not all of these specific problems coexist. Usually, all that is needed to correct these thumbs is a release of the first webspace and stabilization of the MP joint, with or without a transfer for palmar abduction or opposition. When the surgeon encounters a pollex abductus deformity, she/he should next look for abnormalities of the

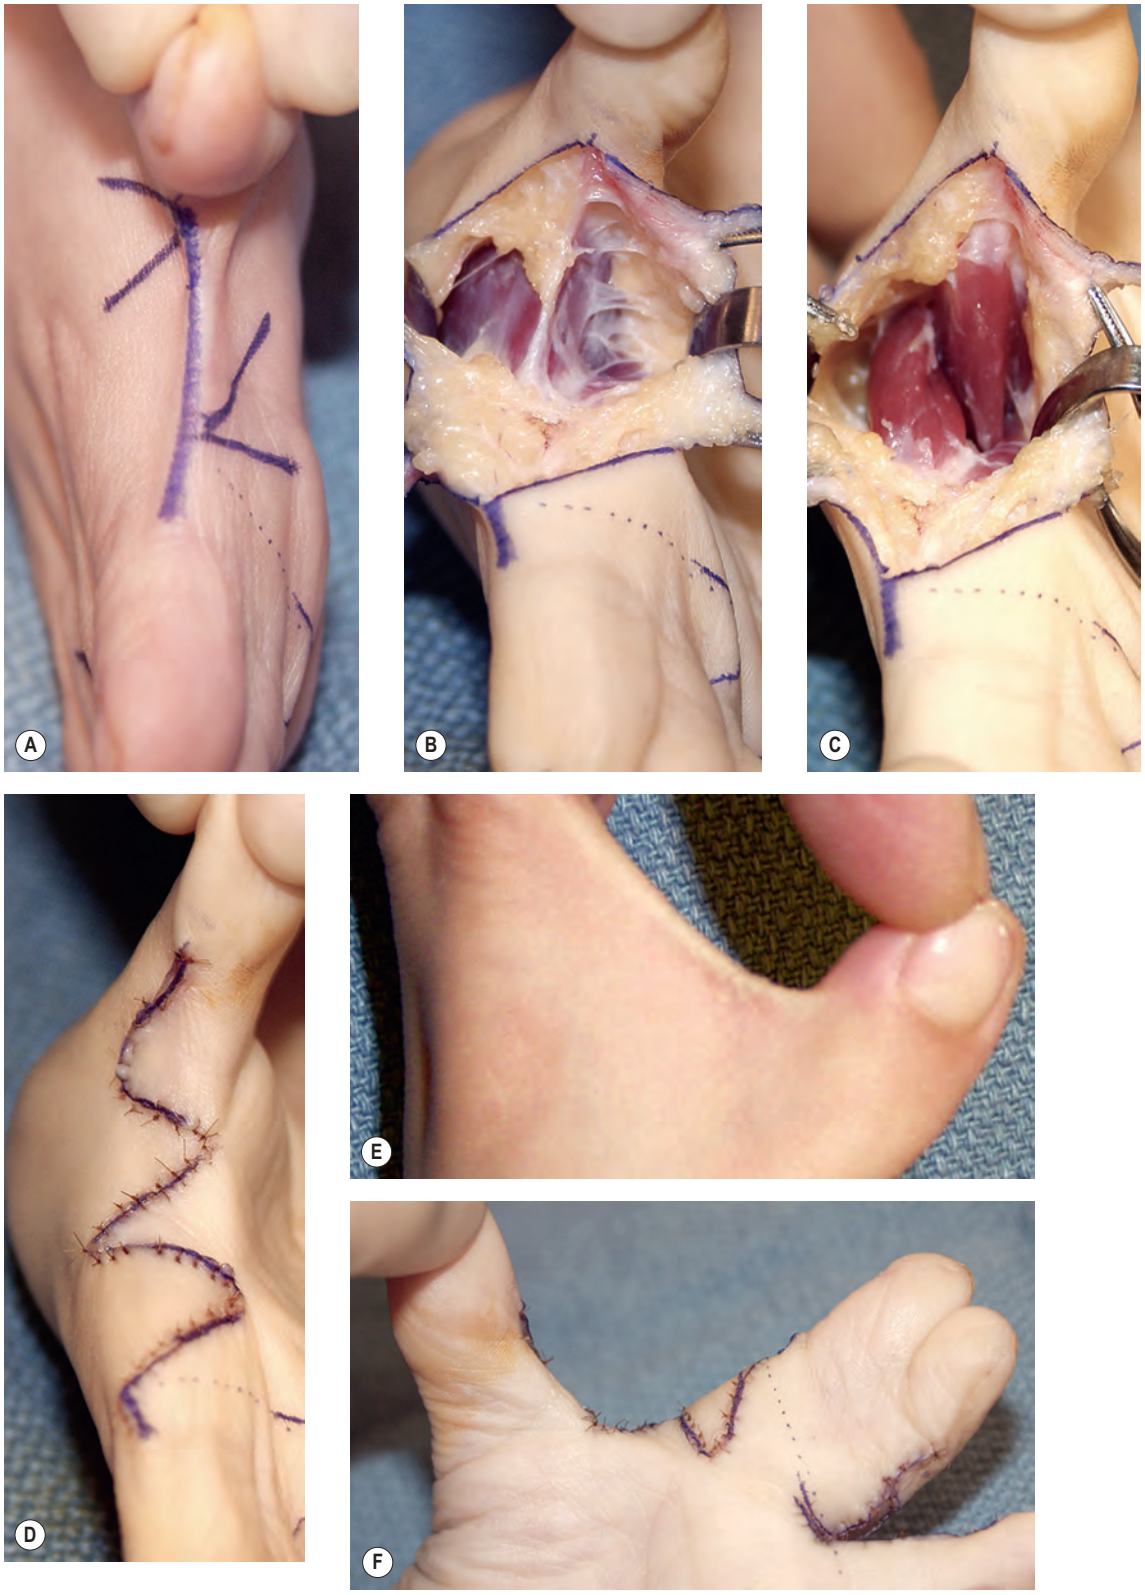

Fig. 27.15 First webspace release. **(A)** The skin markings have been made for a four-flap Z-plasty, which include two 90° incisions perpendicular to the tight web between the thumb and index finger. Each is then bisected at a 45° angle. **(B)** After the four separate flaps have been mobilized, reflected dense septal bands may be identified between the skin and muscle fascia, and larger fascial bands between the intrinsic muscle groups. **(C)** Incision and excision of these bands may require dissection to the carpometacarpal joint level. **(D)** Trimming and minor flap adjustments are always needed with the proper inset of the more mobile dorsal flaps with the more rigid palmar flaps. A skin redundancy on the radial side of the index finger has been eliminated with a straight extension. **(E)** The preoperative appearance is seen with a dorsal view. **(F)** The postoperative contour is shown from the palmar surface. This technique provides the best contour of all available methods of first web release.

flexor pollicis longus (FPL) muscle. A more detailed description of treatment options is presented later in this chapter.

Type IIIA: severe hypoplasia

Most hand surgeons agree that this variation should be reconstructed surgically (see Fig. 27.5). The five individual problems are the same as listed in type II, and the options and preferred solutions are listed below. Most authors opt to complete all necessary procedures including widening of the first webspace, stabilization of the MP joint, and some type of opposition transfer at one time. The major variable becomes the status of the flexor mechanism, which may require a staged approach. After 35 years of experience, our preference has been to replace the very anomalous flexor mechanism with a tendon transfer in the presence of at least one good pulley at the level of the metacarpal head. The treatment of the more deficient type IIIB and IIIC varieties constitutes one of the more interesting ongoing controversies in hand surgery.

Type IIIB, type IIIC: severe hypoplasia

For most hand surgeons in Europe, North America and South America, pollicization is the treatment of choice because a well-performed pollicization provides a much better and more predictable outcome than any alternative types of staged reconstruction (see Fig. 27.6).

However, cultural and parental beliefs may demand one of two alternatives – staged reconstructions with[63–66] and without[67] a microvascular joint transfer, which have both become popular in the Asian countries. Osteoplastic thumb reconstruction has a long history.[5,68–70] The osteoarticular column is connected with an intercalated bone graft between the index and hypoplastic thumb metacarpal (Fig. 27.16). Multiple stages are then needed to first stabilize MP and IP joints and construct pulleys. At that point, tendon transfers are performed for opposition as well as IP flexion and extension. The major disadvantages of this procedure include the lack of CMC mobility, lack of growth, poor motion, and the multiple stages required. Insensate abdominal pedicle flaps have been used to provide tissue for an adequate first webspace. Fig. 27.16 appears online only.

Another alternative is to transfer either the second[67,71–74] or third[75] metatarsophalangeal joint in a hyperextended position to create a new CMC joint and proximal metacarpal. This composite joint must be harvested with a large dorsalis pedis pedicle, which provides venous drainage and adds bulk to the deficient thenar region. Tendon transfers are then performed to provide motion at either the MP or IP joints.

The management of these thumbs remains controversial. Without exception, most hand surgeons prefer a well-performed pollicization over a staged. Any reconstruction will require: (1) stabilization of the thumb metacarpal with first web release; (2) MP joint stabilization and opponensplasty, and (3) staged extrinsic tendon transfers – flexor digitorum superficialis (FDS)-ring to FPL for thumb flexion and extensor indicis proprius (EIP) to extensor pollicis longus (EPL) for thumb extension. Additional transfers for adduction may also be required. The size of these thumbs at birth make reconstruction appear attractive to many parents who are often reluctant, some strongly insistent, about considering any option other than ablation and pollicization. Observation of the child at play will usually direct the surgeon and family towards the best course of management. For instance, a child who bypasses the hypoplastic thumb before reconstruction will usually continue to do so following reconstruction. Most undecided parents usually make up their minds after observing other patients with pollicized digits.

Type IV: floating thumb

Index finger pollicization is the treatment of choice (see Fig. 27.7) unless there are too many cultural or parental concerns, in which case alternatives noted above can be used.

Type V: aplasia

Index finger pollicization is the treatment of choice (see Fig. 27.8). Osteoplastic reconstructions and microvascular transfers are not. The technique is described in detail in the next section.

Clinical conditions and surgical treatment (types I–V)

Deficient first webspace

The correction and widening of the first webspace is the most effective single procedure performed for congenital hand differences! A scar-free web line, created by full-thickness flaps, is essential for thumb mobility and growth. The many options include: (1) local transposition flaps[76–78]; (2) local rotational or sliding flaps with or without skin grafts[2,36,62,79]; (3) regional vascular island flaps[80]; (4) free fasciocutaneous tissue transfer[81,82]; (5) distant pedicled flaps[26,68,83]; and (6) the use of skin expansion.[19,84,85]

For all type II thumbs, local flaps are all that are necessary. Each of the techniques utilizes the same principle, lengthening the contractual limb of the Z-plasty by transposing tissue perpendicular to it. In general, the four-flap Z-plasty[77] is preferred because it provides the most predictable contour and release (see Fig. 27.15). The five-flap ("jumping man") technique[78] is equally effective but usually involves small flaps with vulnerable tips. A simple Z-plasty, on the other hand, does not give the proper contour and usually creates a central depression at the base of the webspace.[86] The surgeon should learn and refine one or two techniques and not experiment with a new one on each case. The use of local flaps with skin grafts, either on the dorsum of the hand or on the index ray, are popular[36,62] but not preferred in this population due to the conspicuous appearance of the dorsal grafts and the associated contracture when harvested along the radial side of the index finger. If the hand requires repeated operations, such as those needed in the Apert hand, dorsal advancement or sliding flaps may be effective because with each procedure the dorsal tissue is re-advanced to create a broader webspace.[84,87] The most frequent error in the treatment of these hands is the tendency to use local tissue when the deficit requires more tissue to be moved into the webspace.

Additional methods must be considered with more severe narrowing of the first webspace seen with type II and type IIIA thumbs. Distally based radial artery or dorsal interosseous arterial flaps can provide more than enough tissue to line the first webspace and allow primary closure of the donor

Fig. 27.16 Spectrum of metacarpal hypoplasia. **(A–D)** There is no arbitrary distinction between specific categories of thumb hypoplasia based on the skeletal appearance alone. These thumbs, which show varying degrees of hypoplasia with a presumably intact carpometacarpal joint, would be classified as type IIIA. **(E–H)** The smaller metacarpals in these examples would signify type IIIB thumbs. **(I–L)** These thumbs, with no skeletal connection, would be classified as "floating thumbs", type IV. When a syndactyly exists between the thumb and index digit, an associated congenital heart defect (the Holt–Oram syndrome) may be present.

site.[80,84] The preferred axial vessel donor is the radial artery. Preoperative Allen testing must demonstrate an intact palmar arch. We do not hesitate to obtain imaging if there is any question. The authors recommend against the ulnar artery distally based flap unless this artery, the major conduit to the hand, is revascularized with a reversed vein graft. Free groin flaps based on the superficial circumflex artery are very effective with minimal donor site morbidity. The major disadvantages are the anomalous vascular anatomy and the specialized training necessary for pediatric microsurgery. Distant pedicle flaps are not indicated and should be considered only under very special circumstances.

Technique of first web release with four-flap Z-plasty

The contractual limb of the Z-plasty is marked first along the leading edge of the web with the thumb and index finger abducted as much as possible (see Fig. 27.15). The length of this limb determines the lengths of each of the four flaps. At each end of this line, two lines of the same length are drawn at right angles (90°), with the most radial line passing along the dorsal side of the web (parallel to the thumb metacarpal), and the most ulnar border passing on the palmar side of the web, which is usually very close to the thenar flexion crease. These two right angles are then bisected, creating four flaps (two palmar, two dorsal), each with a tip angle of 45°. The less mobile glabrous skin on the palmar surface is incised first as minor adjustments are often necessary and more easily accomplished with the mobile dorsal skin. Dorsal veins and nerves are protected with spreading dissection, and all four flaps are retracted as the webspace is inspected. The radial neurovascular bundle to the index finger is protected. Often an arborization of the ulnar digital artery on the thumb side runs along the distal, leading edge of the adductor pollicis muscle. If the procedure has been designed well, the skin flaps fall into place as the thumb and index finger are abducted.

Skin incisions alone are usually inadequate for a full release of this webspace. Tight fascial investments of the thenar muscles and intermetacarpal bands must be excised before a dramatic release is obtained (see Fig. 27.15B,C). If necessary, these explorations extend to the level of the CMC joint, where branches of the princeps pollicis artery should be protected. The origin of the first dorsal interosseous (1st DI) on the thumb metacarpal is next inspected and partially recessed if necessary. Any release of the AddP from the third metacarpal carries a potential loss of important pinch strength. Although the 1st DI and AddP rarely require release with type II thumbs, they are frequently the tightest deforming forces in severe contractures associated with type IIIA thumbs. When muscle recessions or releases are performed as part of the web release, a 0.35 mm C-wire is often used to hold the index and thumb metacarpals in an abducted position for 3 weeks postoperatively. If the radial digital artery (arteria radialis indicis) to the index finger remains as the tightest structure, it can be ligated when there is a common digital artery to the second webspace.

Occasionally in type II thumbs, anomalous muscles acting as adductors may be encountered passing from the flexor surface of the thumb to the extensor surface of the index finger.[42] These muscles should be excised. Additional MP joint stabilization procedures or tendon transfers are performed before the flaps are closed with 6-0 mild chromic sutures.

Metacarpophalangeal joint instability

Often the release of a moderate or severe first webspace contracture will unmask a lax ulnar collateral ligament at the MP joint level. Stabilization of this lax joint in type II and IIIA thumbs can be accomplished with a number of procedures: (1) tightening of the existing ligament and capsule[33]; (2) free tendon graft reconstruction[50]; (3) arthrodesis, or chondrodesis[8]; and (4) ligament reconstruction using the end of a tendon used to improve palmar abduction (opposition).[57,79] In the growing child, all must be performed without injury to the growth plate. Simple imbrication of the attenuated collateral ligament on one or both sides of the MP joint is advocated by some[33] for type II and IIIA thumbs but has not been durable in our series. Reefing of the attenuated ulnar collateral ligament and joint capsule can be addressed by either plication or incision and closure of the lax structures with a "pants over vest" repair. The extensor mechanism, with its attenuated shroud fibers, is usually displaced radially and needs to be identified and mobilized from the dorsal joint capsule. A free palmaris longus tendon graft passed either through subperiosteal tunnels in the young child or through drill holes in the older youngster is more predictable. One portion of the graft must be palmar enough to reconstruct the volar accessory portion of the ligament. Both radial and ulnar sides of the joint require reconstruction in most type IIIA thumbs. When an FDS is used simultaneously for palmar abduction (opposition), one slip is passed through a bone tunnel in the metacarpal neck to be used on the ulnar side and the other slip for the radial side of the joint (Fig. 27.17C). Excess tendon on either side may be used for pulley reconstruction if needed.

In type IIIA thumbs with flail joints and poor or absent extrinsic motors, stability of the MP joint is much more critical than motion. Here a chondrodesis in the young child or arthrodesis in the adolescent is indicated. In the young child, the metacarpal head can be shaved without injury to the growth plate and then fused to the epiphysis of the proximal phalanx.[8,43] Thumbs that have grown in an abducted position and have an asymmetrical joint can only be stabilized by fusion. These stabilization procedures must be held with small wires with the joint in slight (20°) flexion. Unless held rigidly, these thumbs can easily drift into hyperextension with minimal cast motion.

Technique of tendon graft stabilization

A palmaris or another common tendon donor is harvested (ring finger FDS can be used in case of simultaneous opponensplasty) and the MP joint adequately exposed. An extension of the most radial limb of a four-flap Z-plasty provides good exposure for both sides of the joint (see Fig. 27.17). After inspection of the extrinsic flexor and extensor tendons with or without intratendinous fibrous connections (pollex abductus), joint capsule and collateral ligaments are inspected and imbricated if present. A subperiosteal vertical tunnel is made distal to the growth plate along the metaphysis of the proximal phalanx, and a transverse gauge hole proximal to the metacarpal head will provide the bone fixation for the graft. The tendon is then passed from the metacarpal fixation point, beneath the extensor shroud, through the periosteal tunnel from dorsal to palmar. It is then passed below the adductor aponeurosis and shroud to the metacarpal. At this point, it is

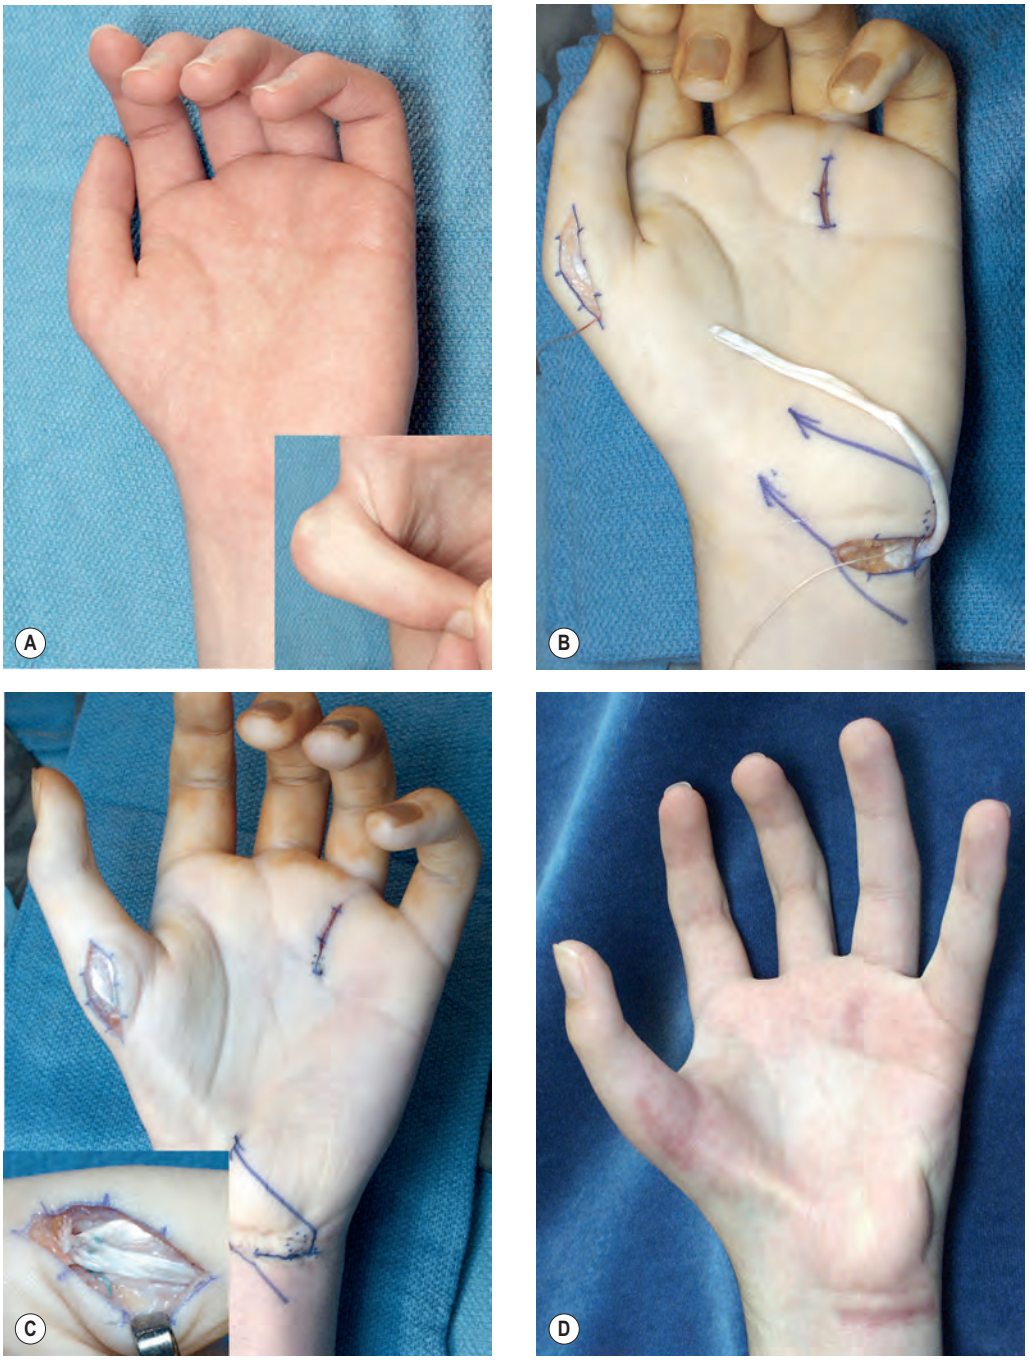

Fig. 27.17 Type IIIA thumb metacarpophalangeal (MP) joint instability. **(A)** The total absence of median innervated thenar muscles and an unstable MP joint are characteristic of a type IIIA hypoplastic thumb (inset). **(B)** The superficial flexor tendon to the ring finger has been looped around the flexor carpi ulnaris and passed through Guyon's canal toward the thumb. **(C)** The transfer is secured tightly and both free ends are used to reconstruct the absent collateral ligaments. The inset shows the upper (cord) and lower (volar accessory) portions of the new radial collateral ligament. **(D)** Three months postoperatively, the transfer is strong and the MP joint stable on both ulnar and radial sides.

important that the upper portion of this graft mimic the cord (upper) portion of the collateral ligament and the lower portion provide stability similar to that of the volar accessory portion of the collateral ligament. If this lower portion is fixed at or dorsal to the axis of joint rotation, an MP joint extension contracture will predictably result. The graft is tightened with non-absorbable sutures in 10–15° of flexion and in neutral between radial and ulnar deviation. Pin fixation should not be necessary.

When the ring FDS transfer is performed for palmar abduction (opposition), either bifurcation of the tendon is of adequate length for radial and ulnar collateral ligament reconstructions. Most type IIIA and some type II thumbs need both sides of the joint stabilized.

Poor/absent palmar abduction (opposition)

The degree of first webspace contracture is a good clinical indication of the degree of hypoplasia of thumb abductors, and the need for opposition transfers can be determined both by thenar muscle examination and assessment of the thumb position during play activities. Often the child tends to use key pinching maneuvers because he or she cannot abduct the thumb adequately to obtain a pulp-to-pulp pinch or grasp

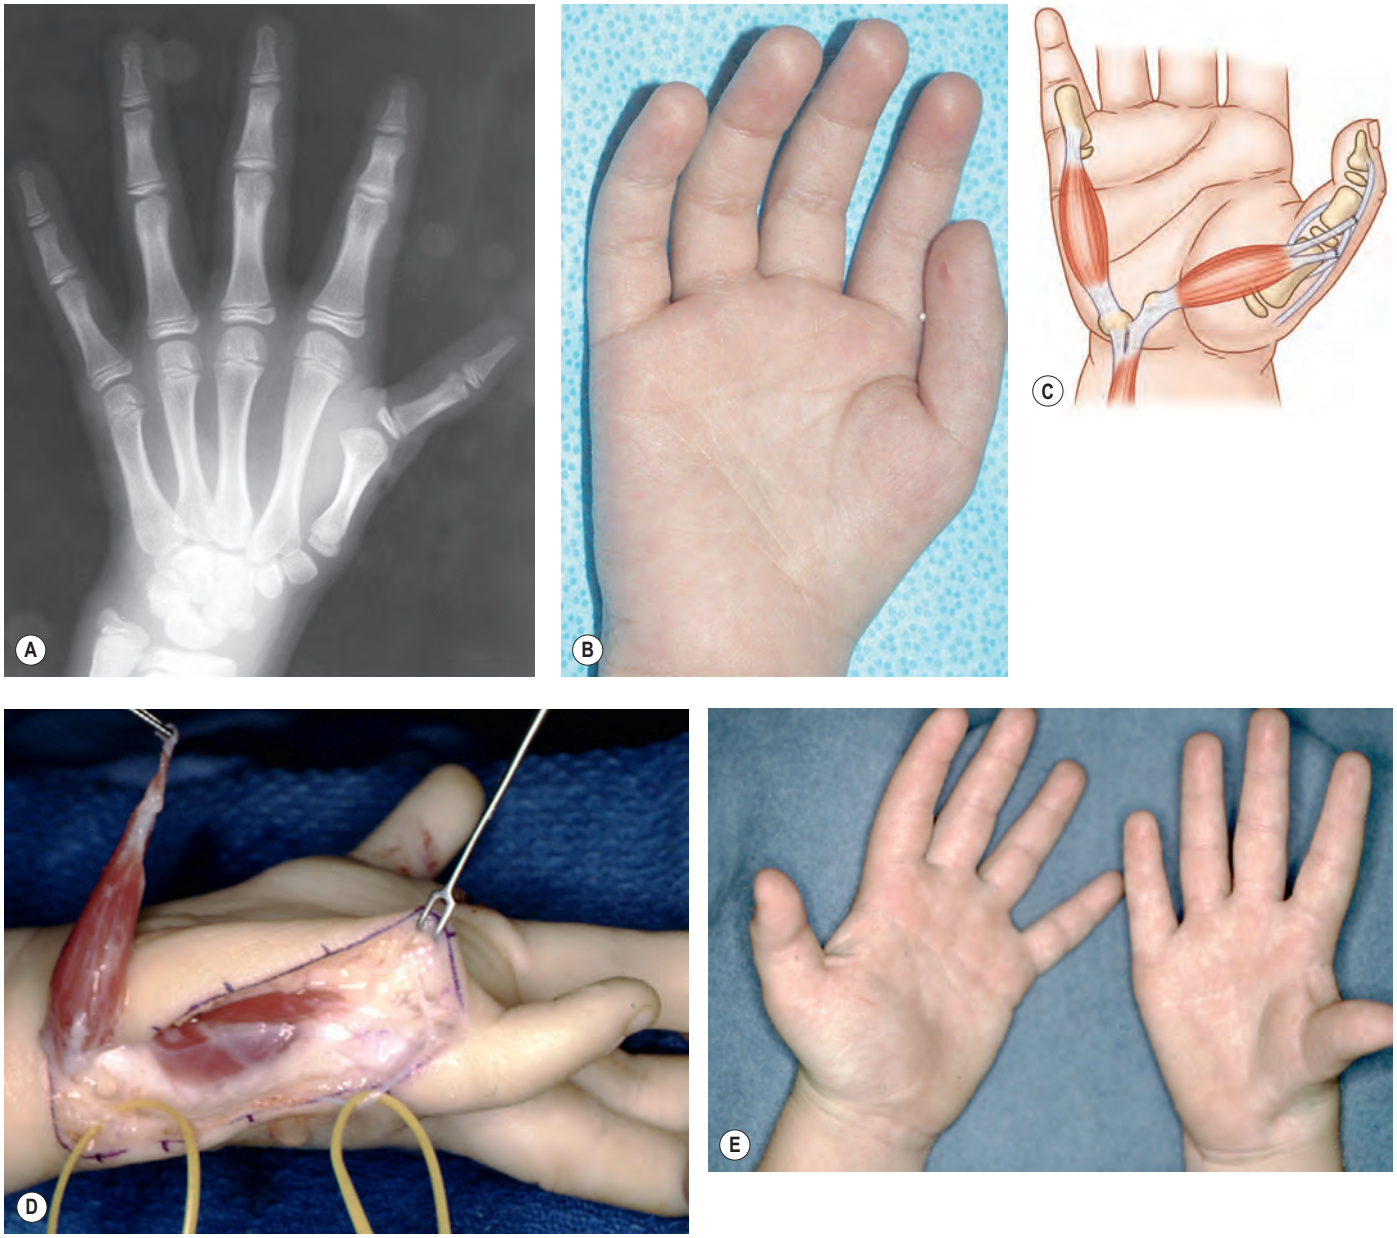

Fig. 27.18 Abductor digiti quinti minimi (ADQM) transfer for opposition. **(A)** The radiograph of this type IIIA thumb shows a small webspace and tightly adducted first metacarpal. **(B)** The clinical photo shows a marked deficiency of the median innervated thenar muscles. The radial and ulnar collateral ligaments are stable. **(C,D)** The abductor digiti quinti muscle is isolated on its origin from the pisiform and passed through a subcutaneous tunnel above the palmar fascia to the radial side of the thumb. If two distal tendons can be dissected, separate insertions into the thumb are performed. If one tendon is present, the preferred insertion is into the radial collateral ligament region. When a proximal dissection of the muscle is performed, its neurovascular bundle must be preserved. **(E)** The patient shown in (A) is seen 16 years later with functional palmar abduction from the muscle transfer.

and will use a two-handed grasp for holding larger objects. Substitution for the missing or hypoplastic thenar intrinsic muscles is not effective without a mobile CMC joint, adequate first webspace, and stabile MP joint. Most commonly, adequate palmar abduction (opposition) of the thumb is created by transfer of either the abductor digiti quinti minimi (ADQM)[88–93] or the flexor digitorum superficialis (FDS) of the long or ring finger (Figs. 27.17 & 27.18).[27,51,94,95] We have used the abductor digiti minimi transfer more frequently in patients with radial dysplasia who have undergone pollicization; in these patients, maximum flexor strength to the ulnar side of the hand is paramount.

Technique of ADQM transfer

The muscle is raised from an incision extending from the pisiform proximally to the midaxial line of the proximal phalanx (see Fig. 27.18). A skin island can be taken with the muscle,[58] which is then detached from its distal extensor and bone insertions. The myocutaneous flap provides the advantages of improving the soft-tissue deficit in the palm and minimizing tightness in the tunnel as a cause of muscle ischemia (Fig. 27.19). Color match is excellent and the borders of this flap are almost indistinguishable on long-term follow up.

This patient had a pollicization procedure but opposition was weak. **(A)** The incisions have been made, showing the markings and position of flap harvest. **(B)** The flap is fully mobilized, the digital nerve to the small finger and dorsal sensory branch of the ulnar nerve have been exposed and protected. **(C)** The flap transferred and inset. **(D)** Long-term follow up showing strong opposition.

Clinical tips

Myocutaneous Huber transfer

The authors have been using a myocutaneous Huber transfer more routinely. The advantage of this flap is that it enhances the bulk in the thenar area, while minimizing ischemia of the muscle as it traverses a tight tunnel in the palm. When harvesting this flap, it is best to place sutures affixing the skin to the underlying muscle to avoid shear injury to small perforators. The skin flap usually looks pale once the tourniquet is deflated after it is fully inset. However, if centered right over the muscle, the authors have not seen any necrosis.

If there are difficulties separating the ADQM from the flexor digiti quinti minimi muscle (FDQM), both muscles must be raised as a single unit.[89] A distal nutrient artery from the ulnar digital artery to the fifth finger must be ligated if present.[96] Additional length can be obtained with detachment from the pisiform[88] and retention on the flexor carpi ulnaris tendon. During this extra mobilization, the proximal axial pedicle to the muscle must be inspected carefully. The muscle is then passed through a very generous subcutaneous tunnel made between the skin and palmar fascia and then attached to the metacarpal, the radial collateral ligament at the MP joint, or the abductor aponeurosis. When a skin island is included, an open incision is made across the palm for inset. Insertion to the proximal phalanx or extensor mechanism should

not be performed with any laxity of the ulnar collateral ligament.

Technique of FDS transfer

Harvest of the FDS tendon to the ring finger is done through a longitudinal incision at the base of the ring finger (see Fig. 27.17). The A1 pulley is released, the finger flexed, and both slips of the FDS pulled into the wound and cut as far distally as possible. The tendon is then delivered through an incision over the flexor carpi ulnaris (FCU) dorsally and then passed through a subcutaneous tunnel to the radial side of the thumb where the insertion options are the same as ADQM. The pivot point for the transfer is either through Guyon's canal or around the FCU. It is not advisable to make a loop from a slip of the FCU through which the tendon pivots. The thumb is placed in 45° of palmar abduction and held with a transverse C-wire through the thumb and index metacarpals. One slip of the FDS tendon is passed through a transverse drill hole proximal to the metacarpal head and secured. The two slips of the ring FDS are then used for reconstruction of the radial and ulnar collateral ligaments as described (see Fig. 27.17). At the same time, the existing ligament and capsule are tightened.

Lack of IP joint motion

The most difficult function to reconstruct in type II and IIIA thumbs is IP joint motion. Dorsal capsulotomy and tendon recentralization will improve the minimal deformities. In the pollex abductus anomaly, flexors and extensors with good proximal excursion need to be centralized with pulley construction. In cases of poor motion, tendon transfers are performed at a second stage or avoided entirely. An available ring FDS is the most appropriate for IP flexion and an EIP for IP joint extension. Secondary transfers for extension include brachioradialis (BR) or extensor carpi radialis longus (ECRL) plus a tendon graft to the EPL.[50]

Pollex abductus

The clinical presentation of thumb abduction with limited IP motion is indicative of this anomaly (see Fig. 27.4).[42,97] Both the flexor and extensor tendons are exposed through a radial incision or via the retracted flap of the webspace release. Exploration and traction on the extrinsic tendons will give an estimation of distal IP motion and proximal muscle belly excursion. The interconnecting bands are divided and excised along the radial side of the MP joint and proximal phalanx. The incision on the radial side of the thumb should be extended until all interconnecting bands are severed and independently restored to both flexor and extensor tendons. The reconstruction here depends upon the degree of anomalous anatomy. Absence of both the short and long thumb flexors (FPB and FPL) will severely impair both pinch and grip functions. In those without a pollex abductus, the FPL is usually satisfactory and the pulley system can be strengthened by a slip of tendon – usually taken from the end of an FDS transfer. A piece of extensor retinaculum will also make a good pulley.[98] The FPL in the pollex abductus has a poor proximal excursion and can be transferred to the base of the thumb to act as an abductor pollicis longus (AbPL). Transfer of these abnormal aberrant tendons into a normal position to improve IP joint motion is not effective.

Following release of the extrinsic tendons and excision of anomalous muscles, a difficult decision must be made with regard to construction of the terminal flexor and at least one strategic pulley. Interphalangeal joint flexion can be created by transfer of an unscarred FDS tendon (ring or long) at the same time that palmar abduction (opposition) is restored by an ADQM (Huber) transfer.

Technique of pollicization

Even though pollicization greatly enhances the function of these hands, it is important to remember that the index finger is only placed in a more strategic position to simulate a thumb (Video 27.1 ▶). The newly created CMC joint was the index MP joint and, therefore, does not have the same degree of freedom as the normal CMC joint of the thumb (Figs. 27.20 & 27.21). Since the normal cone of thenar intrinsic muscles are absent, the strength and stability of these thumbs in both pinch and grasp maneuvers does not approach normal.

Principles

The principles of this procedure, the most elegant in hand surgery, include: (1) transposition of the index digit as a vascular island; (2) a rotation and recession shortening of the ray; (3) a rebalancing of muscles and tendons; and (4) incisions to create a normal first web. Recently described technical refinements to the procedure improve appearance and function.[58] The operation itself is divided into a number of steps.

Incisions and plan

A number of different incisions have been used over the past three decades (see Fig. 29.21A).[15,14,58,99–104] Although the markings of Buck-Gramcko[14,105] are used most frequently, we prefer a modification of the Littler incisions, which permit much greater flexibility for construction of a broad thumb–index webspace.[50,58,106] A racquet-shaped incision is made around the base of the index ray along the MP flexion crease and extends down the radial border of the hand. The site of the new thenar flexion crease is made in the palm, and the distal portion of the incision is connected to the incision around the index ray. It is best to plan these incisions as though no thumb or thumb remnant was present and to incorporate this extra tissue into the flap designs only if appropriate. If a type IIIB, C, or type IV thumb is present, the skeleton is filleted from its soft-tissue envelope and intrinsic muscles transferred to the new thumb. In certain deficient hands, the soft tissue of the extraneous digit can be isolated on a vascular pedicle, as a vascularized adipofascial flap, and placed in the thenar area to augment the deficiency (Fig. 27.22 🌐).[49] Fig. 27.22 appears online only.

Dissection and exposure

The dorsal flap is raised in the subcutaneous fat plane above the large dorsal veins, nerves, and lymphatics – all of which are preserved in a single layer of fat and areolar tissue above the extensor mechanism. Usually one large vein is present on either side of the dorsum of the digit. The neurovascular structures are dissected, and the palmar flap is raised above the level of the palmar aponeurosis, exposing the superficial palmar arch. The common digital bundle to the index–long

DP, Distal phalanx; MP, middle phalanx; PP, proximal phalanx; M, metacarpal; DIPJ, distal interphalangeal joint; PIPJ, proximal interphalangeal joint; MPJ, metacarpophalangeal joint; CMCJ, carpometacarpal joint; EDC, extensor digitorum communis tendon; EIP, extensor indicis proprius tendon; EPL, extensor pollicis longus; 1st PI, first palmar interosseous (ulnar interosseous) muscle; 1st DI, first dorsal interosseous muscle (radial interosseous; abductor indicis); AbPB, abductor pollicis brevis muscle; AddP, adductor pollicis muscle; FPB, flexor pollicis brevis muscle; AbPL, abductor pollicis longus tendon(s). **(B)** The preoperative markings are compared to the **(C)** clinical appearance 6 months following pollicization. The dot in the mid-palmar aspect of the index finger is relocated to the midportion of the thenar flexion crease in the postoperative state.

webspace and the floating thumb (if present) are exposed but individually dissected. Arterial loops around the nerve are present in less than 10% of our cases; however, neural loops around the artery are more common and are opened by gently spreading the nerve back to the level of the superficial arch. Use of microinstruments is recommended. We have not commonly seen the arterial anomalies previously described[107] and do not feel preoperative angiography is necessary. The radial bundle to the index digit is usually hypoplastic but rarely absent. In the presence of a thumb, a common bundle gives one artery to the thumb and one to the index ray. With clear retraction of the neurovascular structures and skeletal and extensor origins of the volar interosseous, first dorsal interosseous and adductor pollicis (if a thumb is present) are detached and the muscles dissected back to their periosteal origin. The index extrinsic flexors are not altered and its lumbrical is left intact. Then the A1 pulley is decompressed. On the dorsal side, the extrinsic extensor digitorum communis and extrinsic indicis proprius to the index are isolated and divided at the level of the MP joint. The lateral bands are gently separated from the common extensor at over the proximal phalanx, which will soon become the new thumb metacarpal.

Skeletal shortening

From both dorsal and palmar approaches, a subperiosteal dissection of the metacarpal is completed and osteotomy sites

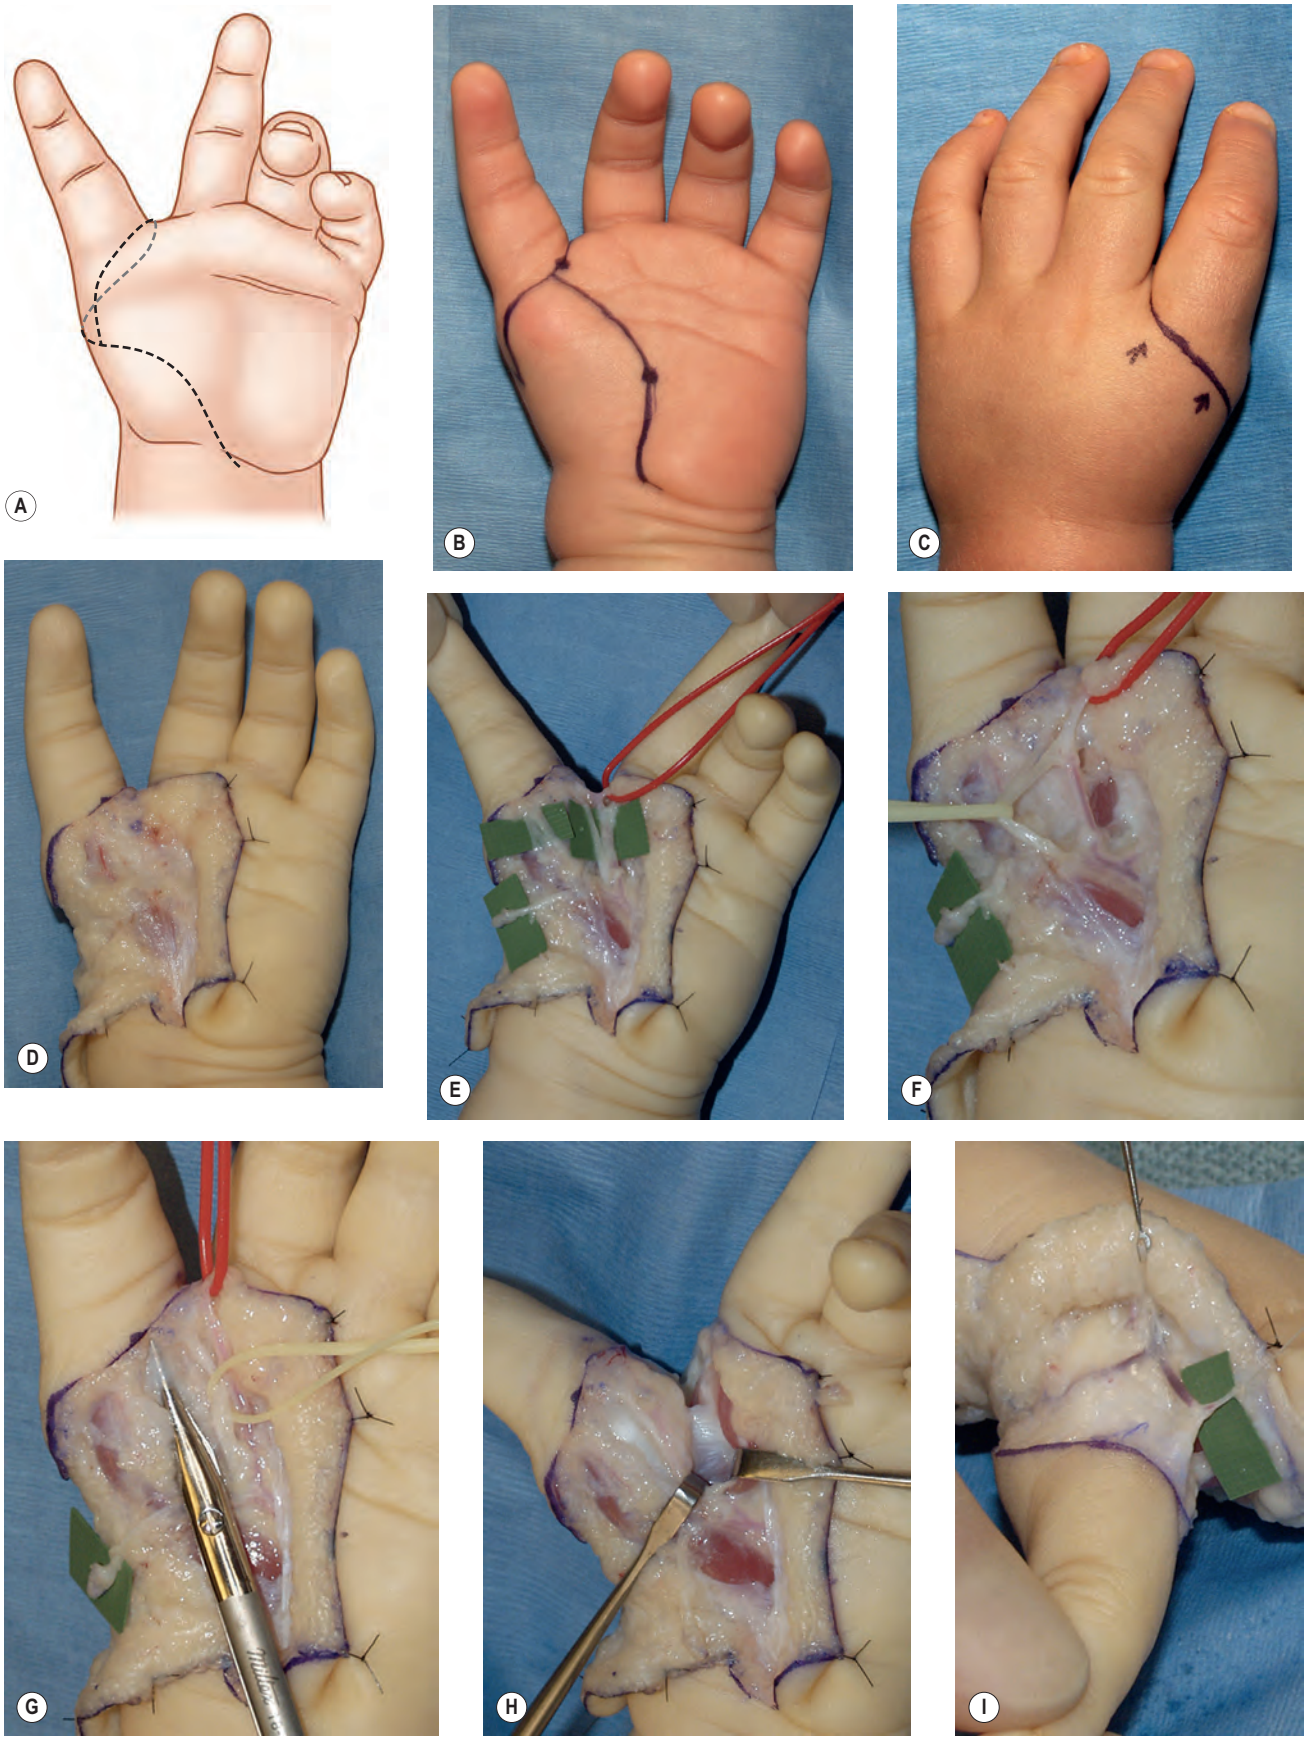

Fig. 27.21 Pollicization technique. **(A)** The illustration and palmar view show the site of the incisions. The most important marking is the location of the future thenar flexion crease within the palm. **(B)** The volar base of the index finger will be the midportion of this flexion crease. **(C)** The dorsal marking is made and the visible dorsal draining veins marked by arrows. **(D)** The palmar flaps are elevated above the palmar aponeurosis. **(E)** The common digital bundle to the index–long webspace is isolated. The arborization to the radial side of the long finger (red loop) will be ligated. Note the neuroma in the dissected sensory nerve to the "floating thumb", which was ligated in the newborn nursery. **(F)** A neural loop around the common vessels to the webspace must be carefully teased apart back to the level of the palmar arch. **(G)** A full release of the first annular (A1) pulley is completed. **(H)** The transverse metacarpal ligament is exposed before its transection, which then provides increased mobility of the ray for the intrinsic muscle dissection. **(I)** The dorsal venous system is easily exposed by scissor dissection between the two layers of dorsal fat/areolar tissue.

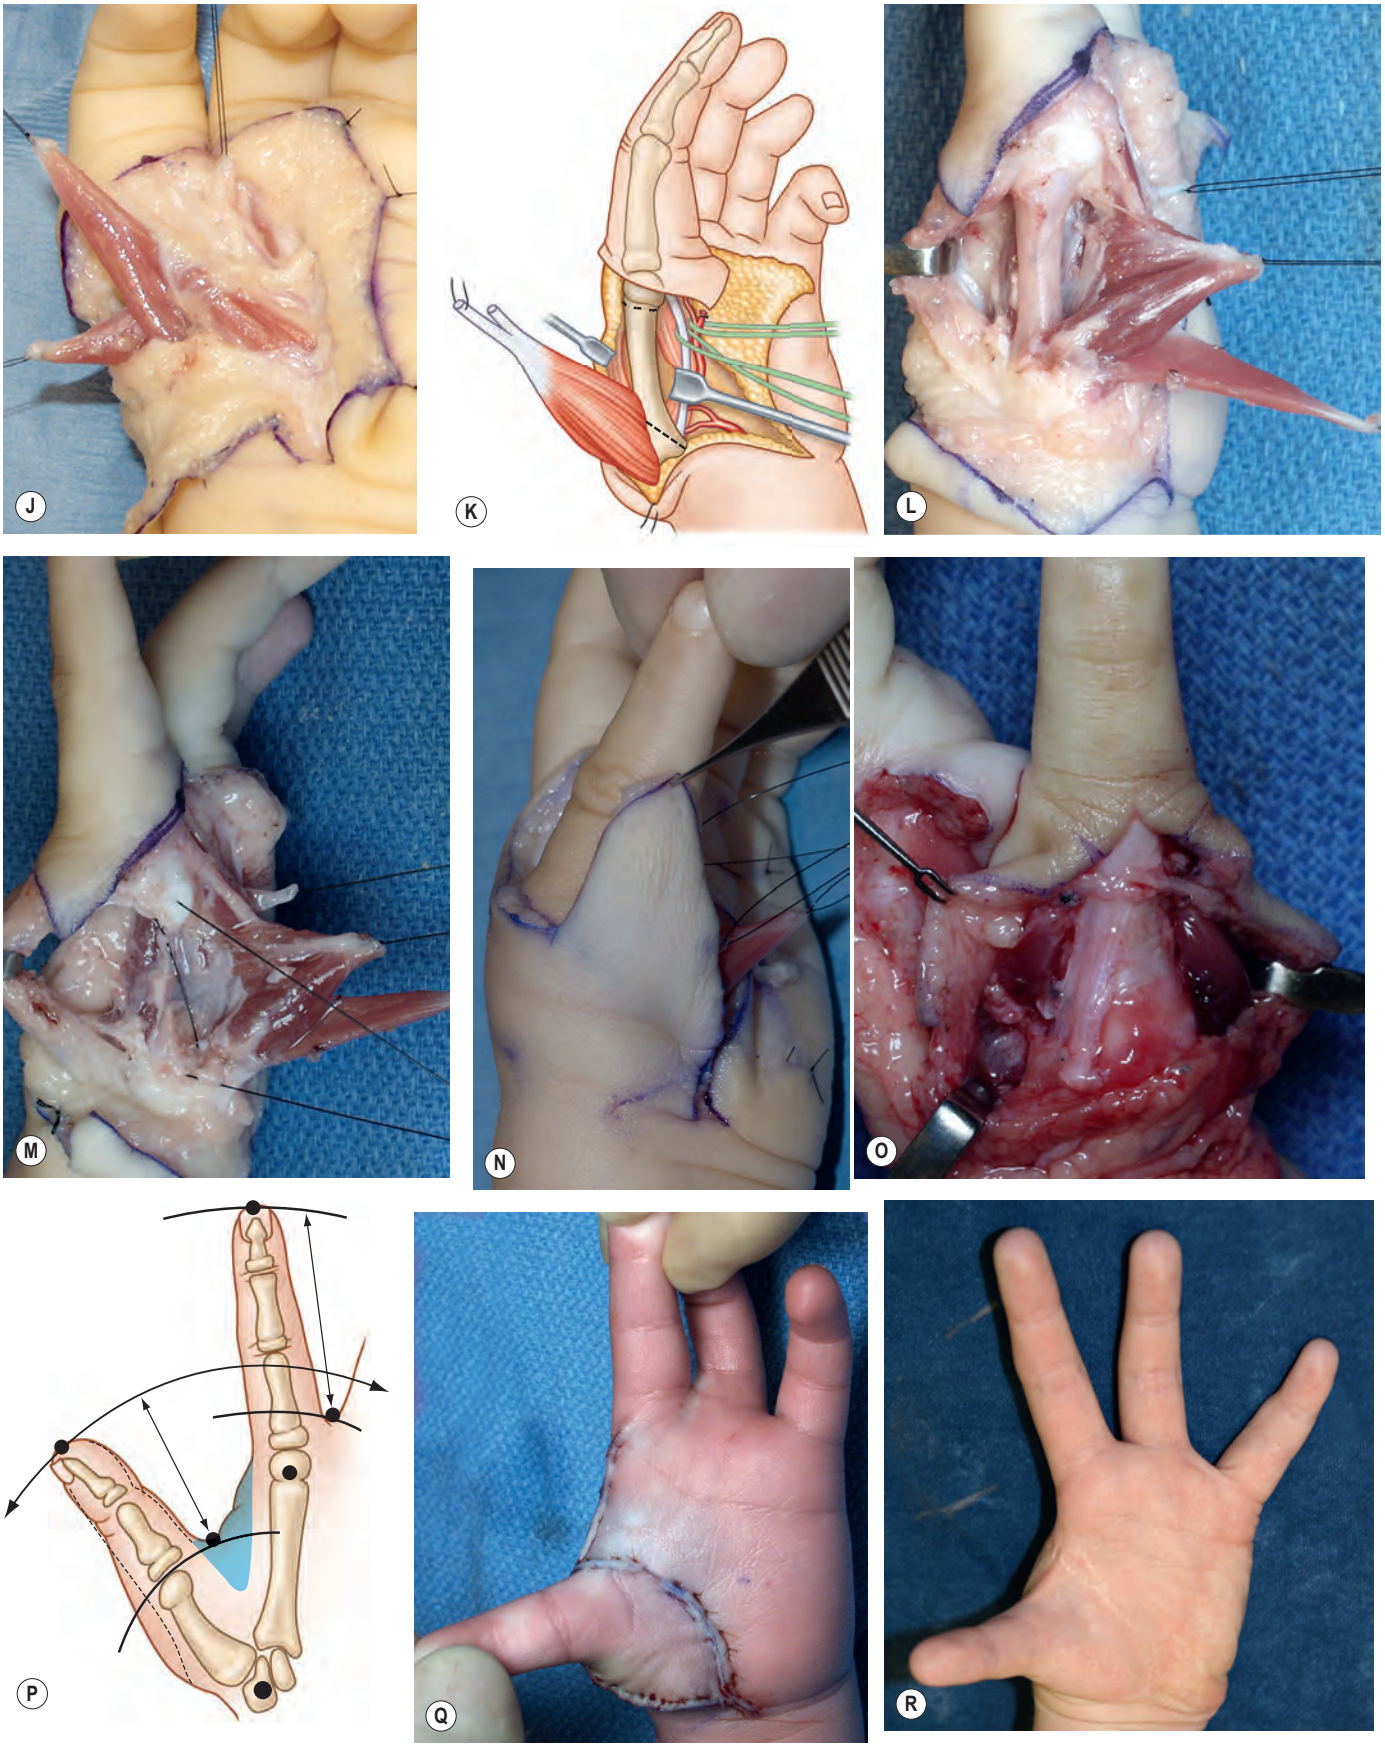

Fig. 27.21, cont'd **(J)** The first dorsal interosseous (abductor indicis) muscle has been detached from its distal bone and extensor insertions. Two distinct muscles are often found. **(K)** The illustration and **(L)** clinical picture show that the muscles are attached to their periosteal origin, which has been elevated off the metacarpal. The distal osteotomy is through the epiphysis and the proximal cut leaves the dorsal cortex of the metacarpal base. **(M)** The metacarpal head becomes the new thumb trapezium and is placed in a hyperextended position in front of the metacarpal base. Interosseous suture fixation is preferred to C-wires, which can cause problems in young children. **(N)** With the thumb in its new position, the available skin is then draped over the dorsal surface before the cut-back incision is made. This maneuver makes maximal use of the all available tissue. **(O)** The extrinsic tendons have been shorted and reattached, and the intrinsic muscles have been attached distally either to bone or the extensor mechanism via the lateral bands. **(P)** The normal appearing first webspace is a gentle curve between the metacarpophalangeal joint of the thumb and that of the long finger. The shaded area represents the area covered by the additional flaps rotated to create this web. **(Q)** After closure, a broad web allowing maximal abduction should be present. **(R)** The same hand is seen 5 years later.

marked (Fig. 27.23). The intrinsic muscle origins are carefully protected during this dissection, which extends anterior to the index metacarpal to the level of the CMC joint. The proximal osteotomy site is marked and an oblique cut made through the metacarpal, leaving a small post of dorsal cortex to which the metacarpal head will be attached. The distal metacarpal osteotomy is made through the epiphysis in order to arrest the growth of the metacarpal head, which becomes the new thumb trapezium. Careful dissection around this area is necessary to avoid injury to the vessels supplying the proximal phalanx.[59] The index finger is now "recessed and rotated"[108] and secured anterior to the base of the index metacarpal with one or more interosseous sutures.[58,98,109] In this position, the MP joint must be hyperextended[110,111] between 60 and 80°, a position which permits only a few degrees of additional extension of the new joint. Non-absorbable sutures are preferred to C-wires, which can become problematic in young children. This difficult fixation is facilitated by optimal assistance and retraction. At this point in the operation, the tourniquet is deflated for a minimum of 30 min. Fig. 27.23 appears online only.

Tendon and intrinsic muscle rebalancing

The dorsal flap is first draped over the repositioned index finger, which is held in 45° of palmar abduction, and the dorsal cutback incision is made (Fig. 27.21O). This incision is intentionally delayed because optimal use of all available skin can be crucial for creation of a broad webspace. Once made, wide exposure to the new thumb is provided. The extensor digitorum communis (EDC) is advanced and sutured to the ulnar base of the index proximal phalanx (now the thumb metacarpal), so that it provides both extension and pronation. The independent EIP is advanced, a portion resected and sutured side by side to the extensor hood with the new thumb held in no more than 10° of MP and IP flexion. Recently, we have accomplished this by simple plication.[13] In rare instances, when there is only one extensor on the index finger, this should be used as the EPL.[105]

The intrinsic muscle rebalancing is critical to the resting posture of the thumb. The small first volar interosseous, which becomes the new AddP, is attached either to the ulnar collateral ligament at the MP joint or into the wing tendon of the extensor mechanism.[13,112] Preferably, the much larger 1st DI (or abductor indicis), which becomes the new AbPB, is inserted into the radial collateral ligament or the radial base of the new proximal phalanx. When two separate muscles are dissected, one is inserted into bone and the other into the wing tendon (lateral band) on the radial side of the extensor mechanism. Nothing is done with the lumbrical attached to the index FDP. Additional muscles may be found and used when a hypoplastic thumb is present to increase the bulk of the thenar portion of the hand. In those cases, where the 1st DI (abductor indicis) is absent,[46,108,113] the EDC can be transferred to the palmar surface of the new thumb metacarpal (formerly index proximal phalanx).

The final position of the new thumb is in extension (not hyperextension), which will be properly balanced within 3–5 months when the extrinsic flexors auto-tighten. Primary shortening of the new extrinsic flexor can be performed initially, but is especially reserved for those with a stiff index finger.[114]

Skin closure and web construction

Following skeletal rotation and recession and reattachment of all available musculotendinous parts, one of the most challenging portions of this procedure, the tension-free closure, begins (see Fig. 27.21P,Q). Each hand has a different amount of tissue with which to create a normal-appearing, broad thumb–index webspace. First, the new thumb thenar flexion crease is sutured with the thumb in the appropriate amount of pronation in the palmar abducted position. In this position, the dorsal flap of the hand is advanced over the new thumb, and the dorsoradial flap of the index finger is advanced toward the MP joint of the long finger to create a normal-appearing webspace.[115] This may require additional mobilization and trimming of flaps. As a rule, we try to avoid a straight-line closure dorsally. Finally, the flaps on the radial side of the thumb are trimmed and closed. This skin closure provides a remarkable amount of stability to the new thumb's position. While many different incisions have been proposed,[116,117] this particular one is a modification of the Littler and Buck-Gramcko approaches.[13,105] The major differences are that the position of the new thenar crease is the most important point to be determined and the cutback incision into the index is delayed until the available skin can be draped over the index.

Treatment of other types of thumb hypoplasia (types VI–X)

Type VI: central deficiencies – cleft hand and symbrachydactyly thumb

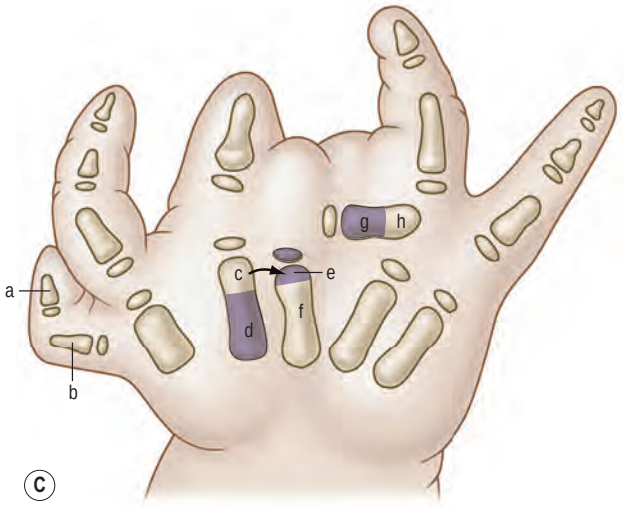
Cleft hand

In treating a patient with the cleft hand anomaly, the following principles should be followed:

1. Release the first web syndactyly and contracture.
2. Maintain maximal thumb mobility.
3. Complete ulnar transposition of the index digit.
4. Preserve the adductor pollicis, if present.
5. Rotate full-thickness skin flaps into the first webspace.
6. Release any syndactyly involving the two ulnar digits.
7. Create an intermetacarpal ligament between index and ring fingers.
8. Treat the thumb polydactyly in a standard fashion.

Several procedures and modifications have been described to accomplish these principles for the management of this condition.[30,54,76,118–122] Flaps of the cleft skin based on either the volar or dorsal surface have been used. Unfortunately, both of these designs suffer from the same anatomical problem: The skin flap from the cleft is a random pattern flap, and the viability of the distal portion of the flap can be suspect. Tajima has described closure of the newly created first web with a dorsal sliding flap.[95] This design poses less risk to the blood supply of the skin flap.

Our preferred method of thumb correction utilizes incisions much like those designed for a pollicization. Incisions are made around the index finger at the same level. The digit is then transposed as a vascular island to the long position. The metacarpal is usually disarticulated and transposed at the CMC joint level. Dorsal and palmar flaps are raised and



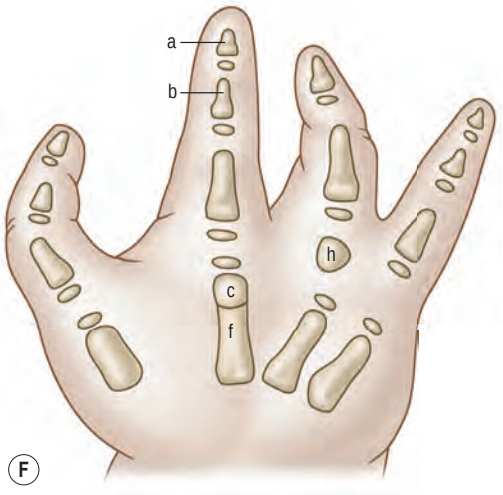


Fig. 27.23 Cleft (typical) hand thumb. **(A)** The left hand and **(B)** radiograph of a young child with an unusual cleft hand shows a triphalangeal thumb, a duplication at the metacarpal level, a short index ray with no distal two phalanges, and a transverse bone connecting the long and ring metacarpals at the metacarpophalangeal joint level. The schematic illustration shows the proposed reconstruction. **(C–F)** In a first stage, the index ray (c) was transposed on top of the long metacarpal (f). Only the ulnar portion of the transverse bone (h) was saved because it articulated with the ring proximal phalanx. At the second stage, shown here, the thumb duplication (a,b) was transferred on top of the index ray to make a longer and more complete digit. Nerves and tendons were all joined. **(G–I)** The patient developed a very functional pinch between the long (and untouched) triphalangeal thumb and the index finger. At skeletal maturity, her hand and radiograph are seen. The patient has become a very confident young lady and, in fact, has won regional New England piano competitions.

sutured directly to the skin flaps created by incision of the ulnar side of the cleft. Simple or complex Z-plasties can then be performed on either side of the thumb–index webspace as deemed necessary for contour improvement (see Fig. 27.22).

When these thumbs are triphalangeal, one of two options is preferred. A stable, well-aligned, mobile but long thumb is usually left uncorrected, and these longer thumbs function very well. However, the longer, flexed, or deviated triphalangeal thumbs should be treated. Shortening the thumb may require excision of the extra phalanx or osteotomies; the former approach invariably leads to stiffness. Improving alignment in the flexed or deviated triphalangeal thumb can also be challenging as the anomalous phalanx can be small. Excision of this phalanx may lead to stiffness and closing wedge osteotomies can be technically difficult. If the extra phalanx is small, the best option is to perform a closing wedge osteotomy and fuse it on its distal or proximal side to the neighboring phalanx.

A number of autosomal-dominant cleft hand and foot syndromes exist. In these patients, a transverse failure of formation of the thumb may be present at the metacarpal or phalangeal level. When no phalangeal segments are present, vascularized toe to thumb transfer using the distal portion of the great toe (if present) is preferred for thumb reconstruction. Distraction lengthening is another alternative.[50,123,124] Motion in these thumbs is poor, but sensation is good, and function is very gratifying because the deformities are always bilateral. Secondary procedures for correction of intrinsic joint laxity or deviation are common.

Symbrachydactyly thumb

Observation of these children at play will provide insight into the need for any thumb reconstruction. Children with symbrachydactyly tend to be among the most functional, as virtually all can oppose (not touch) the thumb to the small finger. They all have the components of a basic hand: a mobile radial ray, a cleft, and an additional ray or post on the opposite side of the hand for pinching and grasping functions. Even those with no phalangeal components can effectively grasp or pinch using only their metacarpal motion. Consequently, most of these children will not require any operative intervention, and to do so may be quite meddlesome. A hypoplastic thumb with good MP motion, stable joints, and present thenar intrinsics should be left alone.

Excision of non-functional nubbins will improve the shape of the cleft and provide a deeper webspace for grip. If these are not removed early in life, some patients and/or their families become psychologically attached to them and resist any suggestion of ablation. Some patients with this anomaly have a thumb deficient in length and unable to oppose to the highly mobile ulnar border digit. Distraction lengthening can improve both function and appearance. These patients may also lack pulp-to-pulp pinch due to poor pronation of the thumb during pinch maneuvers. Rotational osteotomies at the metacarpal level will resolve this problem by placing the digits in a more favorable position. The severely hypoplastic thumb, with an absent or diminutive proximal phalanx and a flail MP joint, is best treated with a non-vascularized toe phalangeal transfer into the proximal phalangeal level (Fig. 27.24). Although motion is not restored, the thumb becomes a more stable, functional post. These transfers are more likely to grow if performed before 1 year of age. Ablation of the small distal phalanx and second toe microvascular transfer is an option best performed between 2 and 4 years of age. Fig. 27.24 appears online only.

The ulnar digit in symbrachydactyly will often have an unstable MP joint and radial clinodactyly due to its asymmetrical proximal phalanx. The flexor tendons are usually strong and the extensors present but unbalanced. Stabilization of MP joints with chondrodesis, bone grafts, and non-vascularized toe phalanges have all been performed with varying degrees of success. When positioned as stable posts, these fifth rays function quite well for hooking and balancing maneuvers. With time and growth, most of these fifth rays are lengthened with distraction techniques.

Type VII: constriction ring syndrome

The following principles apply to the management of these thumbs:

1. Immediate treatment of emergency conditions such as vascular compromise and progressive lymphedema
2. Early liberation of the thumb ray when involved with syndactyly
3. Release of adduction contractures within the first webspace when present and resurfacing with full-thickness tissue if needed prior to any augmentation of thumb length.

Following release of the first ray, the functional requirements of the patient need to be accurately determined and the tissue(s) available carefully assessed. In those with distal amputations at the phalangeal level at or beyond the interphalangeal joint, no operative intervention may be the best course of action. Often all that needs to be corrected is a proximal constriction ring. Although the nail and palmar pulp may be atrophic, these thumbs are quite functional. Instability at the IP joint is easily corrected with a collateral ligament reconstruction using either a tendon graft or local tissues. Thumb length can be augmented utilizing one of three methods:

1. Distraction lengthening at the metacarpal level
2. Non-vascularized toe phalangeal transfer
3. Composite vascularized toe-to-thumb transfer – constriction ring syndrome is the most common indication for toe-to-thumb transfers in children.

Distraction lengthening is best performed at the metacarpal level when satisfactory bone stock is present. The metacarpal can be easily – but slowly – be lengthened up to 100% of its length as a two-staged procedure that includes application of distraction apparatus and osteotomy followed by bone grafting of the intercalated gap and internal fixation (Fig. 27.25). Primary resistance to this process will come from the AddP muscle. In this case, distraction is often limited to 50% of the original length. Lengthening of deficient, terminal, and narrowed phalanges in this condition is not as predictable and the resulting digits are often stiff and thin. Distal non-unions and exposure of phalanges or hardware used for internal fixation are common complications. Therefore, second-toe composite vascularized transfers are preferred to distraction at the phalangeal level. Fig. 27.25 appears online only.

Fig. 27.24 Symbrachydactyly (atypical cleft) thumbs. **(A,B)** The left hand of this child with the Moebius syndrome was reconstructed with a second toe transfer at age 18 months and is seen on the right at age 5 years during the distraction lengthening of the fifth metacarpal. The distraction was done in two stages: (1) osteotomy and application of distractor and (2) bone grafting. **(C,D)** Ten years later, the second toe transfer continued to grow in comparison to the ulnar metacarpal post. **(E,F)** The left hand and radiograph of another patient with generous soft-tissue nubbins, which represent the thumb and digits. **(G,H)** He was an ideal candidate for non-vascularized toe phalangeal transfer to the thumb and index rays. The first webspace was also deepened and widened with local flaps. Despite the limited mobility, this reconstruction was very functional. Despite the limited mobility of the hand, he had very functional use of this hand as a helper hand.

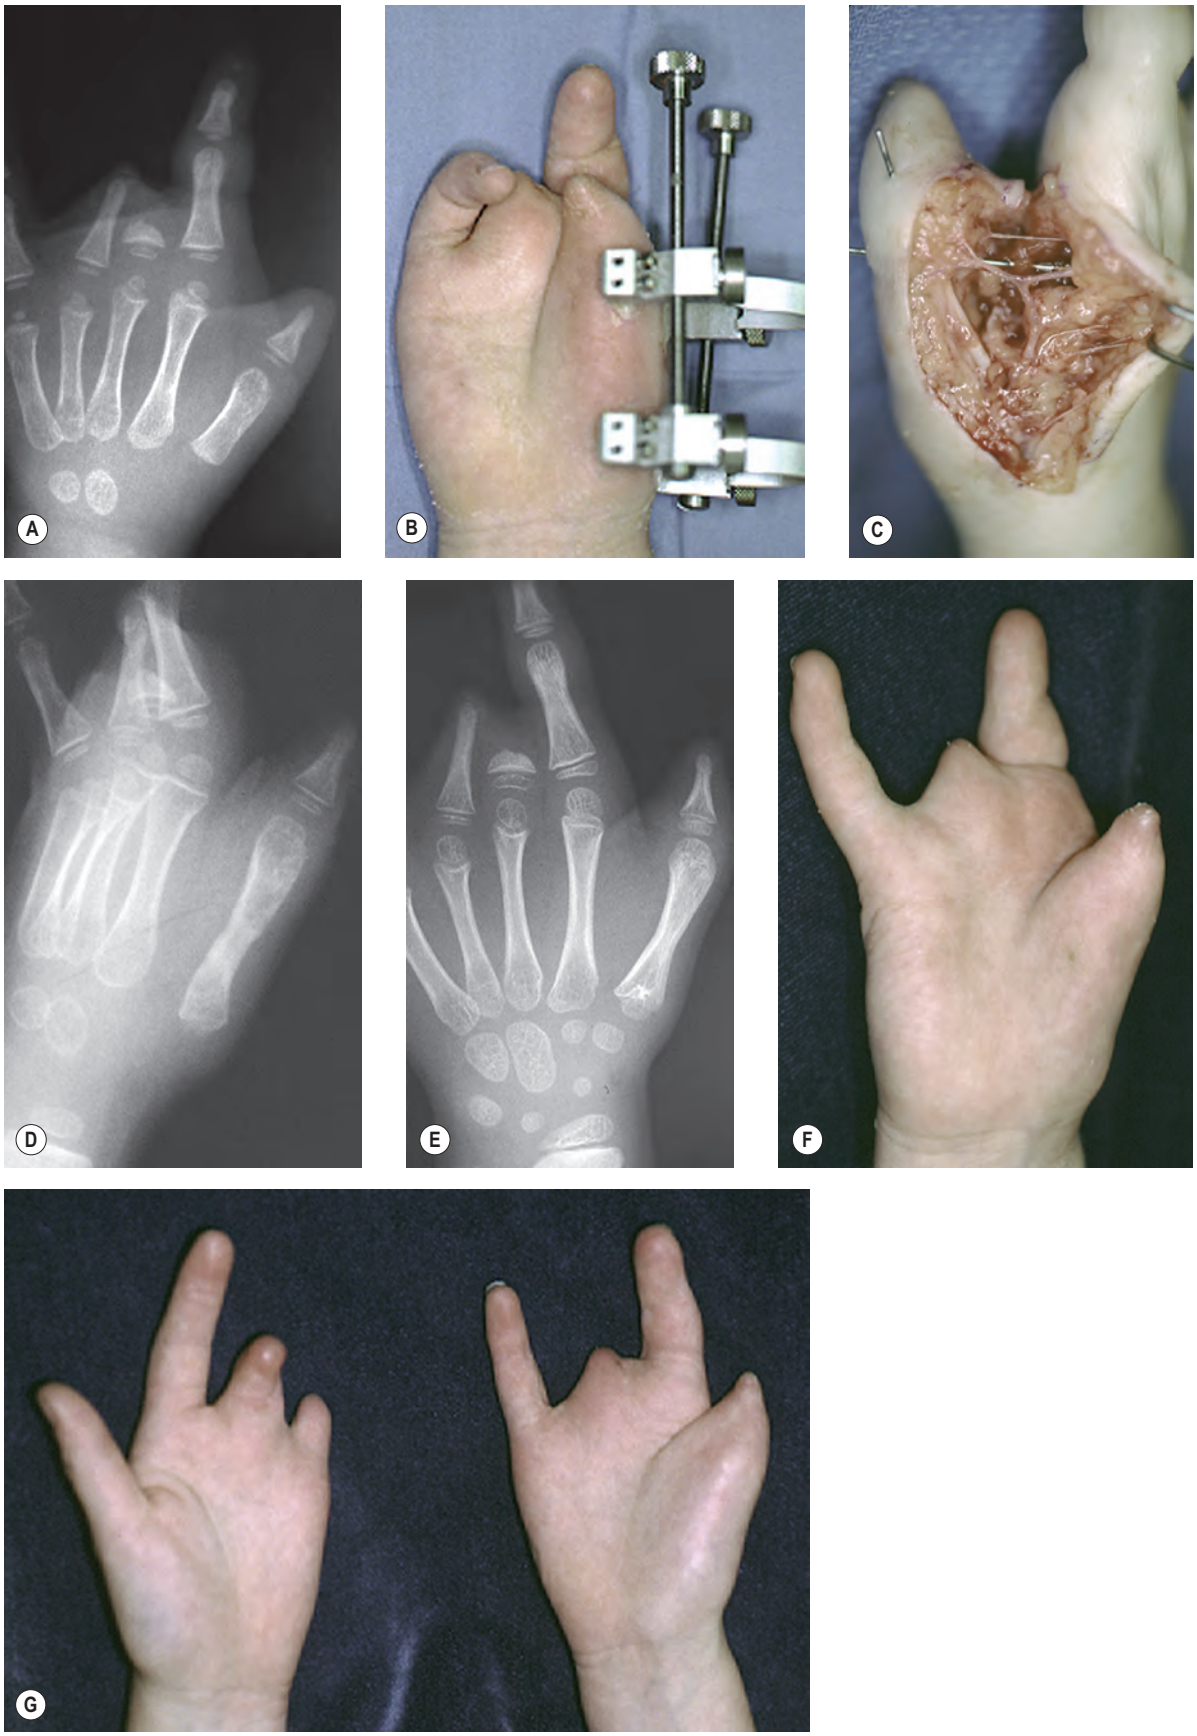

Fig. 27.25 Constriction ring syndrome (CRS) thumb treated with distraction lengthening. **(A)** The radiograph of a young girl with a congenital amputation at the thumb interphalangeal joint level with a tight first webspace. Note the tapered appearance of the proximal phalanx. **(B)** A distraction apparatus in place is pulling each end of the metacarpal away from the osteotomy site at mid-diaphyseal level. One clockwise turn of the screw equaled a 1.0 mm gain. **(C)** The new bone regenerate (callotasis) advances toward the midportion of the gap created. The stretching injury to soft tissue is impressive! All vessels, nerves and tendons are intact. **(D)** This thumb metacarpal is now as long as the index. **(E)** Five years later both metacarpals are growing but the index is now longer. **(F)** The first webspace was deepened to increase thumb mobility and increase its span. **(G)** Although shorter than normal, this thumb has functioned very well on her dominant hand.

Transfer of non-vascularized toe phalanges[125,126] is an excellent way to provide length and growth potential to an empty, redundant soft-tissue envelope – occasionally seen distal to the level of amputation in this condition. Extraperiosteal harvest and transfer of the third or fourth toe proximal phalanx will result in survival and growth of the phalanx in 90% of patients under 2 years of age (Fig. 27.26 ◍).[125] Our own experience has not been as successful since only 70% of these phalanges transferred early in life have retained normal growth potential. Survival and growth will occur in patients over 2 years of age but at a less predictable rate. The second toe is spared so that the entire toe is available for vascularized composite transfer if required. Secondary distraction lengthening of the transferred phalanx can be performed if further length is required. Fig. 27.26 appears online only.

In patients with a congenital amputation through the proximal phalanx or metacarpal, composite microvascular transfer of a second toe has been our procedure of choice. The great toe can be transferred either as a complete or as a modified unit (Fig. 27.27 ◍), but this option has been reserved for uncorrected thumb deformities, which present later in childhood. Since there is normal anatomy proximal to the level of amputation or band and there is an intact CMC joint, an excellent functional and aesthetic result of the "thoe" can be obtained. The presence of functional thenar intrinsics will also enhance the result (see Fig. 27.27 ◍). In several children, we have first lengthened a deficient metacarpal with an intact CMC joint in order to provide a good foundation for second toe transfer. The keys to the distraction procedure are to proceed slowly, to minimize soft-tissue dissection, and to avoid injury to growth centers. The major problem with any toe transfer is the availability of toes, which, like the fingers, may be hypoplastic or aplastic in the CRS. Fig. 27.27 appears online only.

Various types of on-top plasties have been described in the hand literature, and most consist of transfer and distal advancement of composite soft-tissue and bone segments from adjacent fingers. We prefer free transfers to these local transfers, which tend to require extensive dissection and secondary contractures within the first webspace. However, local ray transfers as pollicization procedures can be very effective, especially when the index ray is transferred to augment the thumb. A careful surgeon should avoid injury to the median and ulnar innervated thenar intrinsic muscles, including the adductor pollicis and its origin from the third metacarpal.

Type VIII: five-fingered hand

The optimal management of these patients is to pollicize the radial digit.[127] The technique employed is similar to that for thumb aplasia (type V). Rebalancing of the intrinsic musculature is paramount to the success of the procedure. In the five-fingered hand anomaly, the dorsal interosseous to the radial digit is only unipennate, and secondary opponensplasty with an ADQM or ring FDS transfer is occasionally necessary. The most important procedure is the creation of a broad first webspace with unscarred flap tissue.

When seen later in childhood or during adolescence, two other options are available: (1) the construction of a first webspace with a forearm flap plus arthrodesis of the proximal interphalangeal joint (PIP) joint or (2) a rotational recession osteotomy of the first metacarpal with pollicization and intrinsic rebalancing (Fig. 27.28 ◍). This condition should not be confused with a triphalangeal thumb, in which the thumb is somewhat shorter than the other digits. Fig. 27.28 appears online only.

Although an extra phalanx is present by definition, extrinsic and intrinsic muscle anatomy mimics a thumb more than a finger. The extra phalanx is often angulated and is commonly associated with radial polydactyly.

Type IX: radial polydactyly

The management of patients with radial polydactyly will vary for the level of duplication and are discussed in more detail elsewhere in this book. In general, the surgeon should use the best parts of each thumb to construct the finest thumb possible. Distal polydactylies (types I and II) are usually managed by preservation of the ulnar duplicate, with extra soft tissue provided from the radial thumb. The resulting nail is smaller than the one on the normal side. The Bilhaut procedure is avoided if possible due to the predictable problems of nail ridging, diminished IP joint motion, and a flat nail contour. Baek's modification of the Bilhaut–Cloquet procedure improves appearance outcomes.[128,129] Polydactylies at the proximal phalangeal level (types III and IV) are commonly managed with ablation of the radial partner and closure with tissue from this thumb. Musculotendinous abnormalities need to be addressed with the division of interconnections and centralization of insertions. Advancement of the detached thenar intrinsics into the retained extensor mechanism is mandatory, and collateral ligament preservation and reattachment is key to providing a stable MP joint. The metacarpal head will be broad in these patients and requires trimming on the redundant radial side. Closing wedge osteotomy of the metacarpal may also be required to realign the newly constructed thumb. Appropriate trimming of excess skin should result in wound closure, which should be positioned in the high midaxial position. Polydactylies in the metacarpal shaft (type V) can often be managed by simple ablation of the radial partner and concomitant four-flap Z-plasty for any first web deficiency. Polydactylies at the CMC joint level (type VI) and triphalangeal varieties all need to be dealt with on their merit. Digital transposition of the ulnar thumb onto the retained base of the radial partner is commonly performed. Skeletal realignment, tendon repositioning, and first web releases can usually be completed in a single stage.

Type X: syndromic short skeletal thumb ray

Many patients with short thumbs do not require any treatment as the length deficiency is mild. In those who do have an obvious length deficiency, distraction lengthening with a secondary bone graft to the subsequent bony defect at the metacarpal level is possible.

Patients with generalized syndromes require a multidisciplinary approach to their management, and hand procedures can be coordinated with other required treatments. Children with complex hand anomalies, such as those with Apert syndrome, require special attention so that the function of these thumbs and hands can be optimized.

First web syndactyly needs to be managed in the first 3–6 months of life so that the child can develop prehension without interference. The same options for treatment are outlined in

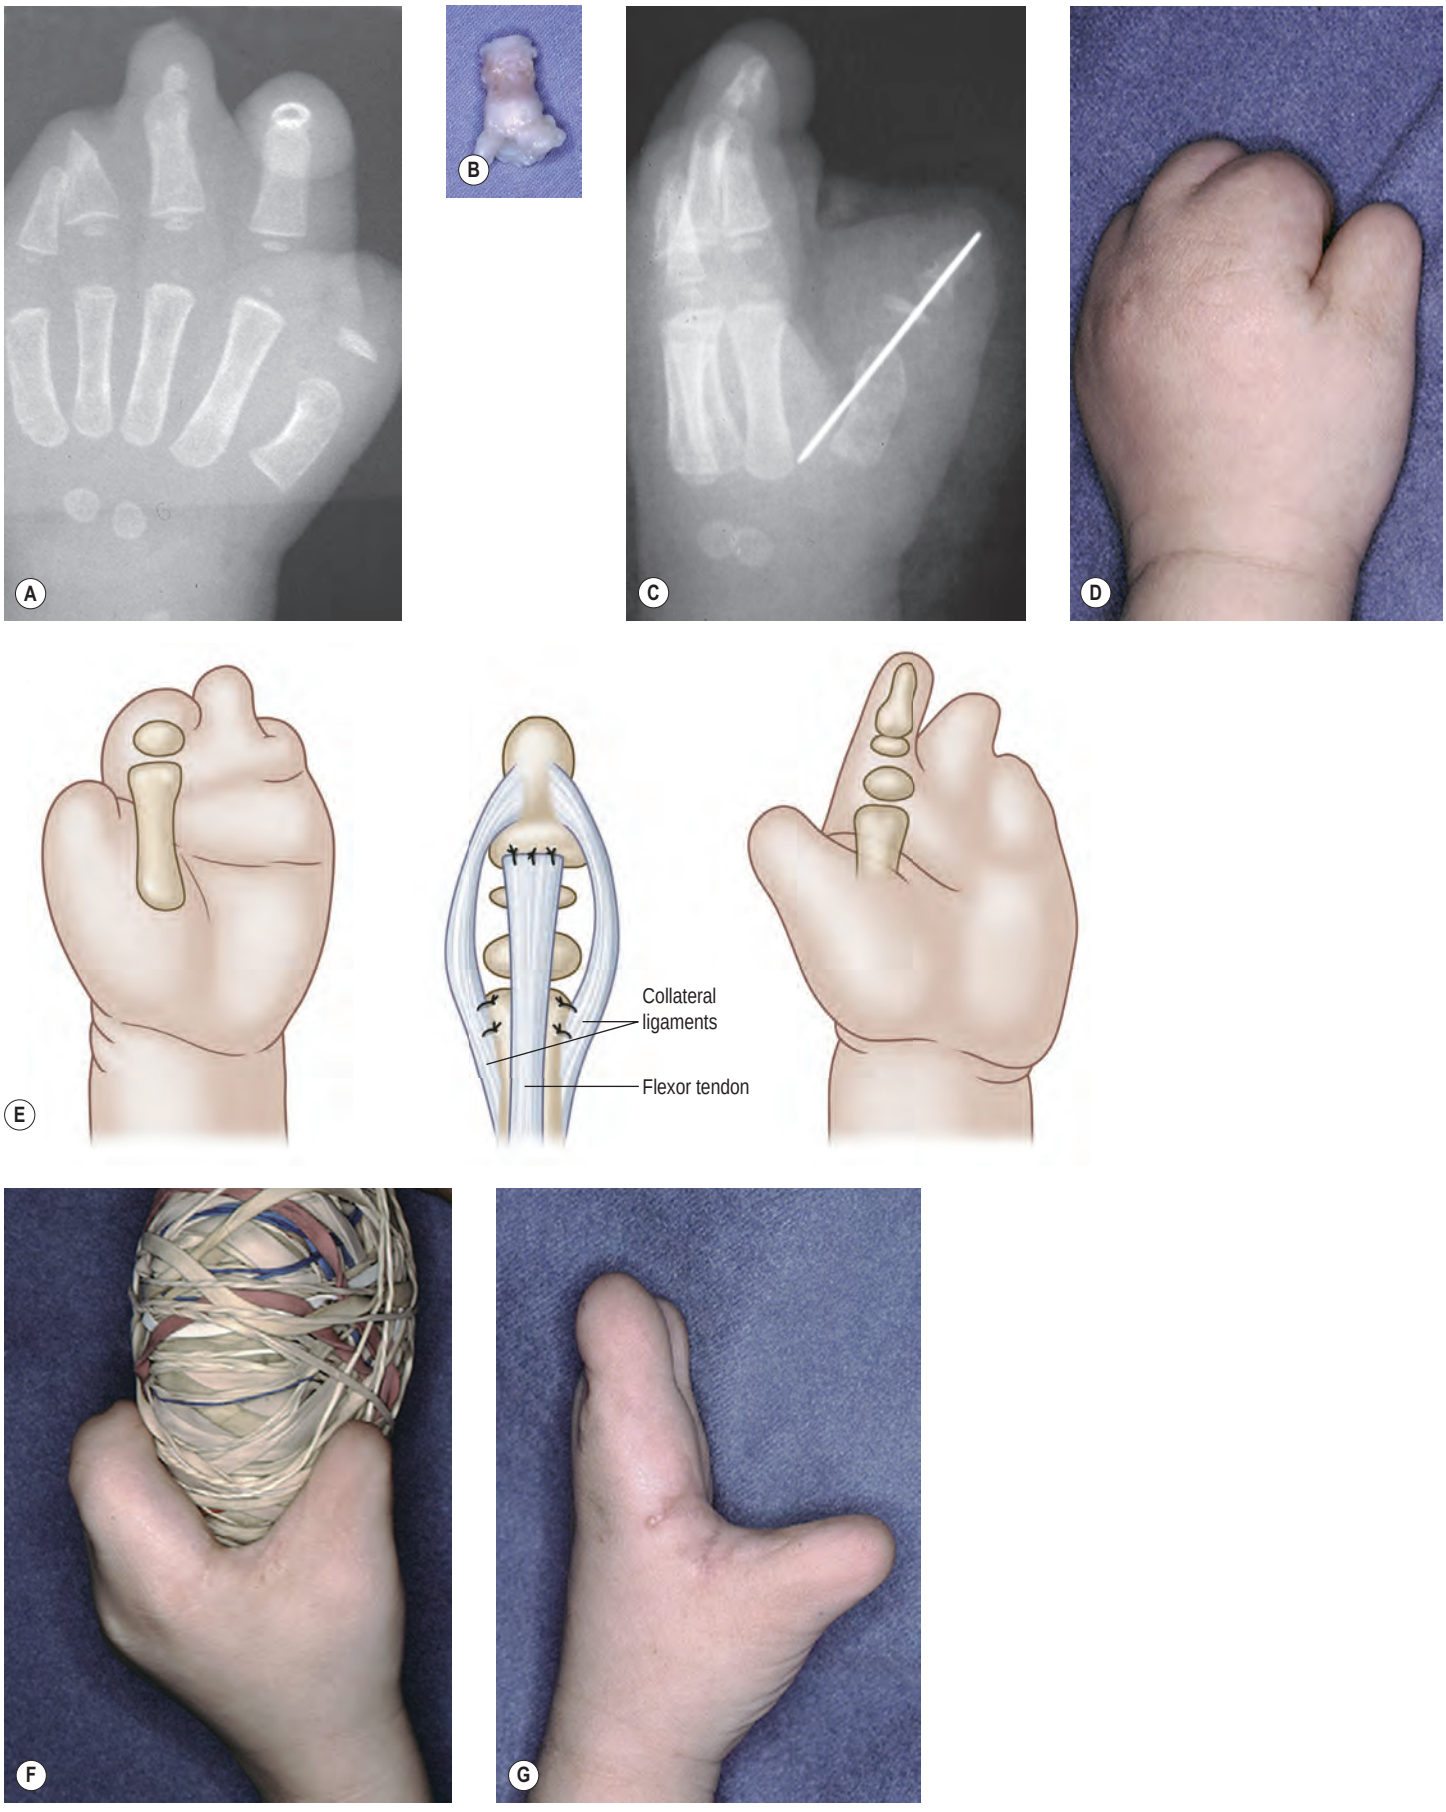

Fig. 27.26 Constriction ring syndrome (CRS) thumb treated with toe phalanx. **(A–D)** This child with CRS acrosyndactyly had the fibrous connections holding all fingertips released in the newborn nursery. The thumb ends at the metaphysis of the proximal phalanx and the index finger at the middle phalanx. Non-vascularized toe phalanges from the third and fourth toes were transferred on top of the index and thumb. **(B,E)** The periosteum is intact, and the collateral ligaments and volar plate are attached to the skeletal part at the amputation stump. Joint motion was preserved in this child. **(F,G)** A four-flap Z-plasty deepened the first webspace and improved her grasping ability. She is now 20 years of age and has had normal growth of the transferred phalanges. No further reconstruction has been performed.

Fig. 27.27 Constriction ring syndrome (CRS) thumb treated with microvascular toe transfer. **(A–C)** This boy, born with acrosyndactyly, demonstrated thumb loss at the interphalangeal (IP) joint level, no first webspace, and congenital amputations of the index and long digits at the phalangeal level. Connecting bands present at birth were released in the newborn nursery. His first surgery was a distally based radial forearm fasciocutaneous flap to the first webspace and release of the camptodactyly of the ring finger. **(D–F)** Thumb length was augmented with a modified great toe transfer. A methylmethacrylate mold of the opposite normal thumb is used to measure and contour the larger great toe at the time of operation. The incision markings are shown on the ipsilateral great toe, and the specimen is seen in transit to the recipient left thumb. **(G,H)** The thumb is seen 4 years later. Sensation is normal, and motion measures 30° at the IP joint and 50° at the metacarpophalangeal joint. The contour has been excellent. No revisions have been performed.

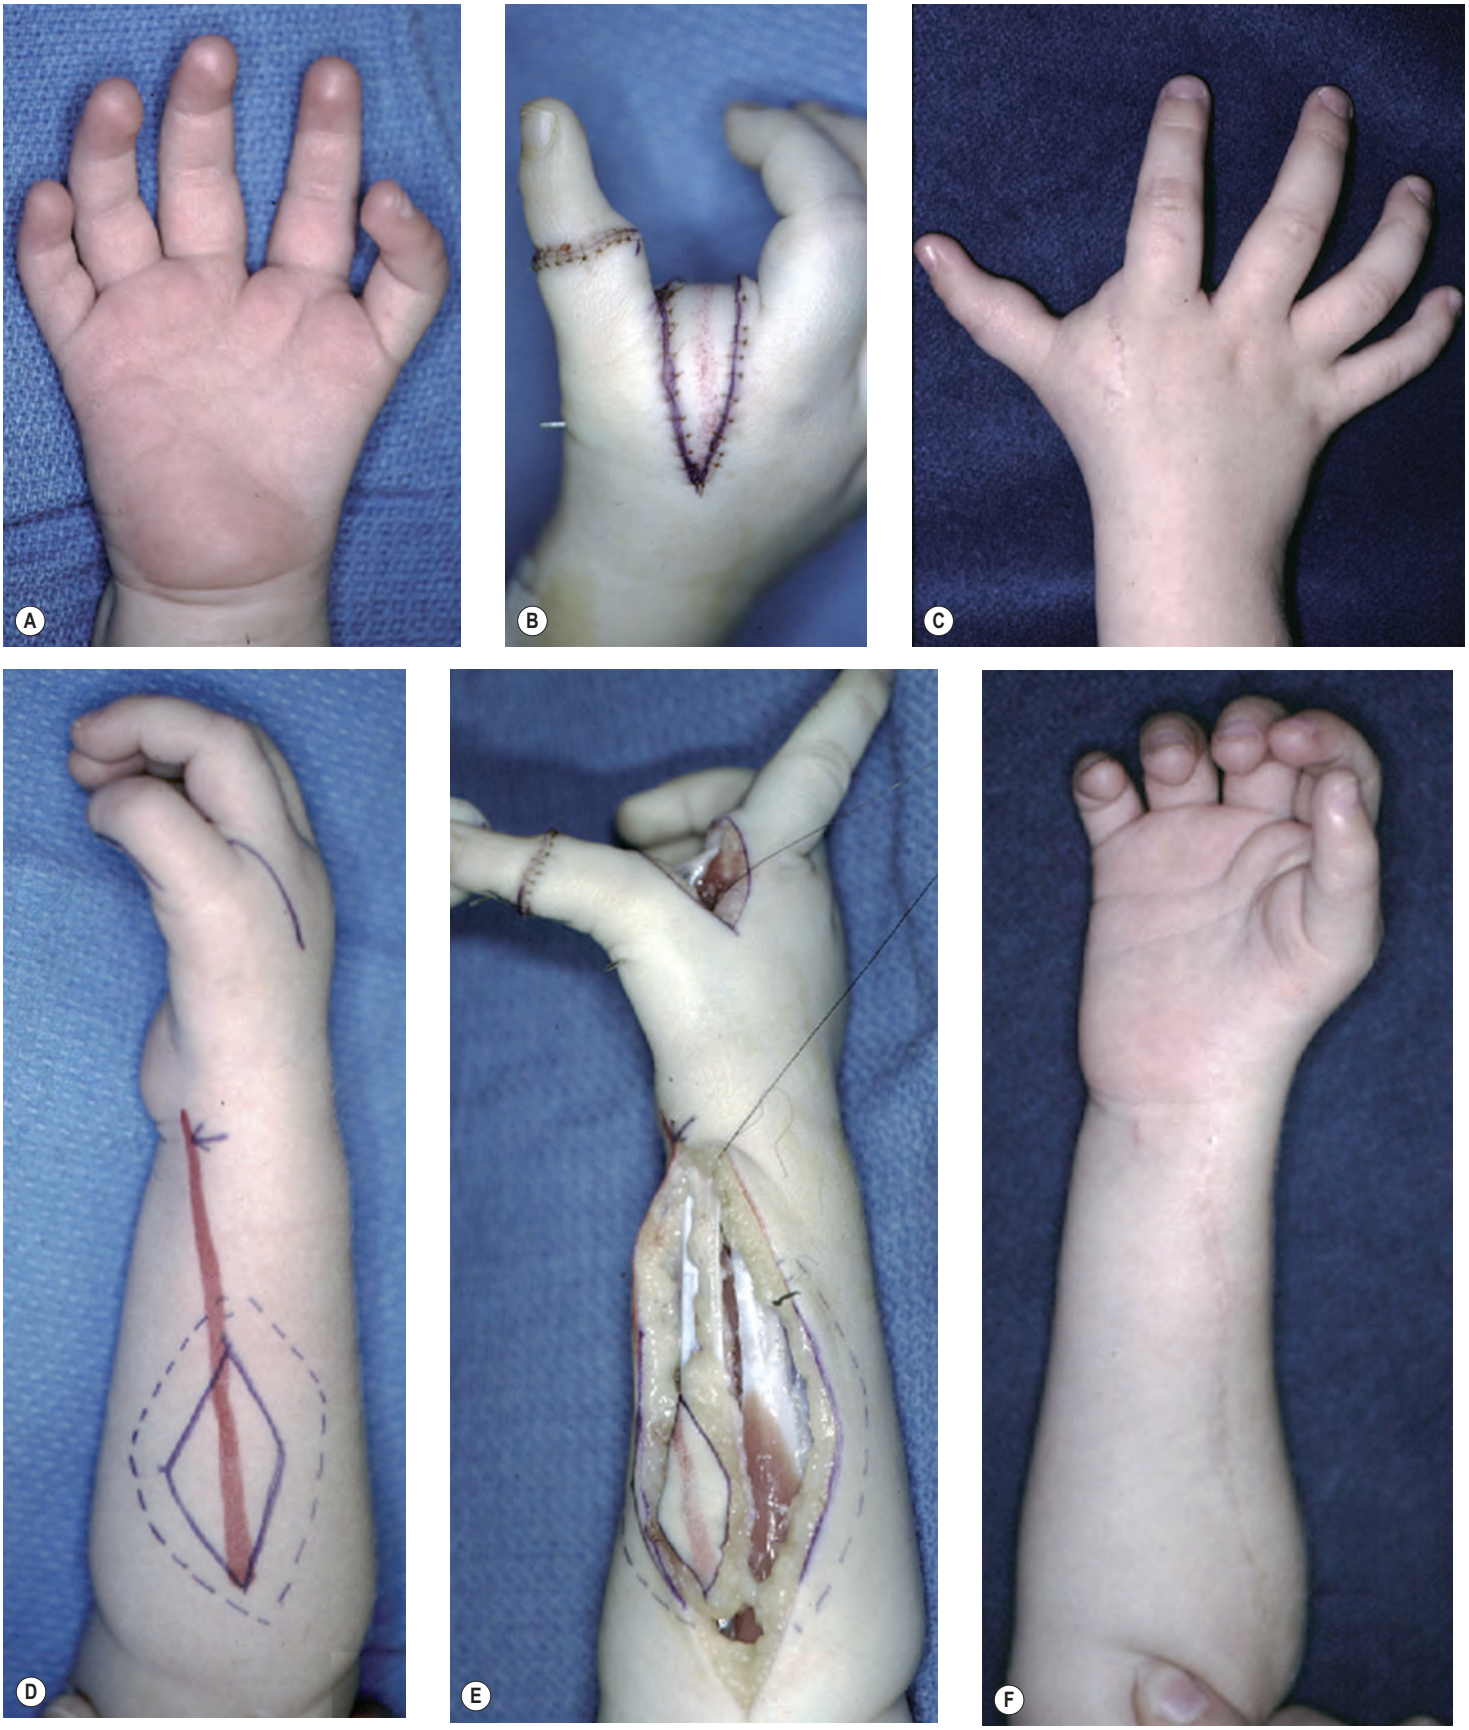

Fig. 27.28 Five-fingered hand. **(A,D)** The right hand of a child with bilateral five fingered hands is shown. She has auto-rotated the most radial digit into a pseudo thumb position in an effort to functional more effectively. **(B,E)** In one procedure, the thumb was shortened and fused at the proximal interphalangeal joint and a first webspace created with a radial forearm fasciocutaneous flap, which is seen below before, during, and 5 years after the procedure. A superficial flexor tendon was transferred to improve palmar abduction (opposition). **(C,F)** There has been no contracture or diminution of this webspace, which was lined with full-thickness flap tissue.

the previous section of this chapter. The deficiency of the first web in the majority of the children with craniosynostoses can be adequately treated with a four-flap Z-plasty. In the more complex type II and type III hand anomalies in Apert syndrome, where there is complete syndactyly of the first web, tissue expansion of the first web can be a very satisfactory means of producing a long-lasting release of the first web.[84] The deficiencies of length and angulation in these complex anomalies can be addressed with osteotomy and an iliac crest bone graft (Fig. 27.29 ◍). More recently, we have found distraction lengthening to be a better alternative. Our preference has been to straighten these thumbs at 4–6 years of age and lengthen them with distraction during early adolescence. The results are remarkable. Fig. 27.29 appears online only.

Postoperative care

For nearly all of the aforementioned operations, immobilization in a well-padded long arm cast is required for at least 3–4 weeks. We prefer to remove the cast under light general anesthesia to minimize the traumatic experience for the child and to inspect and clean the wounds.

Once the cast is removed, for the next 6–8 weeks the hand is wrapped in Coban at night to reduce swelling. A thumb-spica thermoplast splint is worn at night and outside the house for additional protection during this period of time as well. After pollicization, the child works with the parents using special play activities, during which time the long and ring digits are buddy taped to encourage key pinch and grasp using the new thumb. It comes as no surprise that we have seen a positive correlation between good functional results and involved, attentive parents. Other than monthly evaluations by an occupational therapist, no additional therapy is necessary. Some children start to use the reconstructed or new thumb quite early; whereas, others are hesitant. In pollicized digits, return of flexor function may take a few months. By 6 months postoperatively, all children will have actively integrated the thumb into the activities of daily living.

Outcomes, prognosis, and complications

Type I

There are no difficulties with key pulp or nail pinch, grasp, or precision pinch that requires palmar abduction of the thumb. However, the recorded strengths may not reach normal levels. The motion depends on the condition of the joints, and strength of key pinch and chuck pinch are directly related to the existing thenar musculature.

Type II

Although these are not normal thumbs, functional restoration following early surgery is quite good. Although motion of the MP joint is decreased following ligament stabilization or chondrodesis, good mobility of the CMC and IP joints will provide excellent function. Attempts to stabilize through chondrodesis can result in a nonunion. In these thumbs, flexion at the IP joint level is diminished and pinch strength is reduced not because of a poor AddP muscle but due to the weak flexor pollicis longus, which is usually malformed. Precision and power grasp between the thumb and three opposing digits is much less than normal. The amount and degree of loss is proportional to the anatomical variations encountered, including the pollex abductus abnormality, deficient flexor muscle mass, and the amount of surgery required for correction. Stiff thumbs with poor mobility are much more common when there is a partial or complete loss of the radius in the same forearm.

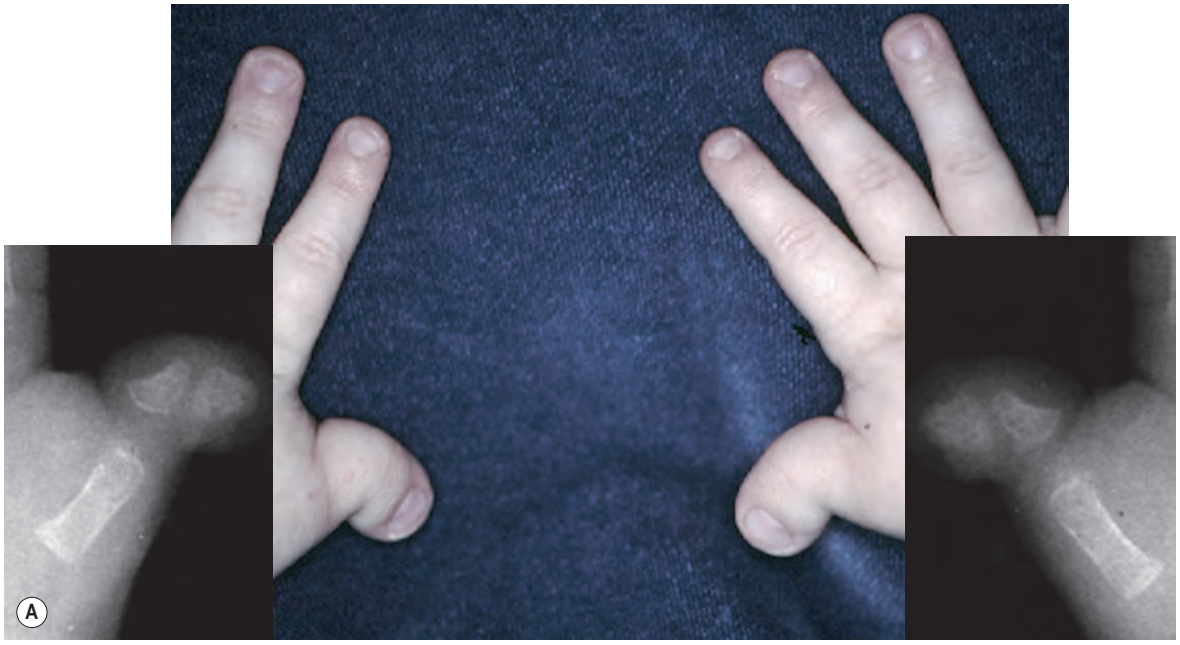
Type IIIA

The type IIIA reconstructed thumbs are short, slender, less mobile than the type II thumbs, and functional use is highly individual. The only certainty is that these thumbs are never normal. Many studies have correlated the outcome with the degree of anatomical abnormality and the amount surgery required.[33,115] Following MP joint stabilization, motion is diminished; following web release, the first ray is much more mobile and grasp is markedly improved; and following opposition transfers, palmar abduction is maintained if the muscle or tendon transfer is functional. Chondrodesis in young children frequently fails and needs to be repeated as arthrodesis when they are older. Thumb IP joint flexion is rarely normal and, in fact, the chance of obtaining good functional flexion in a child born without a flexion crease is very poor. With a pollex abductus anomaly and a lax or flail MP joint, both MP and IP joint motion will be significantly reduced following reconstruction. The average IP motion in Lister's series was 21° following one- or two-staged reconstruction of the flexor mechanism in the presence of multiple musculotendinous anomalies.[130] Children receiving flexor reconstruction also require joint stabilization at either the MP or IP joints. Efforts to release anomalous flexor tendons, interconnections, and/or muscles and use these parts to salvage IP joint motion can be very frustrating, particularly if one watches these children grow beyond adolescence.

Types IIIB, IIIC, and IV

The clinical outcomes following pollicization are not controversial and will be discussed with the type V thumbs. If pollicization is not undertaken, staged reconstructions following intercalated bone graft and/or tendon graft stabilization are predictable. The webspace remains deficient. The thumbs are rigid with poor MP or IP joint motion, and the collateral ligament reconstruction at the MP joint level becomes lax with time. Outcome studies[67,73,131–133] indicate that these reconstructed thumbs are short, slender, and relatively immobile. There is no metacarpal growth, and as teenagers these children often express dissatisfaction with the thumb "they do not use". However, long-term follow-up interviews with a number of these children, now adults, reveal that some of these patients and their families are very attached to and enthusiastic about their small and stiff thumbs.[132]

Some surgeons feel that the functional pinch and appearance is well worth the effort involved in complicated microvascular reconstructions.[72,73,95,134] However, the potential lack of growth and immobility are major deterrents. The advantage of the microvascular procedures to stabilize the metacarpal base and augment soft tissue is that of growth and restoration of an adequate first webspace. The functional results of a



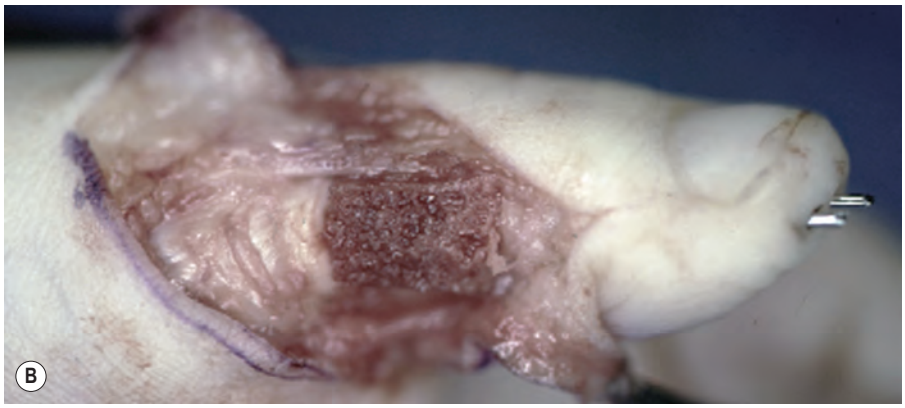


Fig. 27.29 Type X short skeletal ray. **(A)** The preoperative appearance and thumb radiographs of a young boy with bilateral radial clinodactyly of the thumbs ("hitchhiker thumbs") associated with the Rubenstein–Taybi syndrome. **(B)** The soft tissue was lengthened on the radial side with a large Z-plasty, and a composite graft and the bone seen lengthened here with an opening wedge osteotomy and corticocancellous bone graft held with two C-wires. **(C)** The same thumbs are seen 7 years later. The right side has grown normally, and on the left side, the deformity has recurred because of the premature closure of the most radial border of the physis.

number of small series[67,71–73,75,95,135] verify that stability can be achieved but motion is severely impaired. These thumbs are small and have a rudimentary nail complex and scarred webspace, which is generally less aesthetically acceptable than a well-executed index pollicization (Fig. 27.30 ◍). The technical difficulties and risks of any free tissue transfer in young children may also be significant. Fig. 27.30 appears online only.

When a staged reconstruction for a floating thumb (type IV) is chosen, the first ray is small, narrow, and stiff. The thumb does not grow at the metacarpal level if a bone graft has been used (Fig. 27.31 ◍), but will grow and have some CMC joint stability if a vascularized joint has been transferred. Most of these transfers have taken place in Asian countries due to cultural preferences. Fig. 27.31 appears online only.

Types IIIB, IIIC, IV, and V: pollicization

Our experience with more than 300 pollicization procedures is similar to that of Buck-Gramcko, who performed over twice this number.[105,111] It is critical to understand that the new thumb will never be normal. The adequacy of the functional and aesthetic postoperative result depends entirely upon the preoperative condition of the index finger.

A child with normal skin, bones, joints, tendons and muscles will achieve an excellent outcome from a *properly performed* pollicization. A youngster with a stiff, partially mobile digit associated with a radial club hand due to a radial absence will have a less functional outcome (see below). In such a hand, it is important to accurately position the new thumb in greater opposition to the other digits avoid too much CMC extension, which would position the thumb in a very vulnerable posture. Although assessment of these procedures is difficult, there is no paucity of outcome reports.[7,46,60,101,114,136–149] Most corroborate the principle that preoperative condition determines postoperative result.

Although work on the development of more useful outcome measures continues,[148] the most thorough study of long-term outcomes is the report by Manske *et al*.[60] When considered as a single group of patients, total active range of motion averaged 50% of normal, standard grip strength 21%, lateral pinch 22%, and use in normal activities 84% of normal. Interestingly, these results are not significantly altered by the age of the patient at the time of operation. Furthermore, studies have documented that the function and strength of these neothumbs improve as the children grow.[145] The senior author strongly supports this observation.

The appearance of a pollicized digit is much more difficult to quantify due to the subjective interpretation required. Some have tried to quantify appearance by measuring the length of the digit in relation to the PIP flexion crease, the resting posture of the new thumb, and rotation relative to the other digits.[137,143] Meanwhile, others have emphasized the creation of an aesthetic webspace, which avoids the appearance of a finger positioned on the side of the hand.[58,60,106] We have observed that the parents are almost uniformly pleased with the postoperative appearance of pollicization and that the young patients do not express much of an opinion until they are teenagers, at which time many will let you know whether they like their thumbs or not. Just ask!

The influence of the age at the time of pollicization is always debated. As stated earlier, many surgeons postulate that under ideal circumstances this operation should be completed within the first year of life to provide an earlier cortical awareness of the new "thumb". Developmental scientists have demonstrated that the child is aware of the thumb as a radial post by 1 year of age.[150] Some argue that since there is no thumb, the index digit is the radial substitute and that pollicization represents a repositioning of the radial post. Manske's data[60] does not support early pollicization for functional reasons. We feel that the size of the hand and the experience, knowledge, and confidence of the surgeon are more important considerations because the surgeon has only one chance to get a pollicization right.

When considering complications, the major learning curve relates to the incisions, muscle rebalancing, and the creation of a normal first webspace. It has been well documented that complication rates are low in experienced hands.[151] Devascularization due to injury to the neurovascular pedicle can occur, particularly in patients with radial longitudinal deficiency and no radial digital artery. This potential problem is avoided by microvascular repair and vein grafting if needed. Invariably, skin flap necrosis and the resulting contractures and disfigurement are related to technical problems during surgery. Venous compromise has been reported,[151] and may be due to excessive dissection of the dorsal veins, kinking, tight dressings, or abnormal anatomy. Injury to the innervation of intrinsic muscles may go unrecognized during dissection and can be reconstructed with later transfers. To avoid this problem, these muscles are left attached to the periosteum and are not dissected proximal to the level of the palmar arch. Adduction contractures of the new thumb are the result of either poor positioning and immobilization of the skeletal ray or tight first volar interosseous muscle pull. Aseptic necrosis of the new trapezium (formally the metacarpal head) has been seen, as has growth arrest of the proximal phalanx (new metacarpal).[59] Ossification of the periosteal tissue can occur due to the periosteum left behind with the intrinsic muscles. Symptomatic spicules are simply excised.

Other types of thumb hypoplasia (types VI–X)

Type VI: central deficiencies – cleft hand and symbrachydactyly thumb

Cleft hand

Since most of these thumbs would fall into the Blauth type I or II hypoplasia categories, the results are similar. The major considerations for function relate to the adequacy of the webspace construction and the integrity of the 1st DI and AddP muscles that are so important in all types of pinch. Strength will be lost from the thumb when the 1st DI is either recessed or detached during the index transposition. Every effort should be made to preserve what AddP muscle is present and its periosteal origin. When the index is transposed into the long position, this periosteum is reattached to the index metacarpal. Grip strength is more dependent on the ulnar three digits and not on the thumb.

Symbrachydactyly thumb

This thumb is universally smaller than the normal thumb on the contralateral hand. Once stabilized, it provides a mobile radial ray for the rest of the hand, and IP joint motion is either

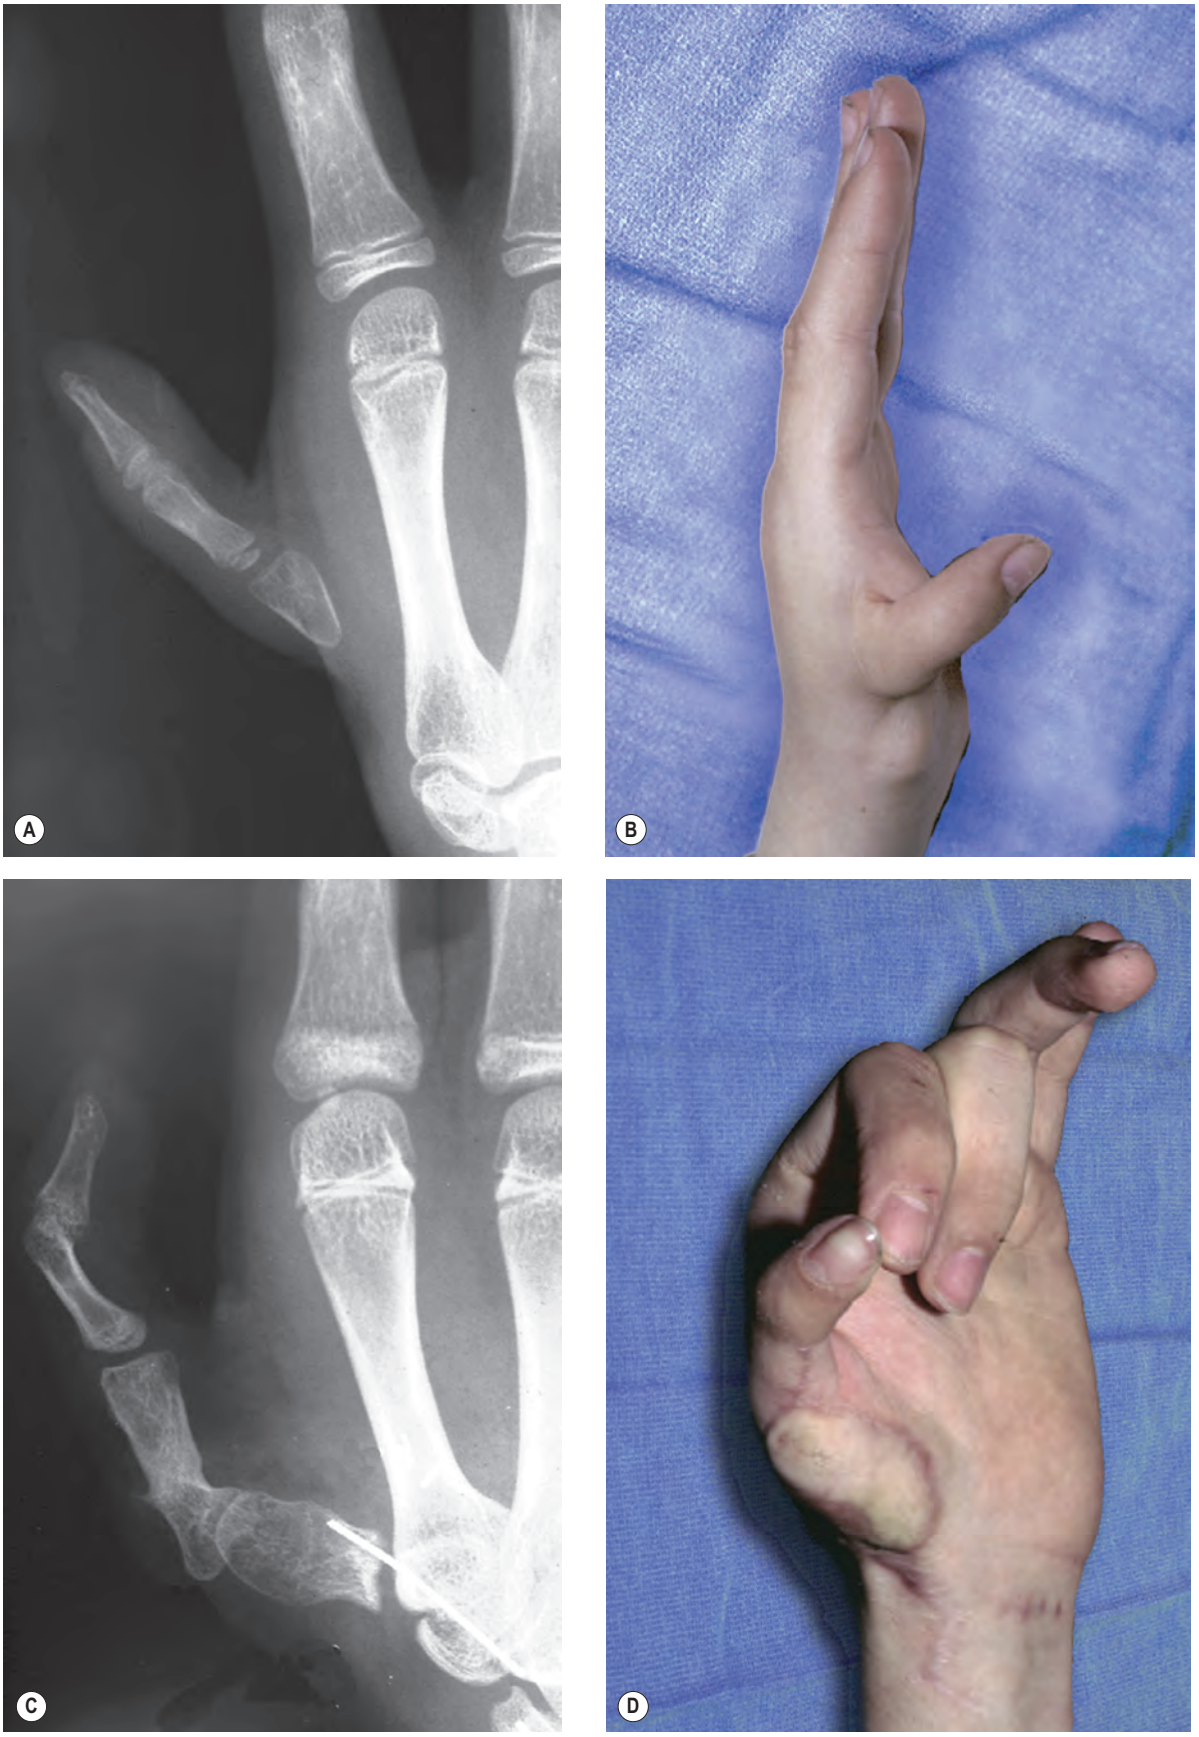

Fig. 27.30 Type IIIB microvascular reconstruction. **(A,B)** The radiograph and clinical picture show a type IIIB thumb in which there is no proximal metacarpal or carpometacarpal joint. This thumb has no skeletal attachment to the rest of the hand. **(C,D)** A second-toe metatarsophalangeal joint, with covering soft-tissue flap, has been transferred to provide the skeletal connection and stability. The picture shown is at skeletal maturity. Tendon transfers were needed to provide extrinsic flexion and extension to the thumb, and the skin flap helped build up the thenar region. *(Case provided by G. Foucher, MD)*

Fig. 27.31 Type IIIB staged reconstruction. **(A,B)** The preoperative radiograph and clinical appearance of a type IV thumb in a child whose parents insisted upon saving it. **(C,D)** A bridging iliac corticocancellous bone graft was used to stabilize the thumb, which became an immobile post and did not grow commensurately with the child. At age 14 years, the same child came to the authors' clinic and asked when she would be given a "normal" thumb.

diminished or absent. When the IP flexion crease is absent at birth, attempts to restore motion with joint releases and extrinsic tendon reconstructions are dismal. Flexor tendon grafts are also disappointing due to the malformed motors in the forearm. If attempted, wrist flexors or extensors should be used. It is difficult to make any generalizations here due to the very wide clinical spectrum of these thumbs.

Type VII: constriction ring syndrome

The functional outcome of a thumb with a congenital amputation at the interphalangeal joint level is excellent, provided there is a broad, unscarred webspace between the thumb and the next digit. Thumbs lengthened with non-vascularized toe phalangeal transfers have the advantage of increased length with little mobility at the MP joint level. Thumbs lengthened with vascularized toe transfers have the advantages of normal length, normal sensation if performed in young children, and the disadvantage of less-than-normal motion.[82] The functional results of these transfers in this group are superior due to the normal anatomical motors in the forearm.

Type VIII: five-fingered hand

The results are similar to those described for index pollicization without radial dysplasia. Similar outcomes have been achieved in those who had forearm flaps followed by rotation–recession osteotomies at the metacarpal level. These thumbs are all well positioned in palmar abduction but lack forceful adduction, power pinch, and grasp. The thumbs are long and slender and do not have normal or close-to-normal key pinch and thumb-to-index grasping strength.

Type IX: radial polydactyly

Refer to Chapter 28 in this volume.

Type X: syndromic short skeletal ray thumb

Results must be individualized to the specific thumb condition. For those with the Apert syndrome, the thumb is longer, motion is present at the MP and CMC joints, and the degree of independent function depends more upon the quality of the first webspace.

Thumbs that have been lengthened with distraction techniques are longer, thin at the phalangeal level, and stiffer at joints distal to the distraction. If distracted slowly, at approximately 0.5 mm/day, damage to the intrinsic muscles is minimized. With a normal CMC joint and intact thenar muscles, these thumbs become very functional.

Secondary procedures

Additional procedures have been unusual in our experience. The most common has been opposition transfers for patients with a partial or complete absence of the radius and inadequate median innervated thenar muscles. In all of these patients, this procedure was discussed as part of the initial "game plan" prior to pollicization. In our series, eight patients have required an osteotomy to correct the CMC hyperextension, and in seven patients (treated early in the series), it was necessary to stop persistent growth of the metacarpal. Eleven children have come back as adults to have symptomatic bone spicules from retained periosteum removed. Extensor tendon tenolysis or shortening was necessary in only ten hands. It is expected that the revision rate would be higher if our patient population were less mobile and diligent about long-term follow-up.

Many revisions have been performed on patients whose pollicization was performed by another surgeon. The most common problems were: (1) poor position of the skeletal ray; (2) excessive scarring from initial skin loss; (3) adherent extensor tendons; and (4) lack of palmar abduction (opposition). Ten patients have come back as adults: five to have a carpal tunnel release and five to have a painful, dysplastic carpal bone removed. Symptoms were related to repetitive activities at work and/or pregnancy, and all patients were between 20 and 35 years of age.

The inadequate index finger

The inadequate index finger deserves special attention because in many clinical cases, a less than normal (i.e., stiff) index finger is available for potential pollicization (Fig. 27.32 ◍). These cases include:

1. A syndactylized index ray in a child with Holt–Oram syndrome
2. An index joined to the long finger with a complete simple syndactyly (i.e., typical cleft hand, index–long syndactyly with absent or hypoplastic thumb)
3. A stiff index finger associated with a complete or partial absence of the radius
4. A stiff index ray with a fixed proximal interphalangeal joint flexion contracture with or without a complete or partial absence of the radius
5. The mirror hand (ulnar dimelia)
6. The five-fingered hand. Fig. 27.32 appears online only.

In all of these cases, the clinical deficiencies of the index ray are obvious on physical examination, and the major question is whether anything can be accomplished surgically to improve either the clinical function or appearance of the hand. The absence of flexion creases indicates that there has been very little if any motion *in utero* and that there are deficient joints, muscles, and/or tendinous structures. At surgery, fibrous bands are present between the phalanges, which may not appear joined on radiographs. Flexion contractures (camptodactyly) may be present in the index or all digits with decreasing degrees of severity from the radial to the ulnar digits. These clinical situations do not present frequently but occur more often than anticipated. In our experience, one of these clinical scenarios is present at least 15% of the time.[106]

There are no standard guidelines for treatment in the literature and surgical recommendations are more dependent upon a given surgeon's experience than on practical reasoning. Most recommendations have been overwhelmingly conservative.[7,51,101,106,111,130,138,139,143,152–156] Options for reconstruction include: (1) no surgical treatment; (2) rotation–recession osteotomy of the index ray[157]; (3) formal pollicization of the index ray; or (4) pollicization of the fifth finger.

The determination of what to do and how to do it can be made much easier by an analysis of larger series of pollicizations.[158] Logically, the quality of the result depends predominantly upon the preoperative condition of the index ray.

Fig. 27.32 Inadequate index finger. **(A)** This 7-year-old boy with bilateral absence of the radius shows his pectoralis major muscle transfer, which is now working as an elbow flexor. After preliminary distraction, the hand and wrist were centralized over the distal ulna. **(B)** The characteristic widening of the distal ulna is seen. From ulnar to radial, the PIP joints of the digits had increasing fixed flexion contractures to the extent that the index finger was flexed 100° and was useless. After a successful pollicization on his other hand, the patient asked for improvement of this hand. **(C)** First, the proximal and middle phalanges were shortened, and an arthrodesis was performed at the PIP joint level. **(D)** Next, a rotation–recession osteotomy placed the new thumb in enough palmar abduction to allow pulp-to-pulp pinch with the long finger and grasping of small objects. This position purposefully keeps the thumb from becoming caught in pants pockets and other objects. **(E)** Internal plate and screw fixation was used. Motion was present only at the metacarpophalangeal joint. Within weeks of the operation, he began to use this previously ignored digit.

For those with syndromic associations, which include major central neurologic deficits, no surgical treatment is indicated. Pollicization alone for the stiff index digit is considered by some for aesthetic reasons alone. Often, a more mobile index has been moved to the thumb position on the opposite hand. It is important to place the stiffer thumb in a more adducted position. Proper length and the creation of a normal web that extends to the index PIP joint in the thumb position are both crucial to a good appearance.

The position of the pollicized index finger is crucial for a pinch to the long finger and a grasp to the fifth finger (see Fig. 27.32). Usually, the new thumb will have diminished extrinsic motion, particularly in extension, because the muscles originating on the radial side of the forearm are either abnormal or absent. It is most important that this thumb be positioned for good opposition to the fifth finger, a posture that places it in less abduction than normal. If placed in too much palmar abduction and extension, this immobile post will become caught on objects or within pockets.

One alternative, rarely chosen for these patients, is the rotation–recession osteotomy in lieu of a formal pollicization.[157] We have preferred this procedure in older children, teenagers, and adults with a stiff, flexed index finger, those with scarring from previous procedures, mirror hands, the five-fingered hand, and the very stiff index ray associated with a radial club hand. The principles of treatment are the same, but the ray is not shortened to the full extent of a formal pollicization. Any intrinsic muscles that are present are reattached and the extrinsic flexors and extensor tendons are shortened as appropriate. The position of the new thumb must be very carefully chosen for optimal pinch. Many patients with radial longitudinal deficiency are born with camptodactyly involving all proximal interphalangeal joints, which becomes progressively more severe in the most radial index and long digits. In these contracted digits, we also perform full releases with Z-plasties or full-thickness skin grafts if needed. Then we consider a rotation–recession osteotomy instead of a classic pollicization.

The possible combination of deformities with congenital hand differences is almost infinite, and there are many instances in which it is possible to pollicize an index digit after a number of previous procedures involving this ray have been completed. Most examples involve either a syndactylized index finger within a mitten hand or a typical cleft hand in which the index and long fingers are joined within a simple syndactyly.[159,160] In either case, the syndactyly is released before formal repositioning of the index digit.

Future directions

The care of congenital thumb differences has not changed dramatically in the past few years. Advancement of knowledge and technique is slow but steady. Investigations in the genetic basis of these differences continues to progress. As we have continued to refine genetic and biochemical understanding of congenital hand differences, a new, more comprehensive classification system has emerged and is gaining broad acceptance. Meanwhile, while the principles have remained the same, technical advancements[49,58,79,93] in surgical treatment continue to improve patient care. Lastly, despite many hurdles, investigators continue to improve quantification and measurement of outcomes in this field,[148,161,162] promising global standardization of measuring outcomes.

Congenital hand IV: Syndactyly, synostosis, polydactyly, camptodactyly, and clinodactyly

Steven E. R. Hovius and Christianne A. van Nieuwenhoven

SYNOPSIS

- Syndactyly is one of the most common congenital differences in the upper extremity and can be classified as incomplete (soft tissue only, not extending to the tip), complete (soft tissue only, extending to the tip), complex (with distal bony union), or complicated (with more than only distal bone fusion).
- Timing of surgery depends on the fingers involved and whether the syndactyly is cutaneous or not. In the simple digit 3–4 syndactyly there is no hurry, while in the simple thumb–index syndactyly release is undertaken early. When bony fusion accompanies syndactyly (complex/complicated), these fusions should be separated early to prevent asymmetric growth if the fused fingers have different lengths.
- Creating a web and nail fold and adding skin to the inner borders of the digits in complete syndactyly are the three key elements in separating the digits.
- Poland syndrome is characterized by unilateral absence of the sternocostal head of the pectoralis muscle combined with ipsilateral short and webbed fingers. The central three digits are most affected. It can vary from a smaller hand, simple syndactyly to symbrachydactyly, up to more severe hypoplasia of the entire arm.
- Apert syndrome (acrocephalosyndactyly) is characterized by craniosynostosis with complex acrosyndactyly of both hands and feet. Common features of both hands in Apert syndrome are: brachyclinodactyly of the thumb, complex syndactyly of index/long/ring finger, symbrachyphalangism and simple syndactyly of the fourth web. Three different types of hand malformations can be recognized: the flat, "spade" hand (type I), the constricted cupped, "mitten" hand (type II), and the coalesced "rosebud" hand (type III).
- The surgical sequence in correction of Apert syndrome is release of thumb and index or deepening of the first web and separation of digit 4 and 5, followed by separation of the other digits and correction of clinodactyly of the thumb. If present, 4–5 metacarpal synostoses can be separated.
- Symphalangism is a longitudinal bony fusion of the finger and/or toe joints. In hereditary symphalangism, the proximal interphalangeal joint is mostly involved.
- In metacarpal synostosis, curvature of the epiphysis, discrepancy in length between the two involved metacarpals, and the shape of the bones will direct the choice of treatment. Surgical treatment in metacarpal synostosis is functional and aesthetic. Consultations are necessary until skeletal maturity because of angulation, length discrepancies, and rotation that can occur due to growth.
- Congenital radioulnar synostosis is less common than the post-traumatic version. In most cases of radioulnar synostosis, the proximal third is involved, with bilateral involvement in 60%. It is common in craniofacial hand disorders. Treatment is recommended in patients with a fixed pronation of more than 60° and complaints of disability in daily life.
- Polydactyly of the hand can be divided into radial, central (digit 2, 3, and 4), and ulnar polydactyly, referring to the region of the extra digit or part of a digit. It can occur isolated or syndromic. Syndromes are more associated with ulnar polydactyly than radial polydactyly. The most commonly used classification for radial polydactyly is the Wassel classification (also known as the Iowa system). Ulnar polydactyly is either classified into two or three types.
- Timing of surgery is arbitrary. Surgery is recommended in the first year of life by many authors, and depends on the severity of the condition. Floating little fingers are often removed early. At the first operation, as much correction as possible is performed on both soft tissues and bones. Correct alignment and balancing forces on the joints and bones is crucial. Growth will make insufficiently corrected tissue worse.
- Inadequate correction in proximal radial polydactyly leads to complications such as S- and Z-deformities mostly due to imbalance. In distal polydactyly it can lead to nail deformities and broadness of the distal end of the thumb.
- Triphalangeal thumb can vary from a longer thumb with deviation due to the extra phalanx to a non-opposable thumb with an inadequate first web and aberrant muscles and tendons, with the thumb in the same plane as the hand, resembling a five-fingered hand. Triphalangeal thumb can be associated with polydactyly, syndactyly, cleft hand, and longitudinal ray deficiency (e.g., Holt–Oram syndrome). It occurs isolated or as an autosomal-dominant trait.
- In less complex opposable triphalangeal thumbs, primary surgical strategies are focused on the distal two joints of the "thumb" comprising correction of deviation, reduction of additional length, and joint stabilization. In more complex non-opposable triphalangeal

thumbs, treatment not only is concentrated on the middle and distal phalanx but also on balancing of the metacarpophalangeal joint and carpometacarpal joint, together with reduction of metacarpal length up to formal pollicization. Additional polydactyly and syndactyly, if present, will also need attention.

- Camptodactyly is a contracture of the PIPJ in the anteroposterior direction (*campto* = arched; *dactylos* = finger). Camptodactyly is mostly sporadic without obvious family history. The most involved finger is the little finger, followed by the ring finger. All fingers can be involved. It can occur in the first year of life and progress further or present during adolescence. Conservative treatment is mostly advocated. Multiple surgical treatment regimens have been proposed, varying from full release, tendon transfers, and skin grafts to correction osteotomy, arthroplasty, and arthrodesis. All techniques have relative merit.
- Clinodactyly is derived from *klineia* (to bend, incline, or slope) and *dactylos* (finger, toe) and is used for a deviated finger in a radioulnar direction. The deviation is caused by an abnormally shaped bone. The middle phalanx of the little finger and the proximal phalanx of the thumb are the most frequently involved. Treatment can be a closed wedge osteotomy, reversed wedge osteotomy or an opening wedge osteotomy, with or without bone graft or a physiolysis.

Syndactyly

Introduction

The distal end of the "normal" web lies on the palmar side roughly at the mid-level of the proximal phalanx.[1] A more distal web is called syndactyly. Syndactyly is one of the most common congenital hand malformations with an incidence of 1 in 2000 live births. Familial syndactyly is reported in 15–40% of syndactylies.[2,3] They are more common in Caucasians than in people from African descent. About 50% of patients have bilateral involvement. Males are more affected than females varying from 46–84%. The incidence of ray involvement in syndactyly is in digit 3–4: 50%; digit 4–5: 30%; digit 2–3: 15%, and digit 1–2: 5%.[1,2] It can appear isolated or in association with other deformities in the upper or lower extremity or as part of a syndrome (like Poland syndrome or Apert syndrome). Syndactyly can be associated with polydactyly and/or clefting (like in synpolydactyly, Greig syndrome, oculodentodigital syndrome and cleft hand).

Syndactyly can be classified as incomplete (soft tissue only, not extending to the tip), complete (soft tissue only, extending to the tip), complex (with distal bone union) or complicated (with more than only distal bone fusion) (Fig. 28.1).[2] For the first web, the terms simple, complex, and complicated are used most.

Basic science/disease process

In the developing limb bud, fingers become apparent at day 41–43 and are fully separated at day 53.[5–7] Apoptosis is needed for separation of the fingers. This process is mediated by bone morphogenic protein 4 (BMP-4).[8] Current understanding relates these anomalies to differentiation disturbances in the developing hand plate.[9]

Diagnosis/patient presentation

Syndactyly can be present in a large variety of forms as it is only a descriptive term. The fingers can be normal or anomalous; the number of affected fingers can differ, as well as the nature of involvement (Fig. 28.2).

In the patient with cutaneous syndactyly, only the soft tissues between the fingers are attached. These skin bridges can vary from supple to tight, influencing surgery. In the incomplete form, the attachment usually ends just before the proximal interphalangeal joint (PIPJ). In the complete form, the nails can be separated with full pulps of the affected fingers to conjoined nails with ridges and insufficient pulp on the attached sides. If the involved fingers have normal bone structure, the joints and tendons are mostly normal. If not, like in symbrachydactyly, the tendons and joints will be affected as well as the neurovascular bundles that can divide more distally. When fingers are of unequal length, the longest finger will tend to bend and rotate more during growth especially if the distal ends are fused.

Complex syndactyly with distal bone fusion involving only two fingers can be recognized by a tapered distal end with inward rotation of the fingers and abnormally ridged or confluent nails. When more fingers are distally fused, they can be flat to very cupped with anomalous nails, abnormal bones with different lengths, and abnormally located, insufficiently developed joints.

Complicated syndactyly is characterized by an abnormal bone structure inside the syndactyly with fusions, rudimentary bones, missing bones, abnormal joints, and sometimes cross bones.[5,10]

Patient selection

Timing of surgery depends on the fingers involved and whether the syndactyly is cutaneous or not.

Early indications for surgery are syndactylies between fingers of unequal length; and/or distal bone fusions; and in complex or complicated acrosyndactyly especially if the thumb is involved. These early indications are to prevent asymmetric growth and/or to create a possibility to grasp.[11] In the simple digit 3–4 syndactyly, there is no hurry.

Simple syndactyly release can be performed from 6 months onwards. Most surgeons will operate on these children between 1–2 years to prevent anesthesia problems.[12]

In complicated syndactylies for some affected rays, the support for the individual fingers is often not enough to let them function well following separation, although parents or children often request to separate these fingers. Careful assessment of the maturity of each individual finger is necessary before release of syndactyly is undertaken. The choice to separate can be extremely difficult, especially in symbrachydactyly.

Treatment/surgical technique

Treatment of syndactyly should not only address the key points of adequate release but also be achieved in the least number of operations while minimizing complications.[12] Release of syndactyly implicates separation of conjoined skin

Historical perspective

By 1801, fingers had already been separated by straight line incisions leaving the wounds to heal by secondary intention. In 1808, Rudtorffer guided a wire from dorsal to ventral between the fingers proximally creating an epithelialized sinus and then separated the fingers distally from it. In 1810, Zeller used dorsal triangular flaps to reconstruct the defect following separation to create a web. As scarring and necrotic flaps developed from these techniques, Dieffenbach performed a dorsal rectangular flap in 1845. Furthermore, Valpeau reported using stitches to separate the fingers in 1847 and Norton reported using a dorsal and palmar triangular flap in 1881. Thus, as early as the last half of the 19th century, the basic techniques of flaps for web reconstruction still used today were described. Concerning the further distal separation, Faniel described, in 1911, a Z-shaped incision to cover the defects after separation. In 1940, Cronin introduced the zigzag approach.[4]

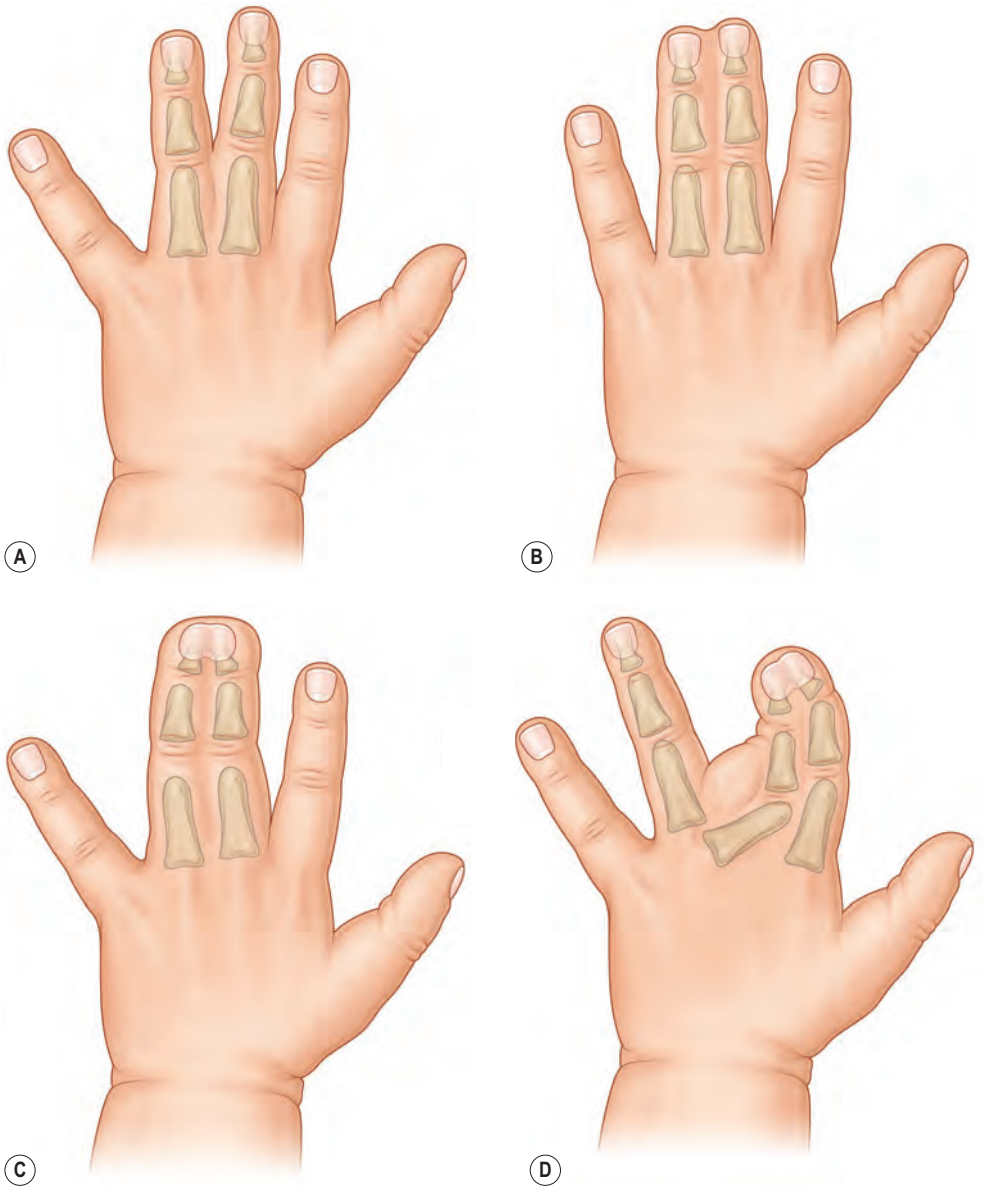

Fig. 28.1 **(A)** Incomplete, **(B)** complete, **(C)** complex, and **(D)** complicated syndactyly. *(Redrawn after Upton J. Management of disorders of separation – syndactyly. In: Mathes SJ (ed.).* Plastic Surgery, Vol. 8, *2nd revised edn. Philadelphia, PA: Saunders Elsevier; 2006:140.)*

and subcutaneous tissue preserving integrity of the neurovascular bundles. Furthermore, conjoined ligaments and bands and existing sites of osseous union are divided. On the dorsal side, subcutaneous fat can be removed but care has to be taken to prevent damage to the neurovascular bundle. For safety reasons, two adjacent complete syndactylous fingers are not separated at the same time as vascular anatomy can be different. In short multiple syndactylous fingers, for instance, dominant digital vessels can only exist on the lateral sides of the conjoined fingers. Sometimes it is necessary to sacrifice one of the vessels in a distal bifurcation. The nerves in these cases can mostly be dissected more proximally. In young children, bone or cartilaginous fusions can be separated by knife or osteotome.[11] Care should be taken to remove possible hidden polydactyly. Especially in cases where the fourth web is involved, a polydactylous distal phalanx and/or remnant of the middle phalanx can be present.

Key points in syndactyly release are[11,13,14]:

- Creation of a web
- Treating the lateral soft-tissue defects
- Separation of the fingertips.

Creation of a web

The web in syndactyly can basically be created by a dorsal flap, a palmar flap, or a combination of both. These techniques have already been practiced in the second half of the 19th century and are still used today. To these techniques have been added flaps with slightly different design or flaps more proximal from the dorsum of the hand.[14–19] We use a dorsal cloverleaf flap or manta ray type flap because the wings will cover partly the lateral side of the proximal phalanx and the tip is interdigitated on the palmar side, preventing linear scars in the web itself as well as palmarly. In an effort to prevent skin grafts, dorsal metacarpal flaps have been used to create the web, followed by primary closure of the fingers

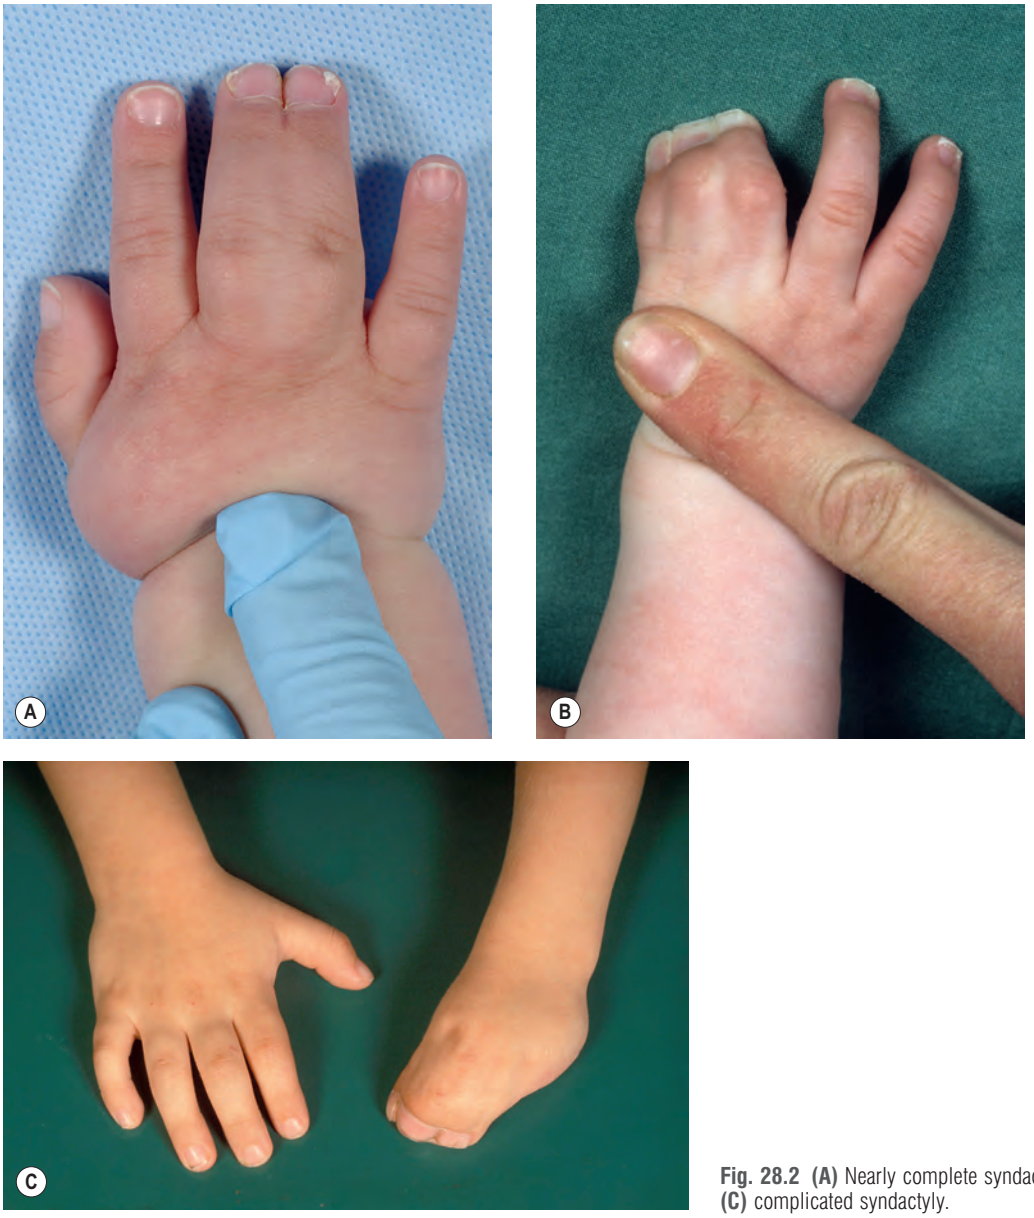

Fig. 28.2 **(A)** Nearly complete syndactyly, **(B)** complex syndactyly radial side, and **(C)** complicated syndactyly.

(Fig. 28.3).[18–20] In order to prevent web creep in the future, we advise the use of a dorsal flap that will cover the newly made web without scars that might interfere during growth. In addition, appearance of the hand is important. Visible skin grafts on the dorsal hand will darken in time, and are experienced as aesthetically less pleasing by patients. Therefore, we advise choosing a flap that will allow for primary closure on the dorsal hand and fingers with the skin grafts at the mid-lateral sides of the fingers, if grafts are needed at all.

For the first web, different kinds of Z-flaps (four flap, double, double opposing, five flap) or transposition flaps from the dorsum of the hand and index or thumb are used depending on the width and deepness of the created defect following release. Also pedicled flaps and free flaps have been advocated for the larger defects.[21] In the first web, the release of the tight fascia on the first dorsal interosseous muscle in combination with the fascia on the adductor muscle is essential to create a deeper web. Sometimes even the insertion of the adductor muscle is shifted more proximally to open the web.

Upton has published an excellent overview of all the different flaps for web reconstruction.[5] For incomplete syndactyly, many variations of rotating Z-flaps have been described for web reconstruction (Fig. 28.4).[22]

Treating the lateral soft-tissue defects

In syndactyly, the shortage of skin is very often underestimated. In the regular simple syndactyly, skin shortage is at least 36% of the circumference of the finger that is separated. Cronin has popularized the zigzag skin separation distal to the flap for web reconstruction.[23] The created triangular flaps provide coverage at the PIPJ. The triangular flaps can either be fully or partially interdigitated depending on the extent of the skin shortage. In this way, the areas for skin grafting can

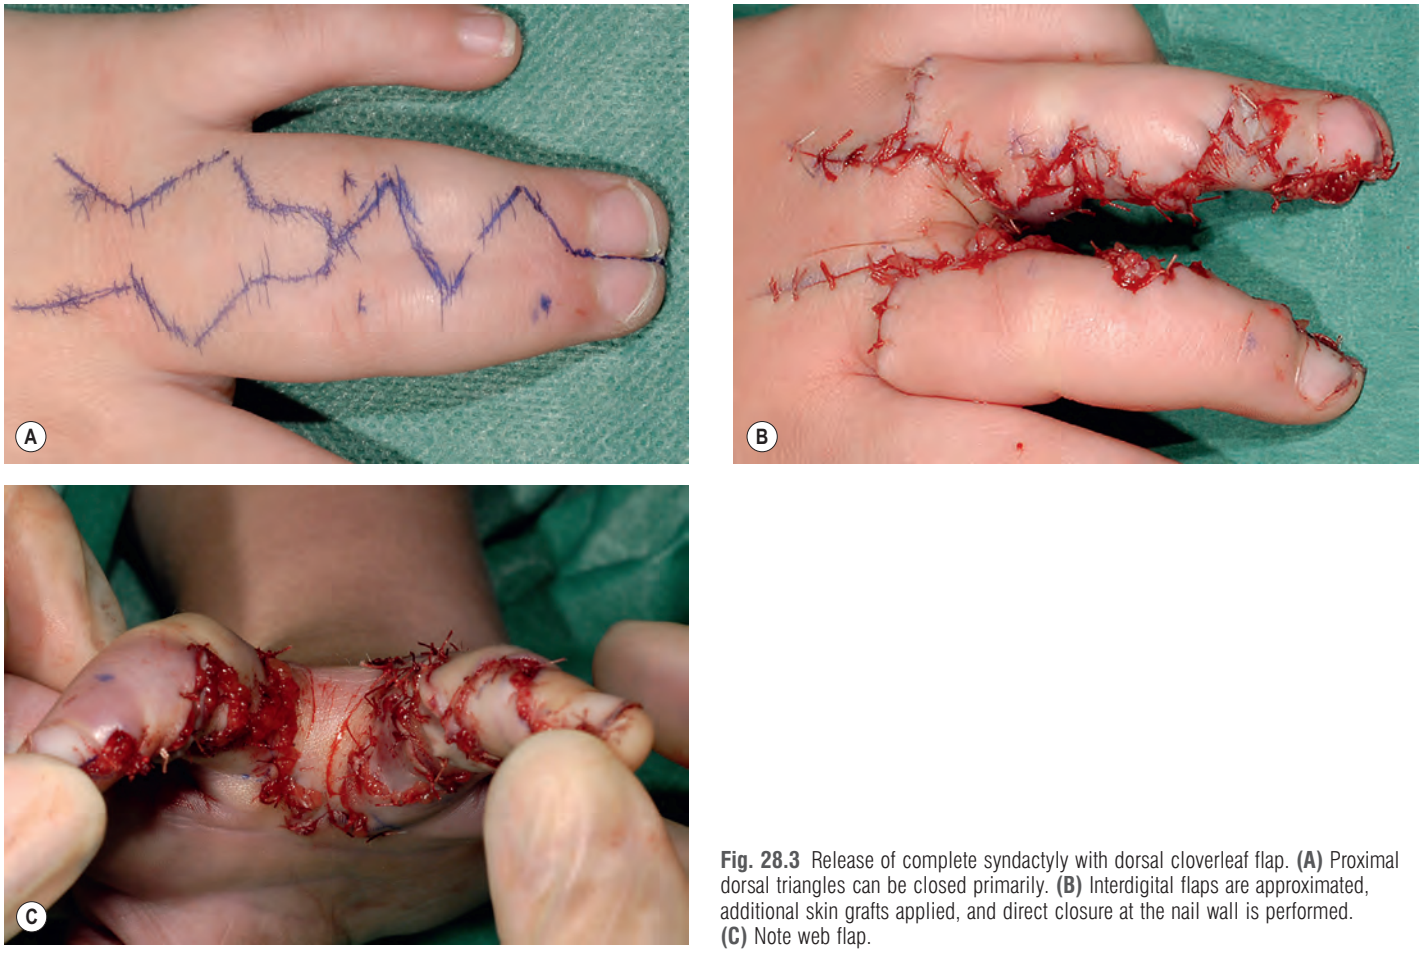

Fig. 28.3 Release of complete syndactyly with dorsal cloverleaf flap. **(A)** Proximal dorsal triangles can be closed primarily. **(B)** Interdigital flaps are approximated, additional skin grafts applied, and direct closure at the nail wall is performed. **(C)** Note web flap.

be diminished and placed on less demanding parts of the fingers. Full-thickness skin grafts (FTSG) are mostly used to cover the defects (Fig. 28.5). They can be taken from the groin more laterally to prevent later hair growth on the grafts or from other sites like the inner side of the upper arm or from the cubital fossa. Also thicker split-thickness skin grafts (STSG) can be taken from the non-weight-bearing part of the sole of the foot. Withey *et al*. used only STSGs at the proximal base of the inner sides of the released fingers together with a large number of triangular flaps. The remaining defects were left open resulting in good scars.[24]

Separation of the fingertips

If the nails are separately developed in complete syndactyly, the pulp can be separated and the skin advanced to the rim. If the nails are partly fused with a deep furrow and indentation on the pulp side, then simple separation and primary

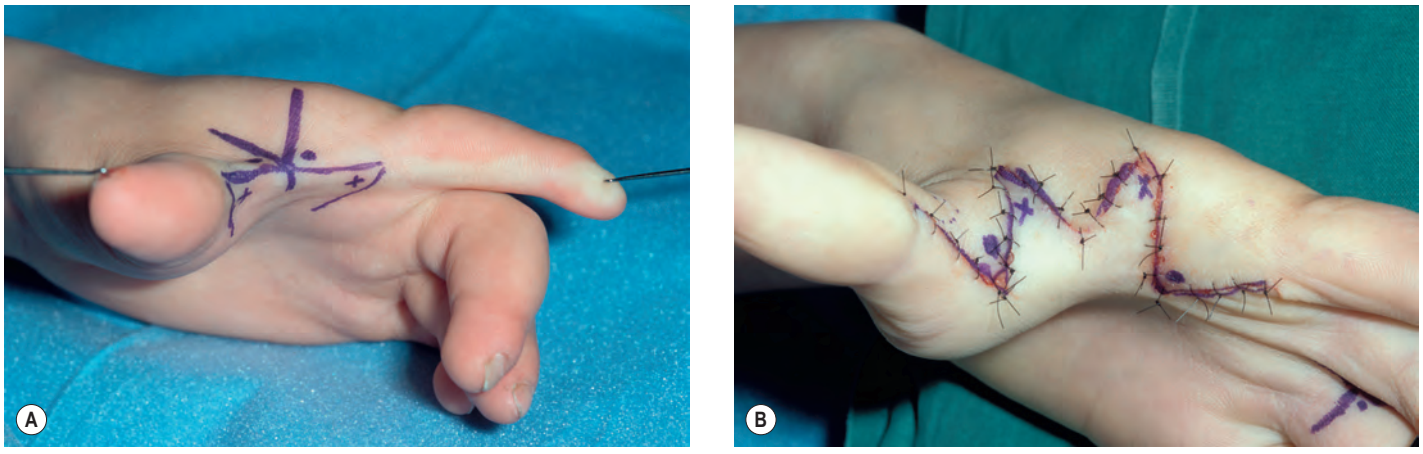

Fig. 28.4 (A,B) Incomplete first web release with five-flap Z-plasty.

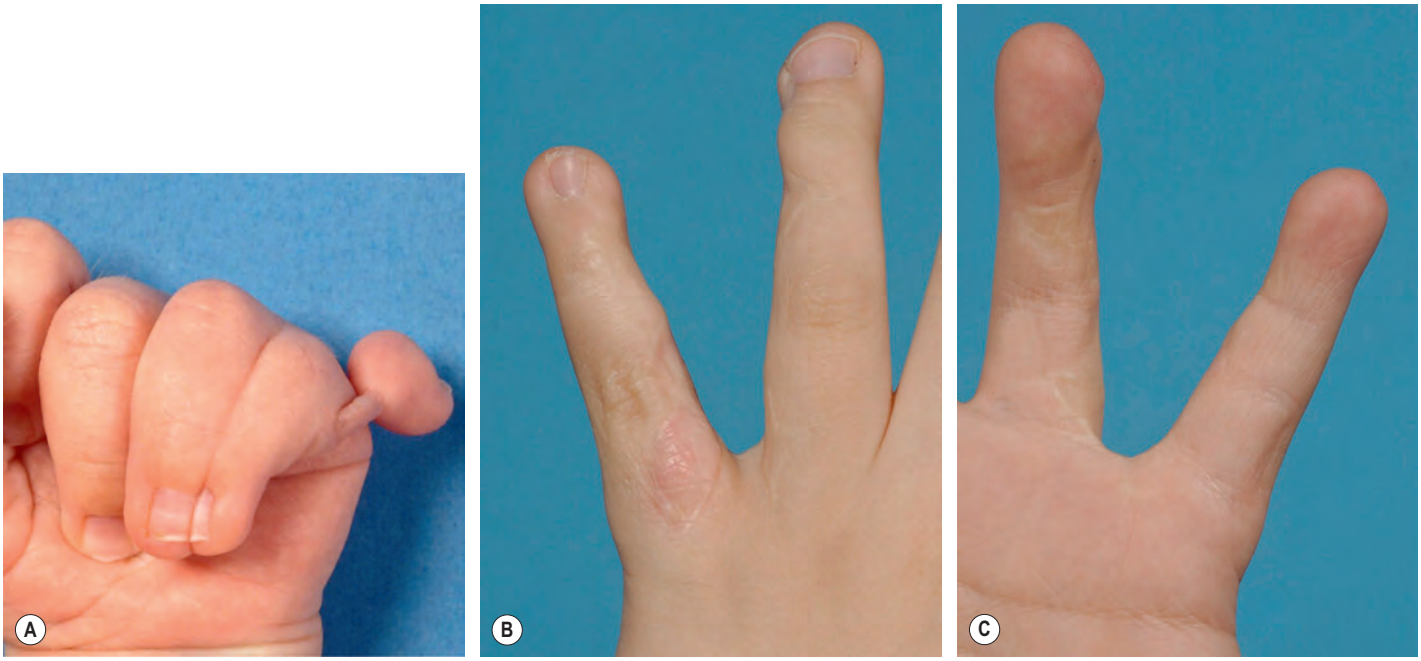

Fig. 28.5 Release of complex syndactyly of digit 4 and 5. **(A)** Note also ulnar polydactyly; **(B,C)** with 10-year follow-up.

closure is often still possible. If the nails are conjoined, with hardly or no ridge, nail wall reconstruction with flaps is necessary. Buck-Gramcko has introduced the pedicled pulp flaps for nail wall reconstruction from the adjacent finger pulp.[25] The disadvantage of these flaps is the sometimes thinner fingertips. Alternatives are the use of a thenar flap, but this has the disadvantage that the finger has to be supple to reach the thenar easily and it is a two-stage procedure.[26]

Surgical pearls

Desyndactylization

- Choose a flap without scars in the web, i.e., dorsal cloverleaf flap or manta ray type flap.
- Perform primary skin closure on dorsal part fingers and hand.
- Reconstruct nail walls with pulp flaps if a confluent nail is present.
- Use full-thickness skin grafts for defects, preferably situated at the midlateral area of the fingers.
- Take time to suture the skin; time spent will contribute to the result.

Postoperative care

Perioperative paraffin gauze is applied on the wounds and grafts, followed by moist dressings, synthetic cotton, and an elastic bandage. The elbow, forearm, and hand are subsequently covered with a longitudinal adhesive bandage to prevent removing the dressing. The general consensus among most authors is to perform wound inspection in the first 2 weeks after operation.[14,25]

In the last 5 years, we introduced a 6-week regimen with fewer complications and a lower workload for the doctor and, more importantly, for the parents. Most additional procedures needing immobilization are covered in this 6-week time span. Only one direct postoperative outpatient clinic contact is needed before starting hand therapy (if necessary). Further immobilization is dependent on surgery for associated malformations.

Outcomes, prognosis, and complications

Outcome can be related to web creep, scarring, graft-take, rotation, deviation and loss of function.

Early complications can be skin slough, flap necrosis, infection, and up to nearly complete adhesion of fingers.

Web-creep has been reported to be from 0% to 12% depending on the technique used, the long-term follow-up, and the variety of included patients. Re-operations have been performed for web creep in up to 8% of patients.[20,27–30]

With regard to skin grafts, FTSGs have a better skin quality than STSGs; they can also create problems such as graft loss; skin contracture; web creep; hair growth; hyperpigmentation, and hypertrophic scarring.[19,25,31–35]

Skin contractures in using STSGs are reported to occur in 40%, while this occurs in only 22% when using FTSGs.[33] Flexion contractures are reported in a series with long-term follow-up to be 13% and rotation and lateral deviation in 12%.[36] Hair growth when using FTSGs from the groin is reported as being 71%.[30] Leaving small areas open between numerous triangular flaps seems to result in less scarring and there is no difference in web creep versus the classical approach.[24] The choice of donor site for skin grafts depends on the amount needed. If little donor site skin is needed, we will use the wrist crease or elbow crease. This skin is more like the skin of the hand. Scars are placed in the crease, and over time, they become inconspicuous. We do not use groin skin anymore but, instead, skin at the abdominal fold in cases where a substantial amount of skin is needed (for example, Apert syndrome or multiple desyndactylized fingers). The scar will be hidden by regular underwear, and the skin is less

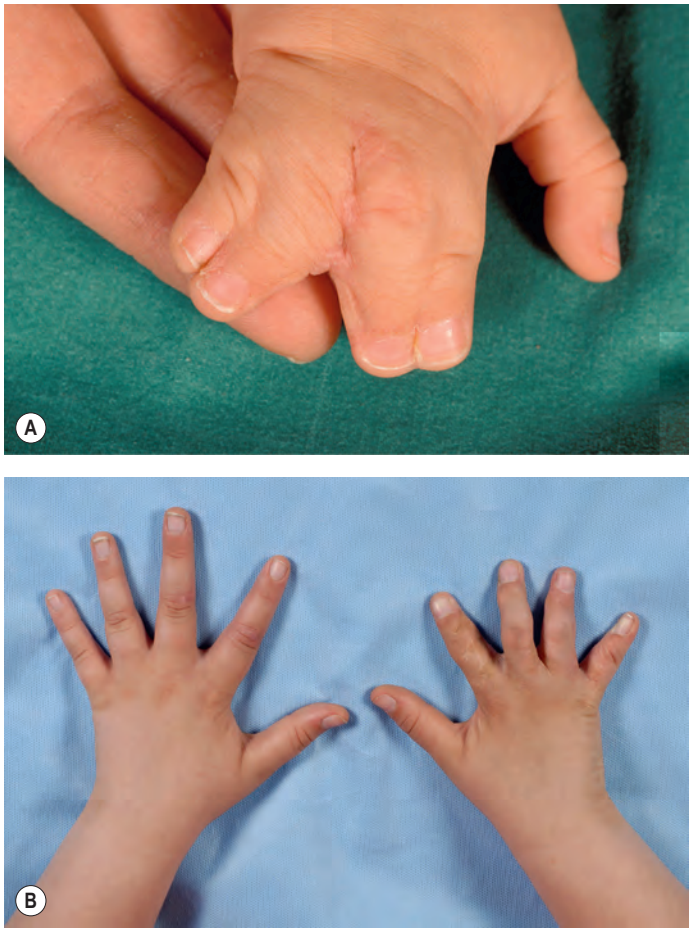

Fig. 28.6 Resyndactyly following separation. Note initial operation with separation 3–4 instead of starting with 2–3 and 4–5 at **(A)** the first operation and **(B)** long-term follow-up following re-separation.

hair-bearing or pigmented than groin skin. Moreover, if skin is needed in multiple operations over time, there is an almost unlimited possibility to harvest skin at this site.

In a group treated with dorsal metacarpal flaps or extended dorsal interdigital flaps and primary closure, results were better, avoiding all the problems with skin grafts.[18–20]

In complex and complicated syndactylies following separation, rotated and deviated fingers can occur, as well as insufficient functioning of the individual separated fingers. Joint instabilities are also possible and may be underestimated. This is, however, a consequence of the initial deformity and is difficult to treat.

Patients should be followed till the end of growth to detect later problems such as web creep, scar contractures, and bony deviations due to different types of delta phalanges. Re-do releases of residual syndactyly is often undertaken, especially at the first web in more complex cases (Fig. 28.6).

Secondary procedures

Secondary procedures are: scar contracture release and re-deepening of webs with or without flaps. In complicated syndactylies, ligament reconstructions, osteotomies, chondrodesis, and arthrodeses may be necessary.

Poland syndrome

Introduction

The reported incidence of Poland syndrome is approximately 1 in 7000–100 000. There is a male predominance, especially in sporadic cases, and the right side is involved in 60–75% of the cases. In females, however, the left and right side occurrence is almost equal. In familial Poland syndrome, the male : female ratio and side predominance is the same.

History

In 1841, Poland[37] described cadaver findings as a student demonstrator of anatomy. He reported deficiency of the external oblique muscle, absence of the sternal and costal portion of the major pectoral muscle, as well as absence of the minor pectoral muscle and portions of the serratus magnus muscle. In the ipsilateral shorter hand, all middle phalanges where absent except for the middle finger, with webbing between the proximal phalanges. However, absence of the pectoral muscle without a hand deformity has been described in 1826 by Lallemand, and Froriep was the first to point out the combination of absence of the pectoralis muscle together with ipsilateral syndactyly in 1839.[38]

Basic science/disease process

Several mechanisms in the pathogenesis of Poland syndrome have been described. Despite some familial occurrence, no inheritance patterns have been determined. The most prevailing theory focuses on the interruption of blood supply to the limb bud in the sixth week of gestation. The interruption will cause hypoplasia to the ipsilateral subclavian artery or one of the branches[39,40] determining the diversity of the defect. However, although most prevailing, this theory is now disputed.

Diagnosis/patient presentation

In Poland syndrome, patients present with a broad range of ipsilateral trunk, upper limb, and hand anomalies. The classical presentation comprises a combination of absence of the sternocostal portion of the pectoral major muscle, hypoplastic arm, and a hypoplastic hand with a simple syndactyly usually of all webspaces (Fig. 28.7). The thoracic deformities might range from the classical absence to complete hypoplastic shoulder girdle with involvement of the ribs and nipple, scoliosis, and seldom dextrocardia.[41,42] Furthermore, Poland syndrome can be associated with multiple other malformations, ranging from craniofacial, internal organs, to the lower extremity.[43,44]

Patient selection

Because of the variety in clinical presentation in Poland syndrome, each treatment is individualized, based on the functional and aesthetic possibilities.

Treatment/surgical technique

Because of the wide scope in presentation of the syndactyly and symbrachydactyly, several treatment options are possible.

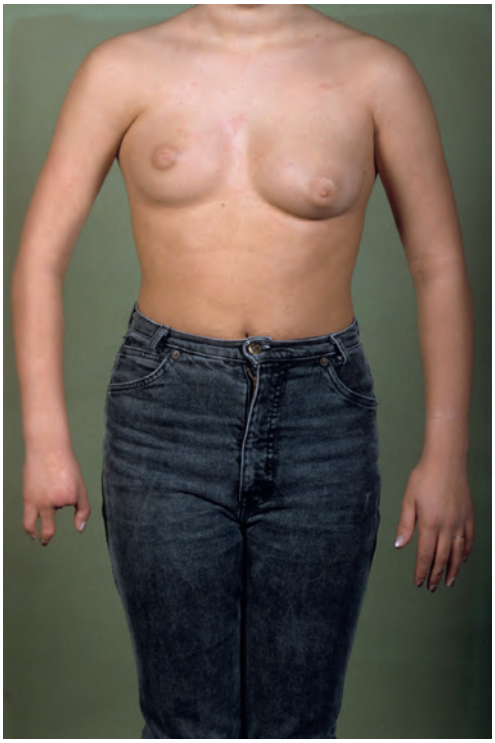

Fig. 28.7 Symbrachydactyly and pectoralis major anomaly and smaller breast on the right side.

Reconstruction of the breast, deficient muscle contour, or chest wall deformity is beyond the scope of this chapter.

Postoperative care

See Chapter 27 for symbrachydactyly treatment.

Outcomes, prognosis, and complications

Outcome is very much related to the original defect and the reconstruction used.

In syndactylous hypoplastic fingers, the separated individual fingers can be less functional than before the operation, resulting in poor outcome. Normally, similar outcome and complications occur as in syndactyly and symbrachydactyly. For prognosis and complications on non-vascularized and vascularized toe transfers, see Chapters 14 and 27.

Secondary procedures

The secondary procedures relate to the broad variety of treatment options available for the treatment of the hand in Poland syndrome. Secondary procedures are mostly re-deepening of scarred webs. If tightened ligaments become lax, arthrodesis of the unstable joint can be done after the growth plate is closed.

Apert syndrome

Introduction

Acrocephalosyndactyly syndrome is characterized by craniosynostosis combined with acrosyndactyly (distal part of the fingers fused) and symphalangism (congenital ankylosis of the proximal phalangeal joints) of the index, long, and ring fingers of both hands and a radial clinodactyly of the thumb in a symmetrical way. The little finger is usually the best finger with a simple syndactyly at the fourth web. Both feet are also affected.

The birth prevalence of Apert syndrome ranges from 7.6 to 22.3 per million live births, the lowest incidence being in Hispanics and the highest in Asians. Males and females are equally affected.[45] In the authors' series, the male : female ratio was 1.5 : 1.

The craniofacial features in Apert syndrome consist of a variety of skull deformities originating from premature closure of the coronal and often lamboid sutures of the skull, and a midface hypoplasia. These deformities can lead to a high incidence of intracranial pressure and obstructive sleep apnea. Craniofacial operations include early cranial vault expansion and, if indicated, midface advancement is performed later in life. Other differences are an oily skin, hyperhidrosis decreased eyesight and hearing, and increased strabismus. Children often display impaired language development and motor skills.

In the lower extremity, the hips become increasingly stiff over time. The knees demonstrate mild to moderate genu valgum. The feet have simple and complete syndactyly. If present, medial polydactyly is mostly at the base of the first metatarsal. The foot deformity causes shoe-fitting problems and an abnormal gait, and possible pain due to calluses over the prominent second and third metatarsal heads. The acrosyndactyly of the feet is encountered less in contrast to the hand. However, the problems caused by the foot deformity in Apert disease is more appreciated. In recent years, treatments have been introduced to improve the aspect of the foot by desyndactylization in the less severe cases and osteotomies to address to the pronouncing metatarsals at the ball of the foot and the malformation of the calcaneal bone.

History

Apert, a French physician in Paris, described nine collected cases in 1906, but probably Wheaton was the first to describe it in 1894.[46,47]

Basic science/disease process

Apert syndrome is caused by a mutation in the gene encoding fibroblast growth factor receptor 2 (FGFR2). The gene map locus is 10q26. Two mutations are well recognized and are related to substitutions at two amino acid positions P253R and S252W in FGFR2. The more severe type of Apert hand is mostly related to the P253R mutation. In our series, nearly all type III Apert hands were attributed to this mutation. Most cases are sporadic, but autosomal-dominant inheritance has been reported.[48,49]

Diagnosis/patient presentation

In the Apert syndrome child, the level of function depends more on his/her intellectual capacity than the severity of extremity involvement. Most Apert children are capable of self care over 5 years of age. Regarding the upper extremity, motion of the shoulder is not normal and decreases with age. In the older Apert patient, a marked deltoid muscular atrophy

is often encountered. These patients appear to have anterior subluxation of the humeral head.[50] The elbow deformities can differ more extensively between these patients than at the shoulder. Elbow function can be slightly decreased, but mostly do not worsen over the years.[50]

Upton has classified the Apert syndrome hand into types I, II, and III for ease of clinical decision-making (Table 28.1). In the type I hand, there is a radially deviated small thumb with a shallow first web. The index, long, and ring fingers display complete or complex syndactyly. The little finger is attached by a simple complete or incomplete syndactyly and can mostly move at the distal interphalangeal joint (DIPJ). The metacarpophalangeal joints (MPJs) have adequate range of motion. In the type II hand, the thumb is radially deviated and has an incomplete or complete simple syndactyly with the index. The index, long, and ring fingers are distally fused, creating a curve in the palm with divergent metacarpals. The little finger is attached to the ring with a mostly complete but simple syndactyly.

In the type III hand ("rosebud" hand), the thumb, index, long, and ring fingers are distally fused either by cartilaginous or bony attachments. The thumb can be very difficult to identify separately from the index. The little finger is united to the ring by simple complete syndactyly. The nails can be confluent or have ridges indicating the distal finger underneath. Proximal synostosis at the base of the fourth to fifth metacarpal can be present, as well as carpal fusions.[51] In the authors' series of 66 patients, the ratio of type III : type II : type I hands was 4 : 3 : 3; although Upton reports that type III is the most uncommon.

Up to 7% ulnar polydactyly has been reported.[52] In the authors' series, there is one case of a duplicated distal phalanx of the index and two cases of duplication at the little finger (5%). In the type III hand, finger nails growing through surrounding skin causing frequent paronychial infections is frequently seen.

The flexion creases are often absent. Dimples on the dorsum indicate the MPJs. Distal to the MPJs, neurovascular structures can vary considerably in branching, or are absent. Distal in the hand, tendons can have a different shape and course. In most cases, either the pulley system is hypoplastic or absent. Regarding the thumb, adduction, palmar abduction, and flexion are mostly present. The first dorsal interosseous is hypertrophic and fan shaped, extending to the delta phalanx of the thumb in the more severe types. The abductor pollicis brevis muscle (APB) is anomalous as it inserts into the radial aspect of the distal phalanx of the thumb causing radial deviation.[53] Lumbricals, if present, act as MPJ flexors. The hypothenar muscles are present and normal.

The proximal phalanx of the thumb is abnormal and triangular shaped. The interphalangeal joint (IPJ) and the carpometacarpal joint (CMCJ) have little motion, while the MPJ is mobile. With skeletal maturity, the IPJ fuses after first being segmented. The distal phalanx and nail matrix are broad.[54,55]

Symphalangism at the proximal interphalangeal joints of the index, long, and ring finger is a persistent finding. In border digits (the index and the fifth), the epiphyseal growth plate can be aberrant at the MPJ causing lateral deviation following separation.

Patient selection

Many articles have been published on treatment timing in Apert syndrome.[51,54,56–58] Most philosophies try to diminish the number of operations by releasing as many fingers as possible in one session. The way this is accomplished varies among authors (Table 28.2).

Treatment/surgical technique

Separation of thumb and fingers, correction of thumbs, and mobilization of the little finger in as few operations as possible is the surgical goal. The authors' preferred method is illustrated in Table 28.3 and Figs. 28.8 and 28.9.

Separation of fingers

Mostly dorsal flaps are used to create webs. For the remaining distal syndactyly, fingers can be separated by zigzag or straight incisions in the fingers with symphalangism. Nail walls can be reconstructed with flaps from the adjacent finger pulp.

The residual defects are covered with skin grafts. Chang only used local flaps and skin grafts, while Zuker *et al*. and Kay use groin flaps for the central digits and the first web, respectively.[21,56,58] Often further corrections are necessary to deepen webs.

Habenicht uses small external fixators to transversely distract the complicated and complex syndactyly of the central fingers, with separation of the distal bone fusions. The created skin is used for coverage of the defects instead of skin grafts. Other methods such as silastic sheets and tissue expanders to separate fingers have been discarded.[59]

Table 28.1 Common features of hands in Apert syndrome

Type	Thumb	Digit 2, 3, 4	Digit 5
Type I	Brachyclinodactyly Incomplete 1st web syndactyly	Symphalangism Complex syndactyly	Simple (incomplete) syndactyly of 4th web or separate digit MC 4–5 synostosis possible
Type II	Brachyclinodactyly Simple (incomplete) syndactyly	Symphalangism Complex syndactyly	Complete syndactyly Duplication P3 possible MC 4–5 synostosis possible
Type III	Brachydactyly Complex syndactyly Paronychial infections Skin maceration	Symphalangism Complex syndactyly Paronychial infections Skin maceration	Complete syndactyly Duplication P3 possible MC 4–5 synostosis possible

MC, metacarpal; P3, distal phalanx.

Table 28.2 Reported treatments in Apert syndrome

Zuker *et al.*[56]	Upton[51]	Fearon[57]	Guero[54]	Chang *et al.*[58]
First stage				
Bilateral 3 months of age	Bilateral 1–6 months of age	Both hands and feet 9–12 months of age	Bilateral 9–10 months of age	Bilateral 6–15 months of age
1st-web four-flap Z-plasty or dorsal skin flap web-index 2nd and 4th-webspace with dorsal flap	1st-webspace with dorsal skin flap Resection index 4th-web release Incision of nailfold/ macerations	Deepening of 1st-web and 3rd-web one hand Release of 2nd- and 4th-web on other hand Similar releases on feet	1st-web release with Buck-Gramcko flap Release APB Release of 4th-web for a three-fingered hand Release of 3rd-web for a four-fingered hand	Release of border digits
Second stage				
Unilateral Before age 3	Within 6 months of 1st stage Unilateral Before 3 years of age	3 months after 1st stage	Unilateral; 6 months between unilateral stages	Unilateral Before age 2; 3 months between unilateral stages
Groin flap in 3rd-web if necessary	Long–ring release Re-deepening 1st-web	Release of the remaining webs on both feet and hands	In four-fingered hand: release of 4th-web In three-fingered hand: release of 2nd-web, removal of 4th ray	Release of middle digit mass Excision of bone, leaving three digits Opening wedge osteotomy thumb clinodactyly
Goal				
Four fingers and thumb		Two-stage syndactyly release of all fingers and toes	Three/four fingers and thumb	Three/four fingers and thumb
Additional				
	4–6 years	**9–12 years**		
	Metacarpal synostosis correction Thumb clinodactyly correction Re-deepening 1st-web	Dorsal osteotomies at "PIP" for anatomic position Correction of radial clinodactyly Addressing foot disorders if present		

APB, Abductor pollicis brevis muscle; PIP, proximal interphalangeal joint.

Table 28.3 Apert syndrome – authors' preferred treatment

Stage	Age	Procedures	Types
First	3 months	Both hands	All types
		Thumb separation with dorsal cloverleaf flap with straight line incision distally	Type II and III
		1st-web deepening with double-opposing Z-plasty	Type I
		Index amputation if necessary	Only severe type III
		4th-web separation with cloverleaf flap with straight line incision distally	All types
		2nd, 3rd, 4th distal digit separation with modified Buck-Gramcko flaps	Only type III
		2nd-web separation with cloverleaf flap with straight line incision distally	Type I and II
		Skin release radial side thumb with Z-plasty and release of APB	Type I, II, III
		Open or reversed wedge osteotomy of clin odactyly of thumb	Type I, II, III
Second	12 months	One hand	In all types
		Separation of 3rd-web with cloverleaf flap with straight line incision distally	In type I, II, and if amputation index in III
		Separation of 2nd-web with cloverleaf flap with straight line incision distally	If no amputation in type III
		Re-deepening of the 1st-web	If necessary in all types
		Synostosis MC4–5 (excised bone can be used for the wedge osteotomy of thumb	If present
Third	<24 months	Same as second stage, on contralateral side	

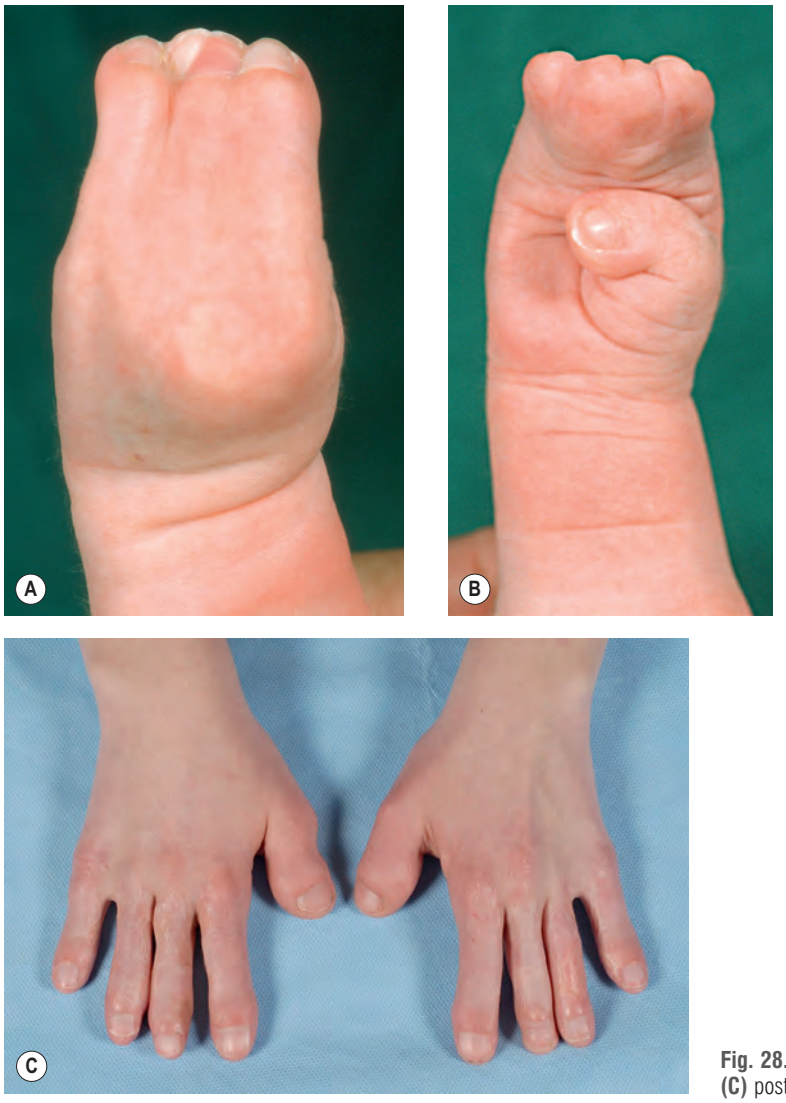

Fig. 28.8 **(A)** Apert hand: left, dorsal view; **(B)** right hand, palmar view; and **(C)** postoperative result at 18 years of age.

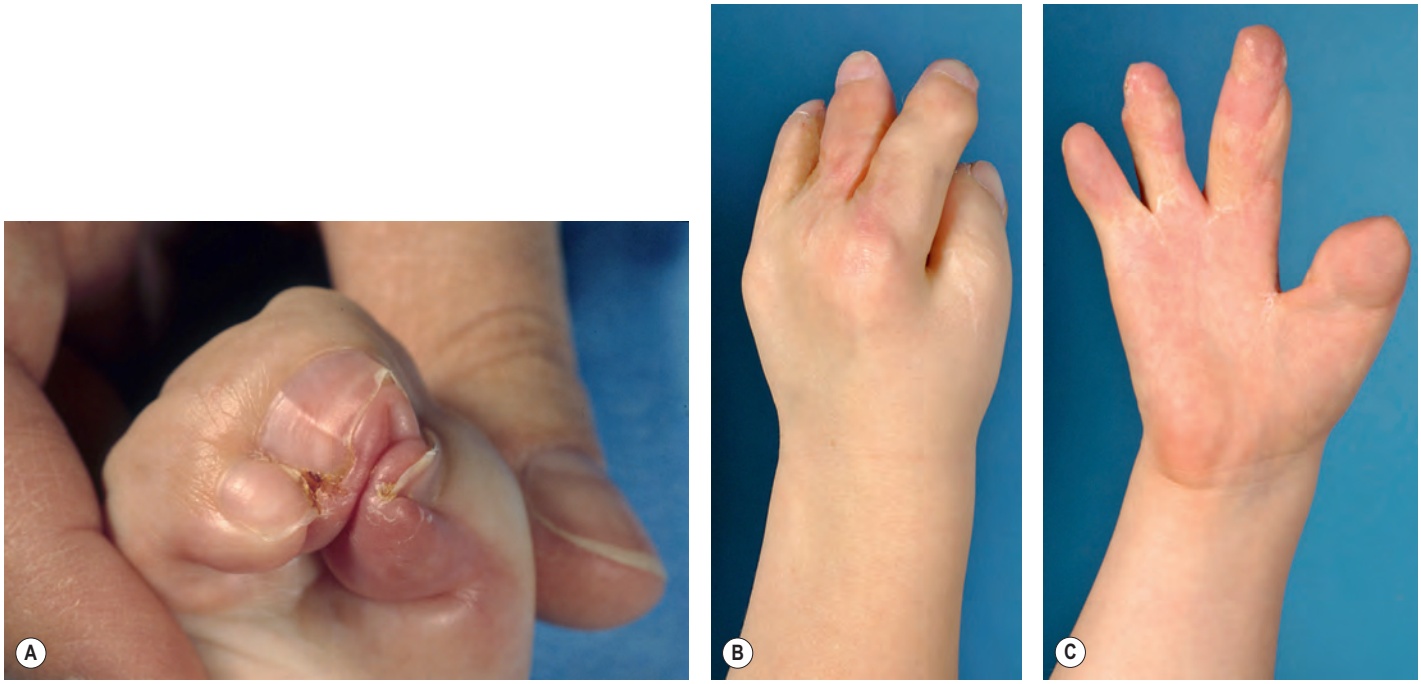

Fig. 28.9 **(A)** Apert type III hand, left. Long-term follow-up: **(B)** left hand, dorsal view; and **(C)** right hand, palmar view. The second ray was amputated because of a very narrow web, shortage of pulp of the index finger and severely rotated and deviated bony structures.

Thumb and first web

A well-separated thumb is crucial in these hands. In a shallow first web (in the type I hand), a four- or five-flap Z-plasty can be utilized. In a complete or nearly complete syndactyly (in the type II hand), a large dorsal flap is used to create a first web.[60] Tight fascia around the adductor muscle is released to open up the first web.

Preferably, a hand with four fingers and a thumb is created. In the type III hand, however, it can be necessary to sacrifice the index to create a useful first web with a dorsal flap[61,62] (Fig. 28.9).

Clinodactyly of the thumb is often corrected in the second stage because of more skeletal maturity. The tight skin on the radial side at IPJ level can be released with a Z-plasty. The APB is released from the distal phalanx. The triangular bone is treated as in clinodactyly (see below). There is a tendency to treat the thumb clinodactyly and APB release at the first operation, interfering the pull of the APB on the deviation of the thumb as soon as possible.

Dao *et al*. considered the abnormal radiodistal insertion of the APB responsible for the deviation of the thumb, and released the APB muscle and tendon distally without performing a corrective osteotomy.[53] In the type III hand, the thumb is short and has less bone volume distally; therefore, an opening wedge osteotomy is performed, secured by a longitudinal K-wire. Due to the increased bony healing in Apert disease, this will suffice.

Additional procedures

Synostosis, if present, at the proximal fourth–fifth metacarpal should be separated early to improve function of the fifth ray in this rather stiff hand. Aberrant growth plates at the index and little finger can cause clinodactyly after separation. Wedge osteotomies may be needed secondarily to correct this deviation. Even without aberrant growth plates, the border digits tend to laterally deviate. Lengthening procedures of the fingers and especially the thumb are performed to improve appearance, and also function in type III hands with short thumbs.

Postoperative care

Postoperatively, the hand is carefully dressed and covered by a small plaster splint. Over this plaster, a completely covering adhesive bandage is applied preventing elbow extension. At the outpatient clinic 6 weeks later, the hand is inspected and if wound healing is achieved after 6 weeks, the hand(s) can be used. Despite the skin abnormality in Apert syndrome, no additional problems are seen using this bandage regime.

Outcomes, prognosis, and complications

Hand function is improved the most if the thumb is separated together with separation of the little finger, as it is the best finger. In this way, the thumb can adduct powerfully with the ulnar proximal part of the thumb. Also, a sort of tripod pinch with the more mobile little finger is ensured. Movement of the fingers, except the little finger is only at the MPJ. Lengthening of the thumb and separation of the remaining fused fingers does not improve function considerably; however, it is requested to improve the appearance.

Complications

The hyperhidrosis and oily skin makes the skin grafts prone to maceration, skin slough, and even infection. Barot and Caplan reported a 22% partial skin graft loss.[63] Guero operates on these children in winter, to diminish sweltering bandages and casts.[54] Secondary procedures for web contractures are therefore common. The revision rate for secondary web contracture varies among authors from 3% to 18%.[54,57,58,63] In the authors' series, there has been 13% secondary contracture release. Revising web contractures depends very much on the surgeon's idea of contracture. Patients rarely complain of web contractures. The author tends to deepen the first web more if syndactyly release of the fingers is planned. Other described interventions are amputation of a finger due to limited opening of the first webspace or because of ankylosis.[54]

Secondary procedures

Secondary operations include:

- Web deepening with advancing of the primary flap or skin grafting the newly created defect.
- Wedge osteotomies of the border digits as necessary to correct the deviation following separation due to partial closure of the epiphyseal plate.
- Extra thumb lengthening is sometimes required in very short thumbs in type III hands.

Synostosis

Introduction

Synostosis is derived from the Greek: *syn* = together, *osteon* = bone; it is defined as a union of two or more adjacent bones. Abnormalities in union of the bones of the upper extremity occur at all levels because of a failure of segmentation. Fusions may occur at more than one level. For instance in Apert syndrome, symphalangism in conjunction with metacarpal synostosis and carpal fusion may also occur. Most synostotic differences present with another condition. The presence of a synostotic anomaly does not necessitate surgical treatment, but is dictated by functional needs and aesthetics.

Symphalangism was first described by Cushing as an autosomal-dominant genetic skeletal disorder[64] and is characterized by longitudinal bone fusions along the finger and toe joints. Most commonly, the PIPJ is fused. Associated bone fusions are carpal or tarsal synostosis, and stapes fixation resulting in conductive deafness. Flatt and Wood[65] classified the congenital difference as true symphalangism with normal length of digits; with symphalangism in symbrachydactyly; or associated with other anomalies (i.e., Apert or Poland). The incidence of true symphalangism is 0.03–4%.[60] Because of the conjunction with other conditions, the general incidence of all types of symphalangism is not known.

Metacarpal synostosis is a rare congenital anomaly, with wide anatomical variations. The fourth and fifth metacarpals are usually affected. The synostosis is more common in patients with a craniofacial and hand difference. Incidences in a large group of congenital hand anomalies range from 0.02%[66] to 0.07%.[67] Buck-Gramcko and Wood distinguished three groups based on the length of fusion: type I, fusion at the base;

type II, fusion of about half; type III, more than half; IIIa, separated metacarpophalangeal joints (MCPJ); and IIIb, common MCPJ.[67] A classification, useful for treatment, has been proposed by Foucher *et al*.[68] It comprises the shape of the synostosis, the growth direction of the epiphysis, the deformity of the finger distal from the synostosis, the webbing, and the hypoplasia of the metacarpal bone.

Carpal coalitions are reported rarely, and often go unnoticed. All combinations of carpal fusions have been mentioned, with the most frequent synostosis being between the triquetrum and lunate, and the hamate and capitate.[69,70] In a predominantly white population, an incidence with a range of 0.07–0.1% has been mentioned,[71,72] compared with 8% in a Nigerian population. Despite the fact that coalition will theoretically impair the movement of the wrist, no disabilities have been described.

Radioulnar synostosis is a rare upper limb malformation and is defined as a fusion of the proximal ends of the radius and ulna, which will prohibit normal rotational movement of the radius around the ulna. Radioulnar synostosis can be unilateral or bilateral (60%), of autosomal-dominant inheritance, or associated with other congenital differences. In one-third of cases, syndromes and anomalies are listed.[5,73,74]

History

The term symphalangism was used by Cushing in 1916,[64] describing a family with dominant inherited ankylosis of the PIPJs of the hand. One year later, Drinkwater reported the anomaly as "Talbot fingers", because of the digital anomaly in the Talbot family in England in 14 generations. Today, the term "symphalangism" is used in isolated finger deformities as well as in concurrent anomalies or syndromes.

Metacarpal synostosis was recognized and illustrated by Kelikian,[75] and is known throughout history by several names, such as fifth ray anomaly, congenital metacarpal malformation, absent fifth metacarpal, bilateral ulnar thumbs, and congenital fusion.

Radioulnar synostosis was first described by Sandifort in 1793, and in 1932, Fahlstrom[76] reviewed 185 reported cases since the first description.

Basic science/disease process

Mutations in genes involved in limb development and mutations in the Noggin gene (*NOG*) have been associated with synostosis. An interruption of apoptosis responsible for the segmentation is believed to be the most common cause for synostosis. The gene responsible for the hereditary form of symphalangism (*SYM* or *SYM1*) is the *NOG*, which maps to human chromosome 17 (17q21–q22).[77] Mutations in *HOXA11* are associated with radioulnar synostosis.

Diagnosis/patient presentation

In hereditary symphalangism, the PIPJ is the most commonly involved joint with a compensatory movement in the DIPJ and normal movement of the MPJ. The DIPJ is involved in symbrachydactyly. At physical examination, the fingers are slender, with atrophic skin, and the flexion creases are absent at the involved joints. The anomaly presents at one or more fingers, from ulnar to radial. The thumb is seldom involved. In radiographic examination of the child's hand, a pseudo joint can be visible, represented by the cartilaginous bar between the two bones. Later in life, radiographs will show a minimal joint space due to full coalition at the joint.

In metacarpal synostosis, the most common fusion is between the fourth and fifth metacarpals (Fig. 28.10A). A short and abducted little finger is seen in these cases. However, the extent of deformity is dependent on the plane of the joint space and the configuration of the epiphysis of the involved metacarpal heads. A radiograph will give insight into the skeletal abnormality and will guide in the abnormalities of soft-tissue alignment.

Patients with radioulnar synostosis (Fig. 28.10B) will present within the first 3 years of life because of the inability to perform tasks in daily life such as holding objects two-handed. In severe cases, they will hyperabduct their shoulder, and compensate with a hypermobility of the wrist for the excessive pronation.

Fig. 28.10 **(A)** X-ray of metacarpal 4–5 synostosis. **(B)** X-ray of bilateral carpal and radioulnar synostosis.

Patient selection/treatment/surgical technique

The treatment of symphalangism is mostly conservative. Because of anomalies of the flexor and extensor tendons, early surgical intervention is not successful. In well-segmented joints only, exploration and release of the collateral ligaments and dorsal capsule may improve function; however, results are not predictable. Arthrodesis in a more functional position of the involved joints at skeletal maturity will improve function and grip. Distraction lengthening of the stiff fingers in symbrachydactyly may improve the pinch between the thumb and a short index finger. It can lead to possible better aesthetics; however, the treated fingers can become thin and stiff.

The indications for treatment of a metacarpal synostosis are both functional and aesthetic, and depend on the type of fusion. The abducted little finger may get caught in pockets and therefore be a problem. The goal of treatment will be a longitudinal, axially oriented ray with the MCP joint in line with the other joints, preserving its motion and joint surface, and correction of angulation and rotation. Less functional digits should be positioned out of the way of the thumb to little finger prehension.[5] Several operative treatments have been advocated, depending on the type of synostosis[5,68] ranging from osteotomy alone[68,78] to lengthening with bone graft or callodistraction[5,68,79] and longitudinal splitting combined with an interposition bone graft.[5]

Carpal synostosis will only need treatment in painful fibrocartilaginous coalition. If this is the case, it is advised to fuse the involved carpal bones.

In radioulnar synostosis, only few patients will need surgery because patients will compensate with wrist and shoulder movement. Treatment is recommended when a patient is compromised in daily actions with a fixed pronation of 60° or more in unilateral and bilateral cases.

To restore movement, longitudinal osteotomy at the fusion site in combination with a vascularized adipofascial flap and alignment of the radial head[80] has been performed. Several types of osteotomies have been described. Only resection of the synostosis is disappointing with rapid re-fusion as a result. To prevent re-fusion, the anconeus muscle has been used, as well as pedicled and free vascularized fat flaps.[80,81] Derotational osteotomies are performed just distal to the fusion,[82] or at the proximal radius and distal ulna.[83,84]

Postoperative care

In symphalangism, postoperative treatment consists of passive movement of the released joints. When an osteotomy is performed, treatment should be focused on the type of fixation. If a metacarpophalangeal joint is released, with or without additional tendon transfers, these should be addressed accordingly.

Outcomes, prognosis, and complications

In most of the cases, metacarpal synostosis will not need treatment. If treating metacarpal synostosis, early problems are the diminished metacarpophalangeal movement, mostly present preoperatively, and insufficient alignment of the involved digits in metacarpal synostosis. Late problems may be a recurrent abduction of the little finger, and a re-ankylosis at the osteotomy site, despite interposition.

In radioulnar synostosis, improved function and decreased musculoskeletal discomfort in adjacent joints are reported, with up to 80% having good to excellent results.[80] As mentioned earlier, even with an interposition graft, re-ankylosis is possible with increased pronation. Neurologic and vascular compromise, and Volkmann ischemic contracture have been reported,[85] especially in cases of longitudinal osteotomy at the fusion site. This should be avoided by monitoring the degree of rotation and removing a segment at the osteotomy site.[5]

Secondary procedures

Secondary procedures performed on metacarpal synostosis and radioulnar synostosis are re-operations because of incomplete correction, re-ankylosis, or loss of motion. Because of the influence of growth, children should be observed until skeletal maturity, especially in metacarpal synostosis. Less motion in the metacarpophalangeal joint should also be addressed.

Polydactyly

Introduction

Polydactyly (*poly* = more; *dactylos* = finger) refers to the disorder in which patients have more than five digits on at least one extremity. Together with syndactyly and camptodactyly, it is the most common congenital upper extremity difference. The disorder is easily detected leading to cosmetic concern of the parents and, if not treated, cosmetic concern of the affected child. Additionally, depending on the level of the duplication, it can cause functional impairment. Polydactyly of the hand can be divided into radial, central, and ulnar polydactyly, referring to the region of the extra digit or part of a digit.[86]

The incidence of polydactyly varies depending on the studied population. Region, race, and combined numbers of all polydactylies, or only radial- or ulnar-sided polydactyly, provide very different incidences in published series. The incidence can range from 2% to 30% when considering all types of polydactylies and up to 40% in the Chinese population. The prevalence of polydactylies is 10.7 of 1000 live births in people with an African descent compared with 2.5 of 1000 live births in Chinese people and 1.6 of 1000 live births in Caucasians. Ulnar polydactyly is 10 times more common in those of African descent and twice as common in males, whereas radial polydactyly is more common in Asians. Central polydactyly is extremely rare in all published studies.

At the authors' center, out of 200 new patients per year with congenital hand deformities, about 15% have polydactyly, including 50% with radial polydactyly, 9% with central polydactyly, and 33% with ulnar polydactyly (some in combination). In the authors' series, 42% of polydactylies are bilateral.

Radial polydactyly is mostly isolated, whereas syndromic association is more common in ulnar polydactyly. Furthermore, ulnar polydactyly is mostly bilateral and can be associated with syndactyly and polydactyly of the feet. Children born to parents with nubbins or floating little fingers inherit the same type of polydactyly. Children born to parents with more developed extra little fingers can present with all types of polydactyly.[87]

Many syndromes have been described in combination with different kinds of polydactyly. Already, over 97 genetic

Table 28.4 Common syndromes associated with polydactyly

Syndrome	Hand difference	Concurrent symptoms
Radial polydactyly		
Holt–Oram	Hypoplastic thumb to bifid thumb Different anomalies of the upper limb, unilateral or bilateral	Cardial abnormalities
Fanconi anemia	Variety of radial differences of the hand Radial dysplasia	Pancytopenia, abnormalities of heart, lungs, kidneys and digestive tract, deafness, eye/eyelid problems, short stature
Townes–Brocks	Polydactyly	Imperforate anus, abnormally shaped ears, kidney abnormalities, hearing loss, heart defects, genital malformations
Ulnar polydactyly		
Bardet–Biedl	Ulnar polydactyly in majority of cases, might be in combination with syndactyly	Poor vision, reduced or loss of smell, cardiovascular disease, urogenital disease, mental and growth retardation, obesity
Smith–Lemli–Opitz	Polydactyly Syndactyly of second and third toe	Microcephaly, mental retardation, malformations of the heart, kidneys, gastrointestinal tract and genitalia
Trisomy 13	Polydactyly Abnormal palm pattern, overlapping fingers over thumb	Microcephaly, mentally and motor challenged, eye defects, meningomyelocele, rocker-bottom feet, cutis aplasia, cleft palate, urogenital defects, heart defects
Combined polydactyly		
Greig syndrome	Variety of polydactyly with or without syndactyly, broad thumbs	Ocular hypertelorism, macrocephaly Polydactyly of the feet (medial and/or lateral)

syndromes have been associated with polydactyly.[88] In syndromes, there may be anomalies of the hands and feet. Moreover, combinations of polydactyly in the hand can occur, such as radial with ulnar, and central with ulnar. In the Greig syndrome (cephalopolysyndactyly), polydactyly can occur in any combination. For common syndromes associated with polydactyly, see Table 28.4.

A separate entity is the mirror hand or ulnar dimelia. In the forearm, two ulnae exist without a radius. Because the medial side is a mirror image of the lateral side, the term mirror hand became popular. It is extremely rare.[75] The classic mirror hand is unilateral, usually with seven to eight fingers without a thumb, and is not combined with other anomalies. The etiology is unknown. The inheritance pattern has not been found. Geneticists believe it to be a spontaneous mutation.

History

Polydactylous hand and footprints have been found when studying rock art and petroglyphs, some dated 1000 AD. The first time that polydactyly was referred to in literature was in the Old Testament, where in a battle in Gath, a giant had six fingers on each hand, and six toes on each foot. The term polydactyly is first described by Kerckring in 1670. Since then, many reports have been made on polydactyly.

Basic science/disease process

Genetic aspects

In the patient with isolated radial polydactyly, a diminished genetic penetrance exists, with a variable expression. Furthermore, in numerous families with inherited isolated dominant radial polydactyly and triphalangeal thumb, a connection with chromosome 7q36 is demonstrated. In this particular chromosome lies the regulatory element of the SHH protein. In isolated ulnar polydactyly an autosomal-dominant inheritance pattern occurs, with a diminished genetic penetrance and a variable expression. It is genetically heterogeneous, implying that the cause lies in mutations in various genes.

Diagnosis/patient presentation

Radial polydactyly

In radial (preaxial) polydactyly, the most commonly used classification is the Wassel classification.

The Wassel classification (Fig. 28.11)[89] is based on radiology and is easy to remember. The levels of duplication of the different types are: type I at the distal phalanx; type II at the IPJ; type III at the proximal phalanx; type IV at the MCPJ; type V at the metacarpal; and type VI at the CMCJ. Thumbs, of which at least one is triphalangeal, are type VII – this can be either at the MCPJ or at the CMCJ.

In most series, the three most common Wassel types are, respectively, Wassel IV (about 50%); Wassel II (about 20%), and Wassel VII (about 12%). The percentages are variable in the different reported series.[90–92] As 31% in our polydactyly series could not be well classified, we modified the classification system.[92] The essence lies in keeping the Wassel classification but naming the differences such as deviation and triphalangism (see below).

At first consultation, following medical history and general physical examination, both upper limbs are examined. If the index to little finger is normal, with normal hand and finger creases, and a normal hypothenar region, the examination is concentrated on the radial side of the hand. In our experience, it is worthwhile performing this systematically, as quite often more anomalies are present than only an extra thumb.

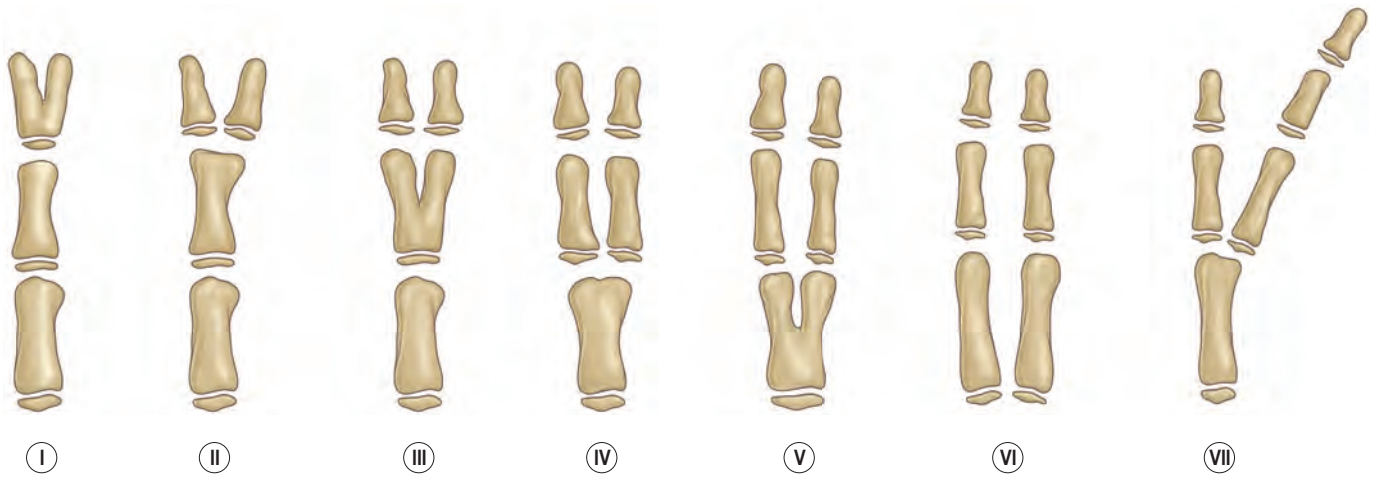

Fig. 28.11 Wassel type I–VII.

The examination is performed from proximal to distal, starting with examination of the thenar muscles. The thenar musculature varies widely from normal to severely hypoplastic. In the Wassel I and II, the thenar musculature is mostly normal, in contrast to the Wassel V, VI, and VII. Hypermobile joints should always be related to the other joints in the hands. It is important to look for creases both dorsally and palmarly. If creases are present, then an active movement in that particular joint can be expected.

The CMCJ in polydactyly can be normal, stiff or hypermobile. If abnormalities in the CMCJ are present, they are mostly encountered in the more proximal polydactylies. If polydactyly is situated at the CMCJ, the MCPJ in the best thumb can be near normal. In these cases, the movement is dependent on the presence of a syndactyly between the duplication.

Depending on the location of the polydactyly, the MCPJ can be stiff, normal moving, or hypermobile and hypoplastic. For instance, in a polydactyly involving the MCPJ, quite often the duplication moves as a block. In most of these cases, the radial-sided thumb is hypoplastic and stiff, and the ulnar thumb is the better one, often moving well at the IPJ. Finally, the IPJ can present with normal movement, stiffness, or hypermobility. If the duplication is at the IPJ, both parts can move as a block. The range of motion in those cases is typically less than in a normal IPJ. In an asymmetric duplication at the IPJ, the best-developed part usually moves better.

Normal examination includes extrinsic and intrinsic movement. In a newborn, it is often difficult to distinguish between these movements. However, flexion and extension can be evaluated, as well as the presence of palmar abduction. In duplicated thumbs, the flexor pollicis longus is Y-shaped in the majority of cases, with a less developed tendon to the most hypoplastic thumb. Therefore, flexion can be seen simultaneously in both thumbs. The extensor apparatus is usually less developed or absent in the more hypoplastic thumb. It can be Y-shaped as in the flexor and asymmetrically attached, therefore, deviating the distal part. The fingertips can be either normal or asymmetric. The asymmetric side is typically found on the opposing sides of the two thumbs. The nails are smaller and asymmetrical in most cases. The first web is nearly always normal in the distal duplications. In more proximal polydactylies, the first web can be narrower than the normal contralateral side.

Ulnar polydactyly

Ulnar (postaxial) polydactyly classifications include either two or three types. In the two-stage classification according to Temtamy and McKusick, type A comprises an extra little finger at the MCPJ, or more proximal including the CMCJ. The little finger can be hypoplastic or fully developed. Type B varies from a nubbin to an extra, non-functional little finger part on a pedicle. In the three-type classification, type I includes nubbins or floating little fingers, type II includes duplications at the MCPJ, and type III includes duplications of the entire ray.[90,93,94]

The most common presentation of ulnar polydactyly is a small appendix on a skin pedicle, in which a neurovascular bundle is present. The appendix, in most cases attached at the ulnar border of the proximal phalanx, has mostly a small nail and thus a distal phalanx, and is non-functional. Sometimes two bones are present. If the extra little finger is more developed, the more common site of duplication is at the MCPJ. In these cases, the fifth metacarpal is broad. Depending on the extent of development and the attachment at the MCPJ, the extra little finger flexes and extends well. Full motion of the MCPJ of the normal fifth finger can be affected. Flexor tendons and extensor tendons are usually Y-shaped and asymmetrical, as in the duplicated thumb. The extra finger is usually abducted at the MCPJ and radially deviated at the PIPJ. The hypothenar muscles are attached at the ulnar side of the extra digit and palmarly at the broad MCPJ.

If the extra little finger is at the base of the metacarpal or at the CMC, the joint of the finger is usually well developed. Physical examination of ulnar polydactyly depends on the development of the extra little finger. Nevertheless, the same rules apply, as described in the examination of radial polydactyly.

Central polydactyly

In central polydactyly, the second, third and/or fourth digit can be involved in the duplication. Fully developed extra independent fingers are rare. In order of appearance, the most frequently affected is the ring finger, followed by the long finger, and ultimately the index finger. Frequently, the duplication of the fourth finger is partial

and hidden by a syndactyly, typically to the third finger. A number of varieties are possible because the duplication often is not confined to one finger. In addition to the bony deformity and aberrant growth plates, anomalies of the flexor and extensor tendons and neurovascular structures are present.

In ulnar dimelia (mirror hand), the hand looks very peculiar and is restricted in function due to the lack of a thumb and the presence of multiple digits. Seven to eight fingers are present without a thumb. Syndactyly can occur. The wrist is broad and mostly flexed. The arm is shorter with a broad elbow, an extension deficit, and restricted forearm rotation and shoulder movement.

Patient selection

Polydactylies are usually treated surgically. Functional impairment can vary from slight to severe, depending on the extent of the deformity. Polydactylies can be a nuisance in, for example, shaking hands, putting hands in pockets or narrow spaces, and wearing gloves. However, most parents visit the outpatient clinic with their child for aesthetic and social reasons. In patients with a syndrome with serious concomitant disease, surgery can be delayed or even be avoided.

Treatment/surgical technique

The timing of surgery is arbitrary. Surgery is recommended at the end of the first year of life by many authors, as it is important to be able to identify the structures properly and to minimize the anesthetic risks. Floating little fingers are often removed early in the newborn nursery under local anesthesia.

Knowledge of patho-embryology and patho-anatomy is essential to obtain long-term good results. Try to visualize aberrant anatomy without too much dissection!

Hints and tips

Radial polydactyly

Principles in treatment of radial polydactyly are:

- "Make one thumb from two, do not simply excise one."
- Decide which thumb should be kept.
- Do not just excise the most hypoplastic thumb but preserve tendons, ligaments and skin to align, balance and augment the residual thumb.
- At the first operation as much correction as possible is performed on both soft tissues and bones.
- Always be aware and search for less obvious anatomical anomalies, besides the extra digit.
- Align articular surfaces as axial and as congruent as possible by transverse and longitudinal osteotomies.
- Perform ligament reconstructions or releases.
- Balance tendon insertions.
- Adjust skin cover as accurately as possible.
- Postoperative dressings should be meticulously applied and resistant to removal by the child.

The surgical technique of Wassel type II and type IV will be discussed further, as they are the most frequent types.

Radial polydactyly at the IPJ (Wassel type II)

Wassel type II thumbs usually have a broad proximal phalanx with two (partial) distal phalanges with varying degrees of fusion of the bones or epiphyses (Fig. 28.12). In the case of an unequal duplication, it is straightforward to select the smaller thumb to be excised. The incision can be made dorsally in a zigzag manner for good exposure. The authors prefer a more lateral incision because it leaves less conspicuous scars. First the nail and nail bed of the smaller thumb is excised and then the skin over the extensor tendon is developed, if present. At the lateral side distal to the IPJ, the collateral ligament with periosteum or a small piece of cartilage is dissected proximally. The IPJ is then opened and inspected. The flexor tendon, if present, is identified and preserved and released distally. In excising the extra phalanx, the cartilage can be cut intra-articularly at the junction, corresponding to the former two thumbs. This leaves a surplus of skin, a proximally attached ligament, either (or not) an extensor and flexor tendon, and a broad proximal phalanx. On the side of the excised distal phalanx, a longitudinal wedge of bone from the articular surface of the proximal phalanx is removed, taking care not to remove the collateral ligament. If necessary, a transverse wedge is removed distally leaving the IPJ surface intact and subsequently placing the IPJ perpendicular to the axis of the proximal phalanx. Then the extensor and flexor of the remaining distal thumb are inspected. Mostly, the smaller part of the flexor will be excised at the border of the remaining flexor tendon. The smaller extensor tendon can be used to augment the extensor tendon of the remaining thumb. This extra extensor tendon is best used as a graft and not left in continuity with the extensor tendon to the remaining (ulnar) thumb. If the extensor tendon is used to reinforce the collateral ligament, it could influence extension of the remaining thumb. The collateral ligament is attached to the remaining distal phalanx. The remaining skin is carefully inserted on the lateral side, taking care to augment the deficient pulp on that side, while bulkiness of skin should be prevented.

In the event of two equal hypoplastic distal thumbs, which are fortunately less frequent, the two outer halves can be joined after excising the two inner halves longitudinally, in the Bilhaut–Cloquet operation.[95] Instead of the Bilhaut–Cloquet operation, the authors prefer a good smaller nail than a larger nail with a broad ridge, which draws attention. Therefore, one nail and nail bed is removed in nearly all cases and the usually insufficient pulp is augmented by the radial pulp of the excised thumb. In rare cases, a modified Bilhaut procedure can be used, augmenting a curved nail by elevating the nail bed from the bone, and supporting the radial side by bone from the radial (removed) thumb.

Radial polydactyly at the MCPJ (Wassel type IV)

Wassel type IV thumbs often demonstrate a hypoplastic or smaller extra thumb on the radial side. The operative technique has great similarities with the operation at the IPJ (Fig. 28.13). The radial thumb is excised preserving the radial collateral ligament with some cartilage, and after dissecting the extensor and flexor tendons, the joint is inspected. The broad

distal metacarpal is treated in the same way as the proximal phalanx in the IPJ in the Wassel type II, by excising a portion. The proximal phalanx is then aligned after exploring the flexor and extensor tendons of the remaining thumb. The flexor tendon can be asymmetrically situated without pulleys. Asymmetric tendons should be realigned in the "ulnar" thumb. If deviation at the IPJ is present, it should also be corrected with a transverse wedge osteotomy at the distal end of the proximal phalanx, as it will not adjust spontaneously during growth. In diamond-shaped polydactylies, IPJ corrections are always necessary. In equal-sized thumbs, the ulnar thumb is usually preserved as the ulnar collateral ligament is more important. The radial collateral ligament is subsequently reconstructed, providing stability on the new radial side of the MCPJ. With the radial collateral ligament, the thenar musculature is also reattached. Again, skin coverage of the radial side should be meticulously adjusted to the residual defect. Adjustment of the first web is rarely necessary in Wassel type II and IV.

Ulnar polydactyly

In the floating little finger type, the pedicle is excised at its base and the neurovascular bundle is buried to prevent painful neuromas in the scar (Fig. 28.14). It can be performed in the newborn nursery under local anesthesia. Care should be taken to avoid residual polydactyly at the base as this can occur when a ligature is used around the pedicle. Revisions may be necessary later in life To prevent this residue, the use of vascular clips has been introduced. These can be positioned flush to the skin of the little finger, only leaving a scar. If a more developed extra little finger exists, the same principles apply as for radial polydactyly.

Central polydactyly

The basic problem in central polydactyly, in the majority of cases, is the often bizarre configuration of the skeleton with duplication and aberrant bones hidden by syndactyly. As the variety in presentation is extensive, basic rules should be followed (alignment of bones and articular surfaces) and, if possible, balanced by available tendons. However, involved fingers are insufficient or hypoplastic, and the joints are stiff. Syndactyly releases should be performed only if the fingers will obtain sufficient support (Fig. 28.15).

Mirror hand

Reconstruction in the very rare mirror hand can include elbow correction, osteotomies at the forearm to improve supination, and correction of flexion deformities at the wrist. The hand mostly involves resecting two or three fingers on the lateral side making a thumb of the best finger (usually the extra long finger) and creating a sufficient first web.[90]

Postoperative care

The reconstructed hand following polydactyly is immobilized for 6 weeks, allowing finger movement in the bandage. Following the initial 6 weeks, and depending on the level and complexity of the reconstruction, further treatment consists of uninhibited full motion to a removable splint for several weeks. Hand exercises under supervision are seldom necessary. In the simple ulnar polydactyly, a bandage is given for 2 days, as in regular wound care.

Outcomes, prognosis, and complications

When reconstruction in a congenital hand is performed, definitive outcome can only be assessed after growth has been completed. Therefore, it is advisable to check children several times during growth. At our outpatient clinic, examination is performed as described (Table 28.5). Specific attention is paid to nail deformities, movement and stability of joints, active range of motion, and appearance, broadness and malalignment of the skin. Older children and parents hardly complain of lack of function even though joints can be stiff. Painful thumbs are very rare. However, they do complain about appearance, often masked by an insignificant functional complaint. Teenagers often visit the outpatient clinic wanting the aesthetic outcome to be improved.

Outcome can be divided into unavoidable and avoidable results. In the unavoidable outcome in Wassel type II, the distal part of the thumb can be from nearly normal to hypoplastic, depending on the initial presentation. Insufficient pulp, smaller nails, and less developed IPJs are inevitable. In nail bed reconstructions, the nail will never be completely normal.

Table 28.5 Polydactyly: sequence of examination of the first ray

Feature	To be noted
Aspect	
Appearance	Normal/hypoplastic
Alignment	Straight/deviated
Position	Flexed/extended
Skin	
Creases	Normal/absent at joint(s)
Fingertip	Normal/asymmetric pulp
Syndactyly	Complete/incomplete
1st-web	Normal/narrow
Nails	
Nails	Normal/asymmetric/broad/small
Joints	
CMC, MP, IP	Stable/hypermobile/unstable Normal/impaired movement/stiff
Bones	
MC, P1, P2, (P3)	Normal/broad/slender
Muscle/tendon	
Thenar	Normal/hypoplastic
Extension	Present/absent/aberrant
Flexion	Present/absent/aberrant
Adduction	Present/absent/aberrant
Palmar abduction	Present/absent/aberrant
Radial abduction	Present/absent/aberrant

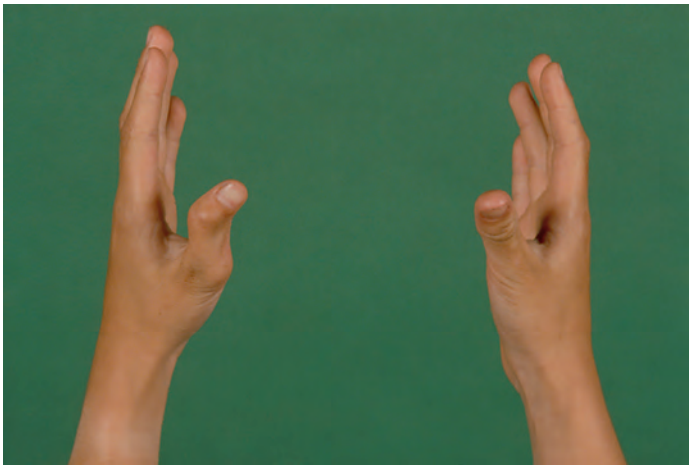

Fig. 28.16 Z-deformity following resection of only radial extra ray without further correction in unilateral Wassel type IV.

Avoidable outcomes in Wassel type II relate to inappropriate alignment, resulting in nail deformities, scarring at the nail wall, and extra nail development. If the collateral ligament is constructed with cartilage or a small piece of bone from the excised phalanx, new formation of bone can be the result. At the IPJ, incongruent alignment causes deviation, instability, or stiffness. Too much resection at the base of the distal phalanx damages growth of the remaining distal phalanx.

In the unavoidable outcome in Wassel type IV, the residual thumb is always less developed than the normal contralateral thumb.[1] The pulp is often less developed, the nail is usually smaller, and motion can vary from nearly normal to stiff, especially at the IPJ.[96,97] Goldfarb found only a difference in nail width; however, motion was not taken into account in this study. But even though the thumb appears smaller, patients are satisfied as long as it is well shaped.[97,98]

Avoidable outcomes in Wassel type IV also relate to inappropriate alignment. IPJ and MCPJ angulation decreases the aesthetic outcome.[96,97] Deviations at either the IPJ or MPJ can mostly be prevented at initial operation by aligning the articular surfaces and balancing the thumb properly. Too much resection at the MPJ results in growth disturbances at the proximal phalanx of the remaining thumb. In late S- and zigzag deformities (Fig. 28.16), proper initial alignment has not been accomplished. Residual unstable IPJs or MCPJs can develop following improper ligamentous reconstruction at the initial stage.

In ulnar polydactyly, a small painful mass can remain following ligation or inadequate resection of the pedicle of the extra floating little finger. If the extra finger originates at the MCPJ, full flexion at the MCPJ might not be possible as the joint is not normally developed.

Secondary procedures

Growth can make secondary interventions advisable without really being complications. Possible secondary procedures, either or not in combination, can include:

- Ligament reconstruction
- Tenolysis
- Tendon rebalancing
- Opposition transfers (sometimes in the more proximal Wassel types)
- Nail deformity correction
- Osteotomy and alignment of articular surfaces
- Neurolysis and neuroma treatment in adult patients
- Arthrodesis of IPJ or MCPJ
- Scar revision.

Triphalangeal thumb

Introduction

The general incidence is estimated by Lapidus as being 1 in 25 000 live births.[99] Of all patients with a triphalangeal thumb (TPT), two-thirds have a family history of thumb abnormalities. They mostly have bilateral deformities and have non-opposable thumbs.[3] TPT can be inherited as an autosomal-dominant trait.[100] Sporadic cases are mostly unilateral and supposed to be opposable. In our series, which comprised many inherited cases, thenar muscle deficiency varied considerably. This muscle deficiency is related to the degree of opposability of the thumb.[101] In the Netherlands, the incidence of TPT is probably higher than stated in most reports, due to a number of families with an autosomal-dominant trait.

History

A thumb with three phalanges was first reported by Columbi in 1559,[75] and later by Dubois in 1826.[102] Many authors have proposed treatment ranging from nothing to extensive surgery.

Basic science/disease process

By combining family pedigrees, the inheritance pattern of TPT is as an autosomal-dominant trait.[100] The location of the gene has been discovered on chromosome 7q36 in 1994.[103]

Diagnosis/patient presentation

A wide variety of phenotypes can occur with TPT. Anatomical differences are not only restricted to the extra phalanx, therefore a thorough examination should be performed of both upper extremities.

The extra middle phalanx is a constant finding in TPT. Its shape can vary from a very small wedge-shaped extra phalanx resulting in a deviation at the IPJ to a fully developed extra phalanx resulting in a long thumb. Other features can be a near normal to very hypoplastic thenar musculature, a near normal to contracted and less deep first web, and an extra partial or fully developed ray. The thumb can be in the same plane as the other fingers with a finger-like appearance, hence the name of five-fingered hand in some of these cases.

In TPT, both IPJs are mobile. In the small wedge-shaped middle phalanx, no clinical distinction can be made in movement at the proximal or distal IPJ. When the middle phalanx is trapezoidal or rectangular, often active movement is possible at both joints.

The MPJ can be stable to very unstable; hyperextension at this joint is common. The CMCJ can vary from hypoplastic to malformed, resulting in variations from a less mobile to an unstable joint. The CMCJ can also be absent. Also the

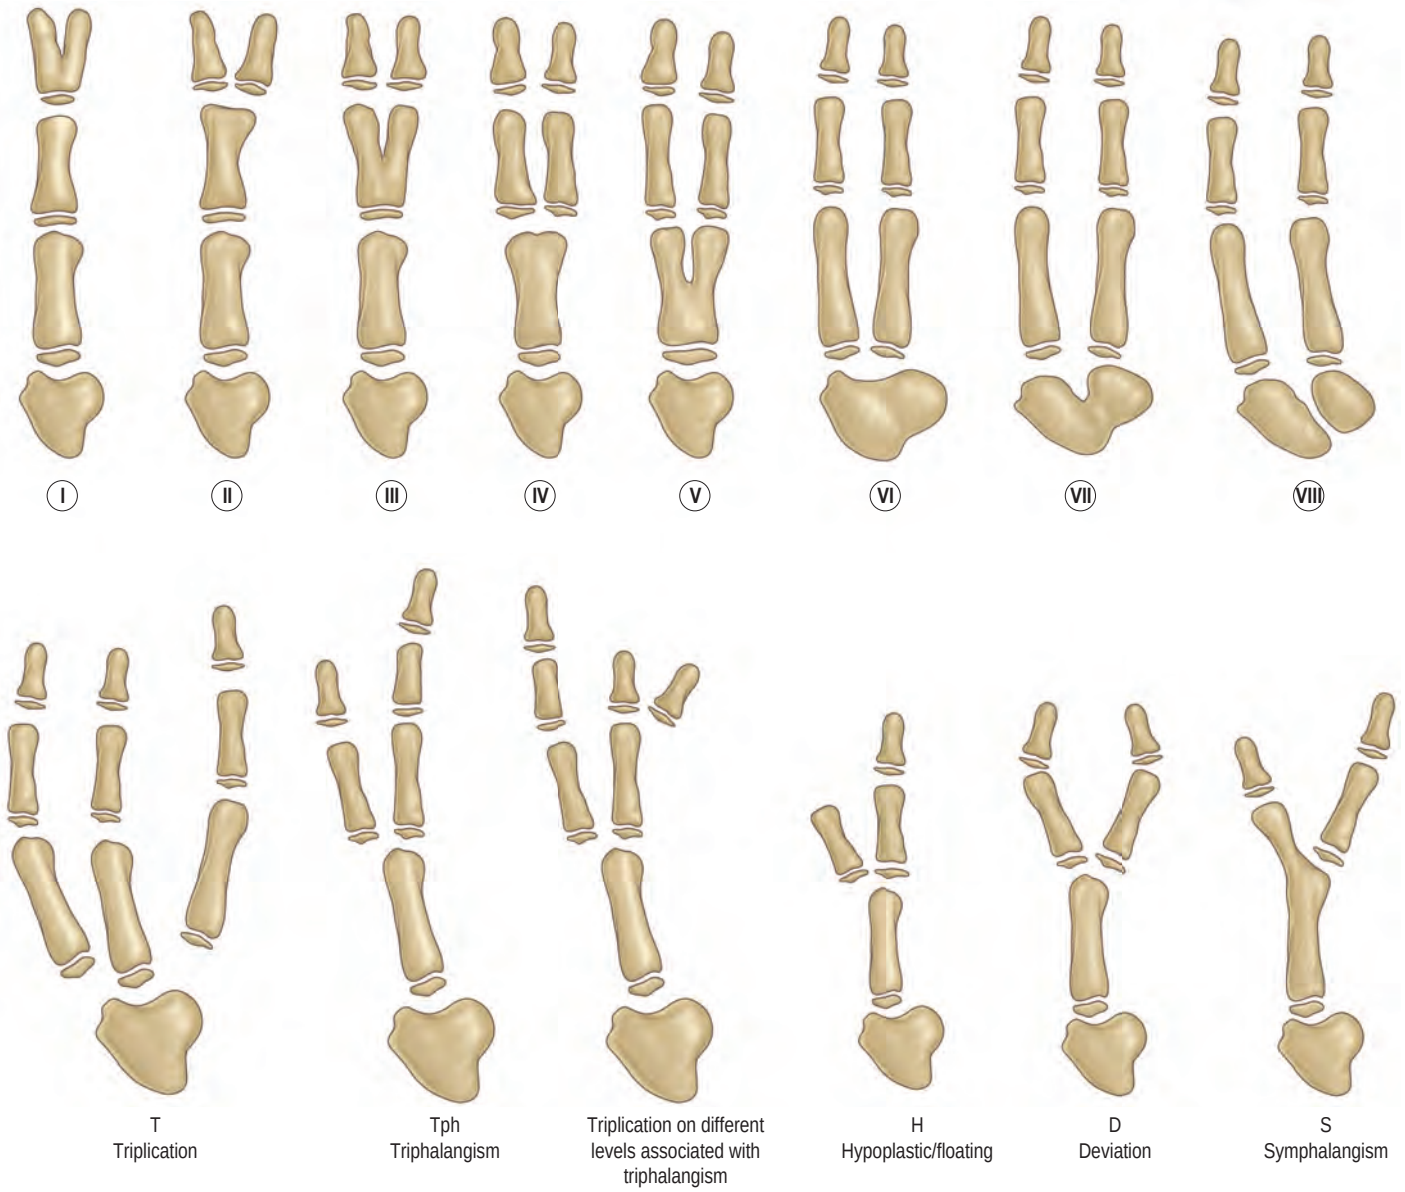

Fig. 28.17 Our radial polydactyly and triphalangeal thumb classification. *(Reproduced with permission from Zuidam JM, Selles RW, Ananta M, et al. A classification system of radial polydactyly: inclusion of triphalangeal thumb and triplication.* J Hand Surg Am. *2008;33:373–377.)*

trapezium and scaphoid can be hypoplastic, malformed, or absent.

In inherited cases, differences are often bilateral. An extra ray is common in these patients, and triplications may occur. The ulnar thumb is nearly always the best developed in cases of two thumbs.

In TPT, other malformations can also occur such as syndactyly, ulnar polydactyly, cleft hand, longitudinal radial deficiency, differences of the lower extremities, and as part of a syndrome with abnormalities in one or more of the other systems.[104–106]

The aforementioned makes classification of TPT difficult. Wood[107,108] classified TPT on the shape of the extra phalanx, distinguishing three types of an extra middle phalanx in the thumb: delta type, trapezoid type, and full rectangular type. Buck-Gramcko created a classification with six types, based on treatment options, including joint mobility, webspace, intrinsic and extrinsic muscle abnormalities. If TPT is combined with polydactyly, further classifications are possible. Wassel classified all possible combinations into Wassel VII. Our group has developed a classification for TPT combined with duplication or triplication, based on the Wassel classification in which TPT is classified according to the joint (Fig. 28.17).

Patient selection

In TPT, the patient's precision grip is impaired as a result of diminished opposition, joint instability, or additional length, leading to alternative, compensating maneuvers. If syndactyly or an extra thumb is also present, proper use of the hand is further decreased. Children may compensate easily for these drawbacks. Parents of young patients and older children with TPT, however, often want the anomaly corrected for

appearance and very rarely for functional deficits. Timing of operation is not always clear in minor defects, such as small triangular phalanges.

The authors' series includes a high number of dominant hereditary triphalangeal thumbs, with or without polydactyly. The affected parent was often intensively teased at school and therefore wished their child to be operated before going to school.

Because of the presence of cortical representation of a thumb, a hard indication to operate very early is not present, as a new learning process is not necessary. In only rare cases is a scissors grip between index and middle finger used. It is advisable to operate on these patients before the age of 2 years for early adaptation of the cortex to the newly created thumb.

Treatment/surgical technique

Bunnell[109,110] advised not to operate on TPTs. Beatson[111] and Milch,[112] among others,[113,114] proposed removal of the abnormal phalanx to reduce length and to correct deviation. After removal of the extra phalanx, the risk of an angulated joint as end result exists.[115,116] Buck-Gramcko[117] stated that resection of the delta type extra phalanx and ligament reconstruction in the young child gives adequate results in a single procedure.

For patients with a trapezoidal or rectangular extra middle phalanx, several types of osteotomies are described such as resection of the distal joint and part of the distal phalanx followed by arthrodesis[116] to excision of the PIPJ.[2] Buck-Gramcko[117] added an osteotomy of the first metacarpal with reinsertion of the intrinsic muscles and widening of the first web. If necessary, an opposition transfer was also performed.

In the "five-fingered" hand, pollicization is advised.[118] If the first web needs only minimal deepening, a four-flap Z-plasty[119] can be used. Foucher[120] described a W-transposition flap in which skin and subcutaneous tissue is used from the dorsoradial side of the proximal phalanx of the index to provide skin for the first web. A large rotation flap of the dorsum of the hand can be used in a non-opposable TPT where, in addition to deepening, lengthening of the first web is required.[117,121] In larger deficiencies of the first web, where the ray is placed in palmar abduction (such as in patients with a five-fingered hand), Upton[122] favors a distally based radial forearm fasciocutaneous flap.

An opposition transfer can be performed if hypothenar muscle deficiency exists. The most used tendon transfers for opposition transfer are the abductor digiti minimi muscle (Huber technique[123]), the superficial flexor of the ring finger,[114] and the flexor carpi ulnaris.[124]

When TPT is accompanied by radial polydactyly, Wassel[89] and Wood[115] advised extirpation of the TPT even if the other biphalangeal thumb is more rudimentary. Wood transposed the rudimentary biphalangeal thumb to the base of the metacarpal of the TPT, creating a shorter thumb. This transposition can be combined with a metacarpal osteotomy. Upton,[125] on the other hand, excises the rudimentary biphalangeal thumb, retains the triphalangeal thumb, and corrects the TPT. No clear evidence exists regarding the best technique as most published series are small.

Timing of operation differs not only for the several types of TPT but also among various authors. Buck-Gramcko[117] excises the short middle phalanx before the age of 6 years, because if the child is older, the joint does not remodel anymore. Wood,[108] on the other hand, operates between 6 months and 2 years of age.

Authors' preferred method of treatment[126]

Delta middle phalanx

In children <6 years, resection of the extra phalanx is performed under fluoroscopy control (Figs. 28.18 & 28.19). Subsequently, the radial collateral ligament at the new IPJ is released and the ulnar collateral ligament tightened. The skin is released on the radial side with a Z-plasty and adjusted on the ulnar side by excision of skin. When the child is older, a corrective osteotomy with arthrodesis at the DIPJ is advised. This latter technique can be also performed in the trapezoidal middle phalanx.

Rectangular middle phalanx and five-fingered hand

Via a Y-shaped incision dorsally a reduction osteotomy of the middle phalanx is made followed by arthrodesis of the distal interphalangeal joint. In this method, a 1–1.5 cm shortening is achieved. The skin is then closed as a "V". As the shortening is not enough, this procedure is combined with a shortening, rotation, and palmar abduction corrective osteotomy at the metacarpal level to correct for position and length of the thumb (1–1.5 cm extra shortening). Furthermore, the extensor tendons as well as the intrinsics are shortened. In recent years, a volar plate tightening at the MCPJ has been added to prevent hyperextension. Basically, this procedure resembles a pollicization. The original CMC1J, even though it is not optimal, is better and more stable than a reconstructed CMCJ in a formal pollicization. For this reason, the author does not use a formal pollicization in the five-fingered hand.

First web deficiency

Correction can mostly be performed with a simple four- or five-flap Z-plasty. When more skin is needed, a flap from the dorsoradial side of the index is used as described above. In case of polydactyly, the extra skin from the radial discarded extra thumb can be used to shift to the ulnar thumb, while the skin of the ulnar thumb is used for the first web (Fig. 28.20).

Postoperative care

For postoperative care, see the section on radial polydactyly, above.

Outcomes, prognosis, and complications

The authors' group performed a long-term follow-up of operated (40 patients, 68 hands) and non-operated patients (15 patients, 29 hands). Patients scored their function and appearance. The improvement in appearance was significant in the operated group; the improvement in function was higher but not significant. There was a trend towards a stronger thumb in the operated group; however, no opposition transfer had been performed.

Treatment of patients with TPT is not easy and often underestimated due to a lack of knowledge of possible deformities that may occur; therefore, many of these are left uncorrected. Skin problems, infection, and mal-union or non-union are

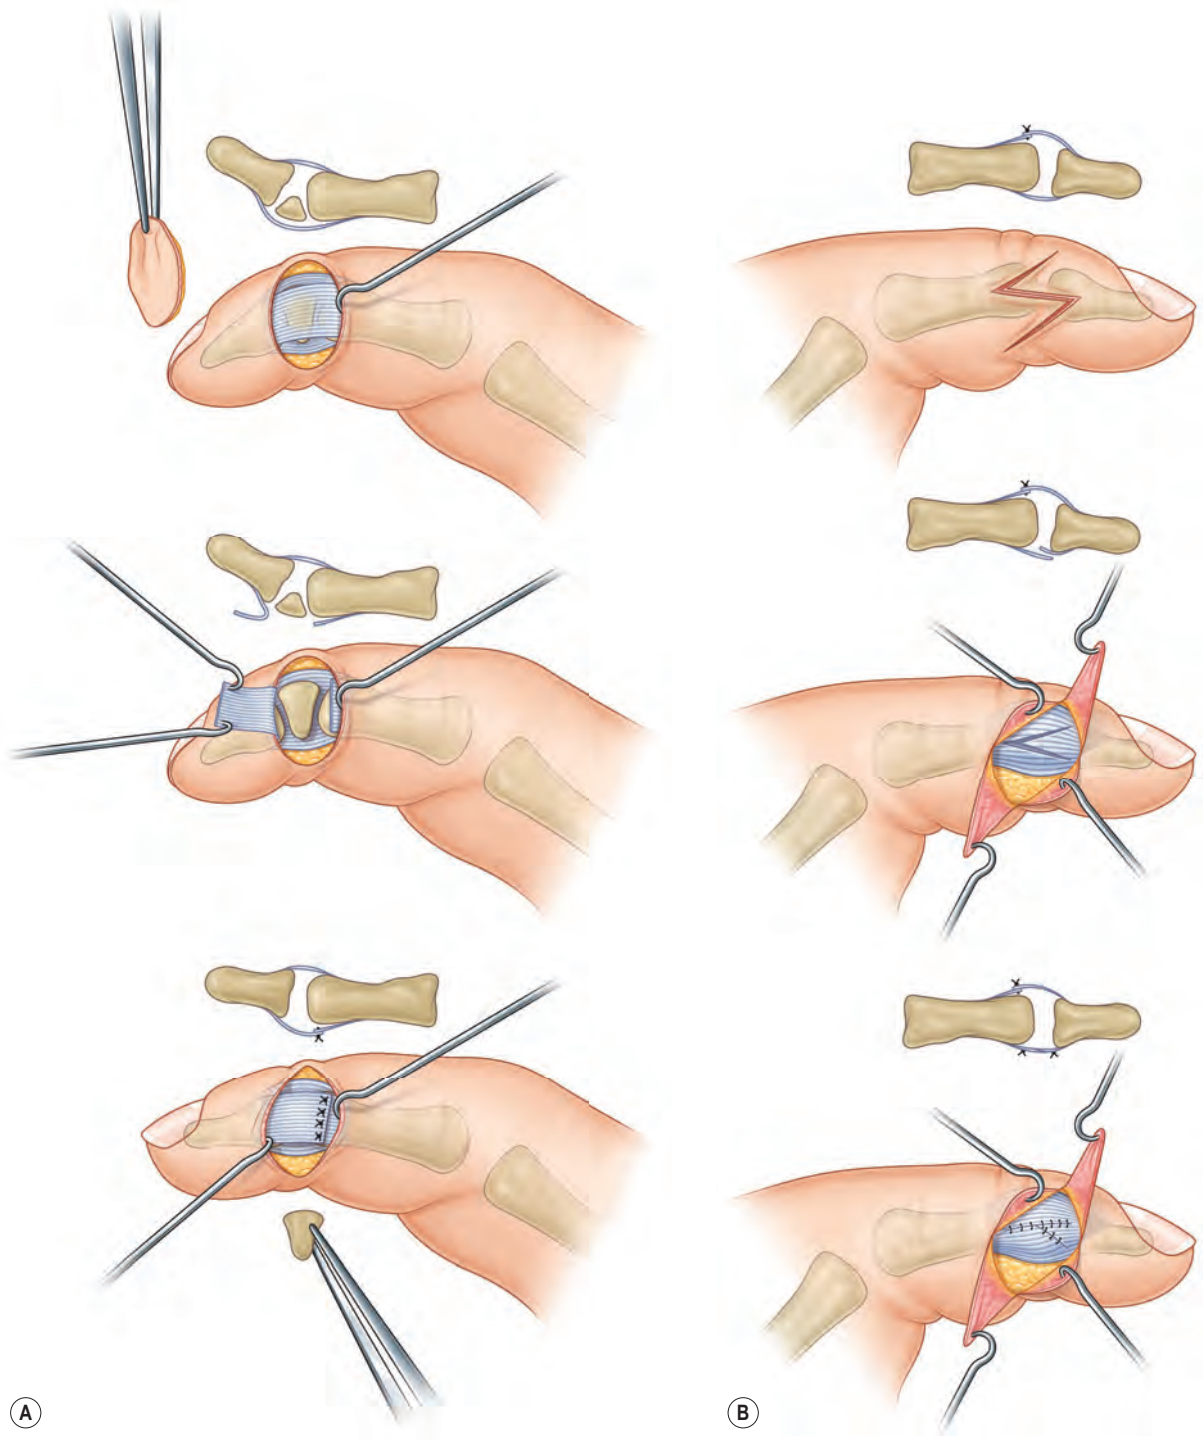

Fig. 28.18 (A,B) Operative technique of extirpation of the middle phalanx in the young child (note the skin and ligament correction on both sides).

very rare. In our experience of treating patients with TPTs, one of the problems is unpredictable growth of the thumb, especially of the first metacarpal after initial shortening. This results in longer thumbs than intended (method of measuring: thumb tip is distal to the PIPJ of the index).[127] Parents and older children should, therefore, be informed. Furthermore, the arthrodesis of the distal IPJ can give a nail deformity. The V-Y approach can avoid this when performed with caution in relation to the nail bed.

Secondary procedures

Secondary procedures that are not directly related to complications include an opposition transfer to improve opposition strength. Not many patients feel this operation is necessary. Thumb length corrections can be performed using epiphysiodesis or shortening osteotomies when growth has stopped. Occasionally, volar plate-tightening procedures are offered for hypermobile MCPJs.

Camptodactyly

Introduction

Camptodactyly is a contracture of the PIPJ in the anteroposterior direction (*campto* = arched; *dactylos* = finger). It occurs as consequence of an anatomical imbalance of the extrinsics and anomalous insertion of intrinsics to the affected finger(s). Camptodactyly can be sporadic without previous family history. Familial cases can inherit in an autosomal-dominant pattern. In about 30% of cases, camptodactyly has a familial background. This condition can furthermore be present in many syndromes such as Holt–Oram syndrome and Poland syndrome. Prevalence can vary considerable from 1–24%.[128] Camptodactyly usually stops being progressive with skeletal maturity.

History

The description of camptodactyly was first introduced by Tamplin in 1846.[129] One of his pupils, Adams, considered the skin deficiency on the palmar side as a secondary effect.[130] The term "camptodactyly" was first used by Landouzy in 1906.[131] Depending on the author, camptodactyly can either be only an isolated PIPJ flexion contracture or also include those fingers where the PIPJ cannot be actively extended but have supple joints.[132] All structures surrounding the PIPJ have been associated with the pathogenesis of camptodactyly. Attention has been drawn to an imbalance of the flexor and extensor mechanism.[133,134] Subsequently, the role of the anomalous lumbrical insertion to the superficial flexor was described as a consistent finding.[135–137] Most authors describe the bone changes of the joint and shortage of the skin as secondary to the contracture.

Basic science/disease process

As a consequence of the imbalance of flexors and extensors, flexion at the PIPJ occurs; this can lead to deformation of the intra-articular bone ends with a stiff joint as a result, and deficient skin on the palmar side. With increasing age, the extensor mechanism becomes more insufficient, leading to a further extension lag. Other mechanisms have also been described, such as circulatory disturbance, skin shortness, subcutaneous bands, lumbrical abnormality, short flexor superficialis, shortness of the flexor profundus, and retraction of the collateral ligaments and volar plate.

Diagnosis/patient presentation

The functional defect is mostly limited, and therefore appearance is mainly the concern. In severe forms however, functional deficit can be substantial, especially when more fingers are affected. The fifth finger is the most affected (>70%), followed by the fourth finger (<20%). The other fingers are involved in less than 10% of patients with camptodactyly.

Patients with camptodactyly can be divided into three groups:

1. The newborn male or female patient with camptodactyly of mostly the fifth and/or fourth finger and sometimes all fingers.
2. The adolescent, mostly female, with sudden onset or increasing camptodactyly of mostly only the fifth finger following growth spurts.
3. Severe camptodactyly associated with other malformations.[138,139] However, it is disputed by others if this group should be diagnosed as camptodactyly.[132]

Foucher *et al*.[140] recognized four conditions: (Ia) the early and stiff; (Ib) the early and correctable camptodactylies; (IIa) the late and stiff; (IIb) the late and correctable deformities. Tests to assess degree of severity of camptodactyly are as follows[140]:

1. Can the PIPJ be actively extended while the wrist is held in a neutral position?
2. Does skin blanching appear while extending the finger as much as possible at both the MPJ and PIPJ?
3. Does the PIPJ flex when the wrist and MCPJ are extended (the superficial flexor tenodesis test)?
4. Can the PIPJ extend passively by tenodesis effect while the MCPJ and wrist are held in flexion (central band or Smith test)?
5. Can the PIPJ actively extend while the MCPJ is held in slight flexion (the Bouvier maneuver)?
6. Is the flexor digitorum superficialis (FDS) of the little finger independently working from the fourth finger?

Patient selection

The best patient to operate on is the patient who has a supple PIPJ but cannot actively extend the PIPJ well. Furthermore, patients should be selected on the basis of expected compliance to hand therapy.

The older patient with a stiff PIPJ is a bad candidate for release of the PIPJ with the intention to obtain a reasonable moving PIPJ.

Treatment/surgical technique

A splint is applied for all patients with camptodactyly in which the PIPJ is not supple (Fig. 28.21). The splint stresses the PIPJ gradually to as much extension as possible. The MCPJ is in flexion in a forearm splint. A reduction to <30° extension lag is considered good enough to refrain from surgery.

The duration of splinting therapy before further surgical treatment varies from 3 to 12 months. Some authors consider an extension lag of 60° as an indication for surgery.[132]

If the splinting program demonstrates a passively improved joint without improved active extension or if the joint movement is not improved, surgery can be indicated. In the older patient, one should think twice before surgery is performed, especially when joint movement is not improved. In noncompliant patients or parents, surgery is not recommended.

A variety of operations has been proposed as the etiology is unclear. Operations range from skin plasties, arthrolysis, tenotomies, tendon transfers, and osteotomies to arthrodesis. The authors' preferred technique is based on the algorithm and description of the operative technique by Foucher.[132,140]

In the correctable PIPJ, mostly skin and fibrous bands release are performed, with exploration of the lumbrical muscle, interosseus muscles, FDS and flexor digitorum profundus (FDP). Very often, the lumbrical is anomalous together with the FDS (Fig. 28.22). If the FDS is usable, and pulling on

the lateral band gives extension to the PIPJ, an FDS tendon transfer to the lateral band will be performed.

In the non-correctable PIPJ, which improves after splinting, an extensive skin release is performed with a Malek flap (proximally based palmar homodigital flap). Subsequently, the flexor sheath just proximal from the PIPJ is opened transversely and the checkreins, accessory ligament, and if necessary the palmar plate is released creating passive extension. The intrinsics and extrinsics of the operated finger are explored and released if an anomaly is present. An FDS tendon transfer is used from the same or otherwise adjacent finger to restore active extension. The transfer is attached to either the lateral band, if sufficient, or to the central band, if the lateral band is not sufficient.[132,140]

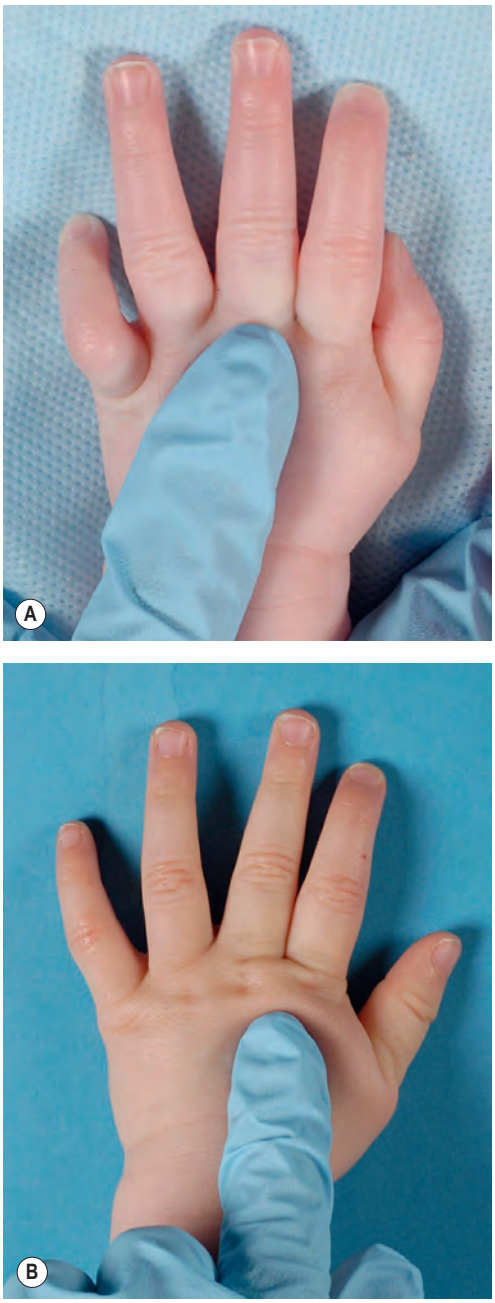

Fig. 28.21 **(A)** Note the flexed proximal interphalangeal joint of digit 5 and less of digit 4 before splinting. **(B)** After long-term night splinting.

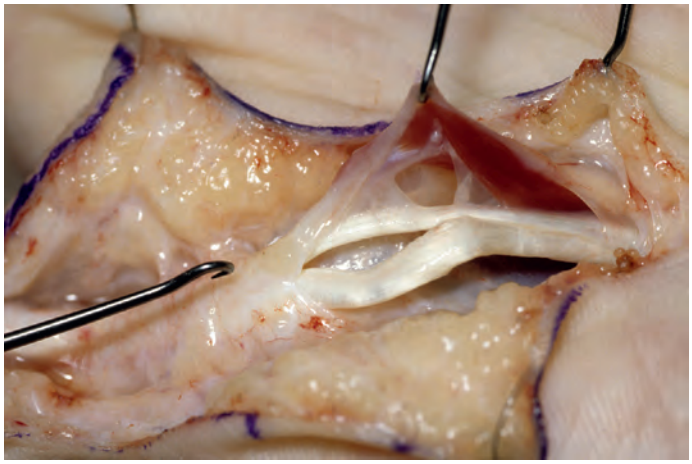

Fig. 28.22 The lumbrical muscle inserts into the flexor digitorum superficialis at the A1 pulley.

Postoperative care

Postoperative care consists of a splint, the duration of which depends on the technique used. A K-wire for 2 weeks can be used for the PIPJ following release of the joint. Compliance to hand therapy is essential.

Outcomes, prognosis, and complications

In the young child, long-term splinting during the night of the stiff PIPJ results in a good outcome, with an 80–92% improvement rate after long-term splinting.[141,142] In the Caucasian hand, these good results could not be achieved in the same way. Young children with stiff joints do react well with splinting, resulting in a mean improvement of 40° following 19 months of splinting.[139,140] The variety of operations that has been proposed inevitably results in various outcomes ranging from 14% to 35% improvement.[132,143] Because of this insufficient outcome, and even sometimes worsening of the contracture, some authors prefer to rely only on splinting.

Foucher created an algorithm in which patients presenting late with a stiff joint are not operated. In all other patients, splints were applied. If no satisfactory improvement in extension was present, surgery was performed resulting in improvement rates from 68% to 88%, depending upon whether or not the joint was passively correctable.[140] Complications can include: insufficient possibility to extend the PIPJ after surgical treatment, osteoarthritis, recurrence of contracture, and stiffness and pain.

Secondary procedures

Secondary procedures include: re-release of capsular contracture, corrective osteotomy, or formal PIPJ arthrodesis.

Clinodactyly

Introduction

Clinodactyly is reserved for radioulnar deviations in the hand and lateromedial deviations in the foot. The angle of deviation defining clinodactyly varies among authors from >8° to

>15°.[144,145] Clinodactyly is a symptom and not a disease. It may be isolated or may be associated with other congenital malformations, such as in Down syndrome or Apert syndrome. Burke described 25 syndromes associated with clinodactyly.[146] The incidence varies from 1–19.5%, depending on the degree of angulation used to determine clinodactyly.[147] Depending on the inclusion criteria, different groups can be distinguished: familial clinodactyly usually without associated differences (brachymesophalangism); clinodactyly with associated malformations; asymmetric injury to the growth plate; and triphalangeal thumb.

Brachymesophalangism is the most frequently encountered form of clinodactyly. It is the result of an articular surface that is not perpendicular to the longitudinal axis due to the abnormally shaped bone. The phalanx looks like a delta phalanx without the osseous rim as in the delta phalanx with a C-shaped epiphysis. The middle to distal phalanx ratio is 1:1, compared with 1.3:1 in normal fingers.[148]

Second, an aberrant growth plate surrounding one side of the delta phalanx in a "C" shape results in deviation at the involved joint(s). Other names for delta phalanx are triangular bone and longitudinally bracketed epiphysis.[149–151] Reports suggest that anomalies with a delta phalanx should be clearly distinguished from the classical clinodactyly.[152] As it is not clear, the authors would reserve clinodactyly for a congenital difference with or without a C-shaped epiphysis. Angulations after injury to the growth plate in an otherwise normal finger or a deviation in a joint following syndactyly release are secondary conditions.

History

Early reports exist on curvatures in the finger in the dorsopalmar plane.[153] Clinodactyly, however, refers to an angulation in the radioulnar plane. Smith described the condition in mongolism in 1896.[146] As clinodactyly is a physical sign, defining this group is difficult and has been variably described over the past century.

Basic science/disease process

Clinodactyly is considered to be a congenital deformity at the phalangeal level. The mode of inheritance of clinodactyly is as an autosomal-dominant trait with incomplete penetrance.[154] The middle phalanx is ossified later in embryonic development than the other phalanges, and latest in the little finger. Brachyphalangism therefore appears most in the little finger.[155] In proximal phalanges, however, aberrant growth plates also occur resulting in clinodactyly and brachyphalangism, and often in selected fingers. The exact etiology is still unknown.

Diagnosis/patient presentation

The most common form of clinodactyly is seen in the middle phalanx of the little finger presenting with an inward deviation of more than 10°. A positive family history in these patients is frequent. These little fingers mostly do not scissor over or under the ring finger, making this deformity more an aesthetic than a functional problem. Scissoring can also be prevented by abducting the little finger in the MCPJ. The deviation is clinically not only visible at the PIPJ but also at the DIPJ.

Fig. 28.23 Clinodactyly of the thumb.

The thumb is next in line in frequency of occurrence (Fig. 28.23). The thumb can be an isolated occurrence or as part of a syndrome. The angle of deviation can amount to 70°. In Apert syndrome, the thumb can be severely deviated. The fingers are less involved and, in most series, the least affected is the long finger. More than one digit can be affected. Over half of the patients present with a delta phalanx. As a considerable number of patients present with clinodactyly after epiphyseal closure, the presence of a delta phalanx is difficult to assess radiologically. X-rays of both hands and affected fingers in two directions are a prerequisite in making the diagnosis.

Patient selection

Clinodactyly in the little finger without scissoring is not often treated operatively because of the risk of impairing joint motion in a normal functioning finger. In those patients where function is impaired, an indication to operate can exist. In a more severe deviation with a longitudinally bracketed epiphysis, age of surgery depends on the technique. Resection of the lateral physis with interposition of fat is performed at a younger age than a formal wedge osteotomy with or without bone graft. In syndromic clinodactyly, correction of clinodactyly depends very much on the associated abnormalities.

Treatment/surgical technique

Treatment for clinodactyly can be divided into the following procedures:

- Opening wedge osteotomy with or without bone graft
- Closing wedge osteotomy
- Reversed wedge osteotomy
- Release of soft tissues on the concave side

- Tightening of soft tissues on the convex side
- Physiolysis.

Although a closing wedge osteotomy is advised for moderate and severe deviations (>30°),[156] the authors are not in favor of using this technique, as the affected finger will be further shortened.[157] An open wedge osteotomy lengthens the digit the most and is preferred. In the more severe deviations, however, bone correction only will not be enough. Release of soft tissue (collateral ligaments and the skin) on the contracted side is also necessary. The thenar musculature at its insertion in the radially deviated thumb should also be released, otherwise recurrence is inevitable. Tightening of soft-tissue structures, especially collateral ligaments on the convex side, can also be useful.

In the less severe deviations, a reverse wedge osteotomy works well but is technically more demanding (Fig. 28.24). The advantage of the reverse wedge is that no other donor site is necessary. In the open wedge technique and in the reverse wedge technique, the graft is transfixed with a percutaneous K-wire either with or without a suture to hold the bone graft in position.

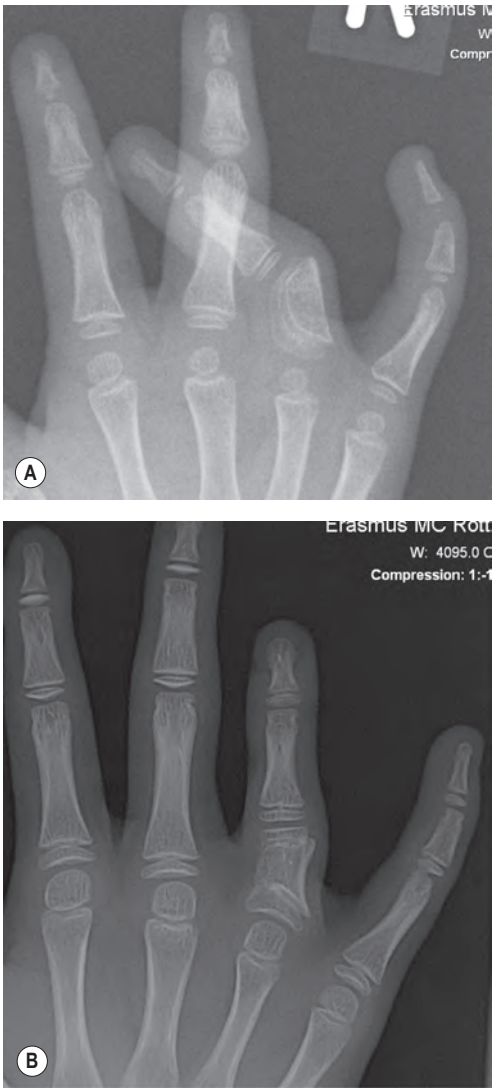

Fig. 28.24 **(A)** Reversed wedge osteotomy of the ring finger preoperatively and **(B)** postoperatively, the wedge is placed at the radial side of the proximal phalanx.

In 1987, Vickers described a new technique by excising the continuous region of the physis and diaphysis in the isthmic region of the middle phalanx via a lateral incision. The bone is further removed in this region with a burr or curette. The remaining cavity is filled with a fat graft. This operation is called physiolysis and works well in younger children (under the age of 6 years), with less severe clinodactyly, and a trapezoidal phalanx.[158,159]

Postoperative care

In the physiolysis technique, the operated finger can be taped to the adjacent finger for approximately 2 weeks. In the closing wedge technique, 3 weeks of immobilization is enough. In the reverse and open wedge osteotomies, also depending on the soft-tissue correction, 4–6 weeks immobilization is often carried out.

Outcomes, prognosis, and complications

Reversed wedge osteotomies normally heal well. Slight angulations in the dorsal–palmar plane following surgery mostly disappear during growth. In open wedge osteotomies, skin and ligament release can be insufficient, leading to skin tightness and recurrence of angulation. In physiolysis, results in children over 5 years are not as good as in younger children. Furthermore, it works well in less severe clinodactylies.

Complications of the bone can be mal-union or malrotation. Non-union in children is very rare. Even if the X-ray demonstrates a non-consolidated osteotomy, the fibrous tissue bridging the two parts can prevent movement, and will have no clinical implications. Furthermore, extensor tendon adhesions can result in a mallet-like deformity. In some cases, stiffness of joints can occur. Pain is rarely an issue.

Secondary procedures

Secondary procedures mainly address recurrence of the deviation either by insufficient release or excision of the physis or by inadequate soft-tissue release. A new osteotomy and soft-tissue release can be performed.

Future directions

The OMT classification

When classifying congenital hand and upper limb differences, the Oberg, Manske, Tonkin (OMT) classification is used. This classification was first introduced in 2010,[160] and was approved by the Scientific Committee for Congenital Conditions of the International Federation of Societies for Surgery of the Hand (IFSSH)[161] to substitute the Swanson classification.[162] Since 2010, the OMT classification has been subject to assessments with subsequent modifications, the last being published in 2015.[163] At this moment, the OMT classification is still a flexible and fluid classification, adapting to new developments and additional conditions.

The OMT classification is designed to accommodate the current knowledge of limb embryogenesis, classifying congenital hand and upper limb differences in one of three groups: malformations, deformations and dysplasia (Fig. 28.25). The malformations group comprises the most

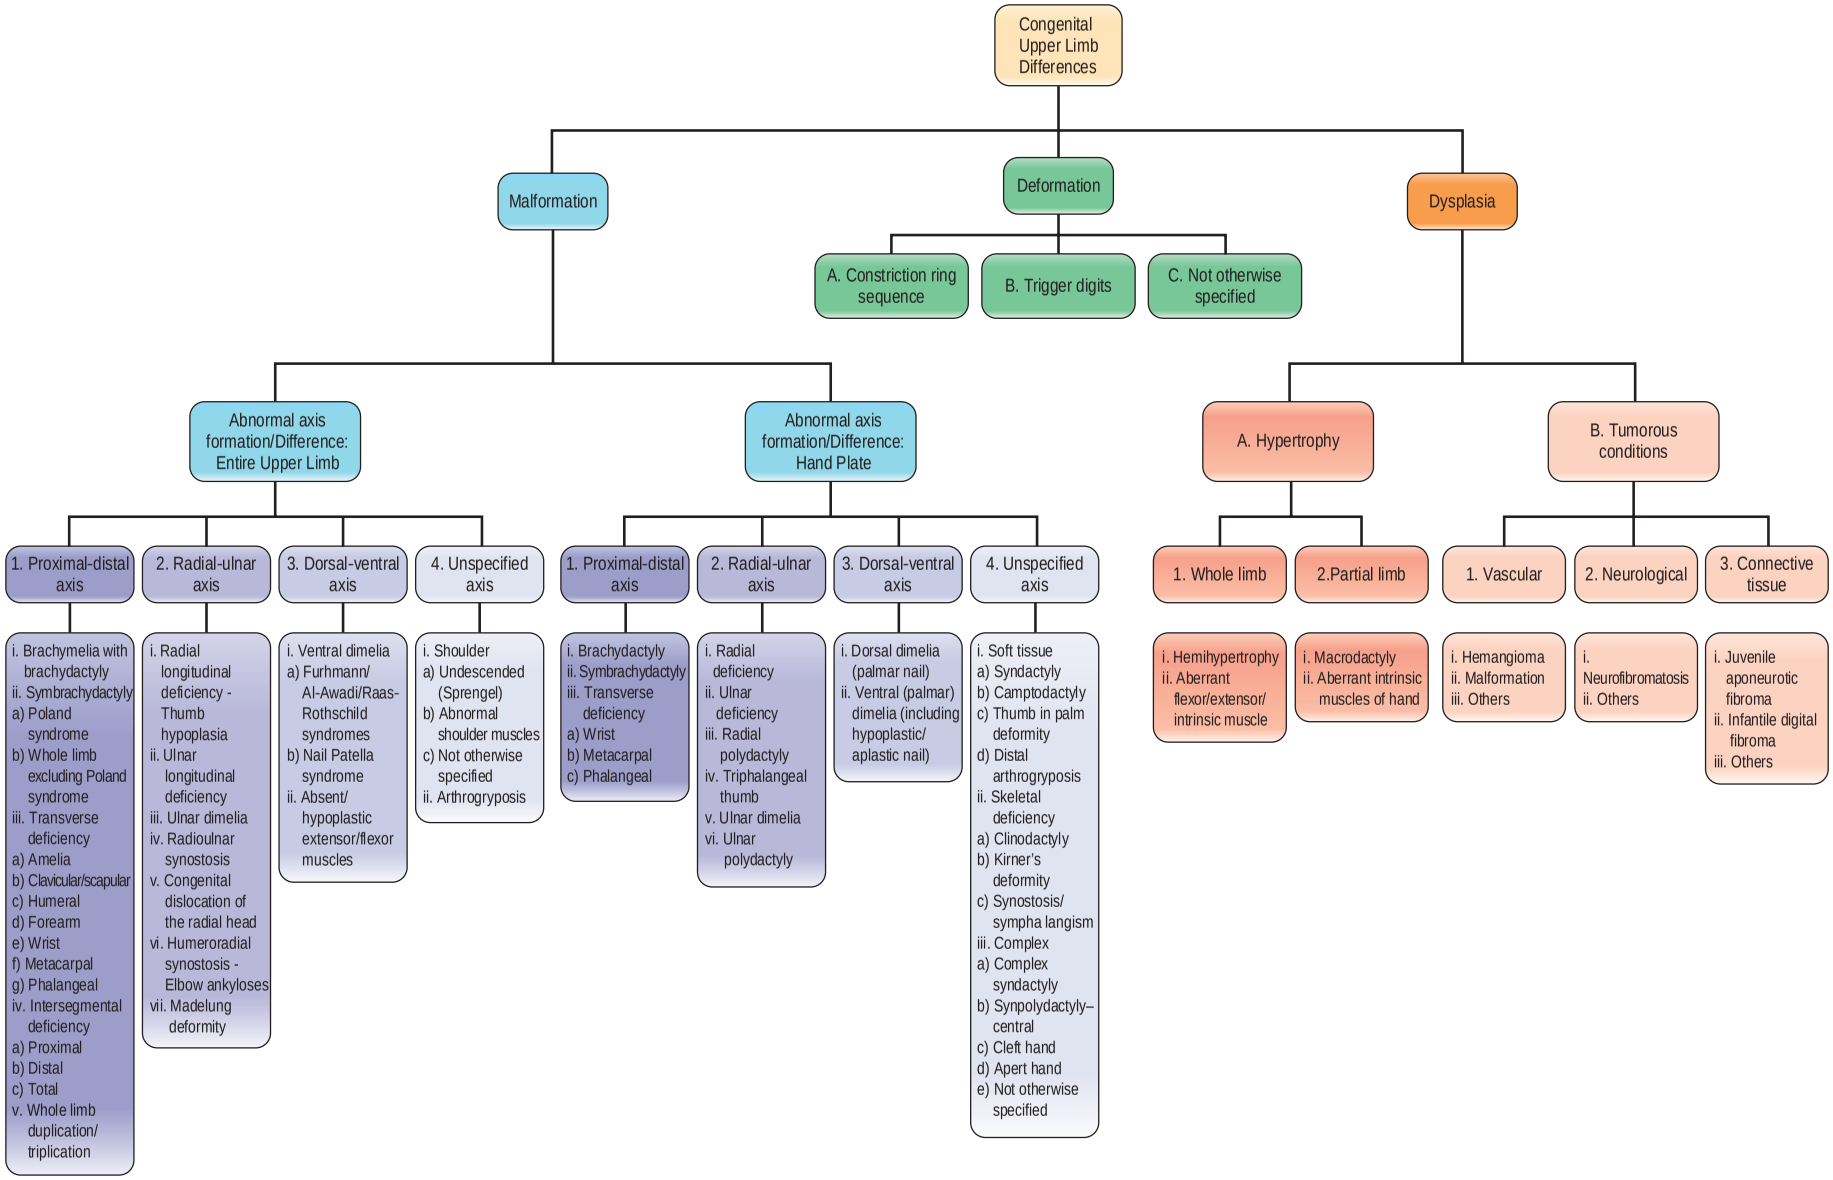

Fig. 28.25 Oberg, Manske, and Tonkin (OMT) classification. *(Reproduced with permission from Oberg KC, Feenstra JM, Manske PR, Tonkin MA. Developmental biology and classification of congenital anomalies of the hand and upper extremity.* J Hand Surg Am. *2010;35:2066–76; and Ezaki M, Baek GH, Horii E, et al. IFSSH Scientific Committee on Congenital Conditions.* J Hand Surg Eur Vol. *2014;39:676–8.)*

diagnoses (74–90% of total in several analyses) and is further divided according the involvement of the whole limb or the hand plate alone. These two groups are subdivided according the three axis of limb development (i.e. proximal–distal, radial–ulnar, dorsal–ventral) and an additional unspecified axis. The deformations group is subdivided into: constriction ring sequence, trigger digits, and not otherwise specified; the dysplasia group is subdivided into hyperplasia and tumorous conditions, with further subdivision (see Fig. 28.25). Additionally, if a syndrome is present with a congenital upper limb difference, this will be cross-referenced according to a list of syndromes that can be or are accompanied with a syndrome.

As yet we do not have a full understanding of the basis of all differences at the level of cell signaling and molecular pathways, but as this becomes clearer, its incorporation into the classification is possible, giving a fuller categorization of congenital hand and upper limb differences. With regard to this changing knowledge, the IFSSH Scientific Committee for Congenital Conditions has been advised to review and improve the OMT classification every 3 years.

With regard to future obligations regarding patient-related outcome measures, the OMT classification can form the basis of classifying the subjects researched. It is therefore important that the most recent OMT classification is used when presenting data on outcome. Furthermore, with the Patient Reported Outcome Measurement (PROM) getting a lead in reporting quality of care and outcome of healthcare providers for research purposes or in evaluating healthcare by insurance companies, outcome measures for congenital hand and upper limb malformations should be formalized and incorporated by the teams treating them. At this moment, an outcome set specifically for congenital hand an upper limb differences is being formulated and will be evaluated globally by congenital hand teams with incorporation of this outcome set in daily practice as an ultimate goal.

Postoperative regime

With regard to changes in insight and the will to improve healthcare, with minimal stress for the patient and their parents as a goal, we have introduced a different regime of postoperative bandage in our clinic. With the phases of wound healing in our mind, we decided to treat our patients postoperatively with a bandage that would stay put for 6 weeks. In this period, complete wound healing takes place for regular wounds and skin grafts. Furthermore, the best moment for taking care to achieve an ultimate position of the fingers and hand after reconstruction in the bandage is at the time the patient is under general anesthesia. With respect to the debate on children and general anesthesia, our goal is to minimize the number of operations and duration of an operation. Because of this combination, we decided to have the bandage removed after approximately 6 weeks and start hand therapy according to a regular schedule. Parents receive information about alarm signals regarding the bandage, as is given with the regular shorter bandage regimes. Preliminary data of the last 5 years show far fewer infections with the new regime, with fewer prescriptions of antibiotics. An additional advantage to this regime is the number of bandage changes the patient is subjected to: instead of daily changes after 2 weeks until 6 weeks after the operation, this is decreased to only one after 6 weeks. This decreases the stress for the patient and parents in a period where bonding between the both is important. Because of this outcome, we introduced this regime as a standard practice, fitting our ideas on wound healing, anesthesia, psychology, and logistics of our outpatient clinic.

Congenital hand V: Overgrowth, undergrowth, and generalized skeletal deformities

Julie Colantoni Woodside, Shelley Noland, and Terry Light

SYNOPSIS

- Contemporary understanding of limb embryology and morphologic characteristics has shaped the Oberg–Manske–Tonkin (OMT) classification of upper extremity anomalies. The OMT classification categorizes congenital upper extremity anomalies as malformation, deformation, or dysplasia.
- Undergrowth of the upper extremity affects a portion of or the entire extremity. Variable presentations include hypoplasia or aplasia of bone and soft tissue. These may be associated with a syndrome.
- Overgrowth includes syndromes as well as isolated conditions of enlargement such as macrodactyly. The presentation and natural history of macrodactyly in the upper limb varies greatly. Treatment by debulking or amputation may require sequential procedures to balance growth, appearance, and function.
- Generalized skeletal anomalies of the hand include conditions such as multiple hereditary osteochondromas, Maffucci syndrome, and Ollier disease. Treatment of skeletal abnormalities of the hand and forearm requires accurate diagnosis and careful monitoring during years of rapid skeletal growth. Surgical intervention is indicated to preserve joint motion.

Classification

Historically, the Swanson classification, accepted by the International Federation of Societies for Surgery of the Hand (IFSSH) in 1974 has been the most widely used classification for congenital abnormalities of the upper limb.[1] A new classification system, developed by Oberg, Manske, and Tonkin (OMT)[2] is based on a more contemporary understanding of developmental biology. The OMT system uses dysmorphologic descriptions and the three axes of the limb development to classify conditions based on their effect on the hand plate and/or the entire limb. The IFSSH adopted this classification with some modifications in 2014[3] (see Chapter 25 and Table 25.2 for most recent update).

The OMT classification categorizes abnormalities as malformations, deformations, or dysplasias. Malformations are further divided into the developmental axis (proximal–distal, anteroposterior, and dorsal–ventral) and the extent of involvement as either affecting the entire limb or simply the hand. Deformations include any disruption to a portion of the upper limb that has already been formed. Dysplasias are abnormalities in size, shape, and organization of cells including conditions that are associated with cellular atypia or tumor formation.[2] The intra-observer reliability of the classification system is 85–99% with perfect agreement in inter-observer reliability of 64%, moderate of 19%, fair of 3%, and slights of 13%, and poor of 1%. Undergrowth conditions and brachydactyly show poor agreement, while arthrogryposis, Madelung deformity, and symbrachydactyly show slight agreement.[4]

Overgrowth

Introduction

Congenital limb enlargement and overgrowth is a rare condition affecting 1/100 000 live births.[5] The natural history and presentation of overgrowth conditions such as macrodactyly varies greatly. Upper extremity overgrowth can be associated with several syndromes including Beckwith–Wiedemann, Proteus, and CLOVES.[6] The diagnosis and understanding of these conditions has advanced in recent years with genetic sequencing of involved tissues. Mutations in the *PIK3CA* gene are associated with overgrowth of fibroadipose tissue. Segmental and progressive growth of the subcutaneous, muscular, neural, and skeletal tissues can be found in tissues with the *PIK3CA* gene mutation.[7]

Keppler-Noreuil *et al.*[7] studied 35 patients with overgrowth and found 25 had phenotypes consistent with fibroadipose overgrowth, hemihyperplasia, multiple lipomatosis, or macrodactyly. Thirty-three of 35 demonstrated one of two genotype mutations. All of these patients had progressive,

asymmetric overgrowth. Six had upper extremity manifestations. The distal aspect of the limb was often the first to area to manifest overgrowth; proximal progression of enlargement could develop with further growth. Sixty percent (21/35) of cases were unilateral, 42% had renal abnormalities, and all patients showed adipose dysregulation. In the patients with hand manifestations, all had surgery, none had ovarian/testicular manifestations, one had an enlarged kidney (this patient had global, bilateral presentation), one had a congenital heart defect, and four had vascular malformations.[7] Overall weight and height were normal except in three patients whose height was less than fifth percentile.[7]

Neurofibromatosis may also present with overgrowth in which the skin and subcutaneous tissue planes are enlarged by soft-tissue neurofibromas, schwannomas, and other nerve sheath tumors.[8]

Proteus syndrome has a variety of soft-tissue and skeletal abnormalities in addition to overgrowth of the hands or feet. These patients have cerebriform, hyperkeratotic skin on their palms and soles. They may develop cartilaginous masses, joint stiffness (flexion contracture), angulation, and rotational deformities in the hands. This is a progressive overgrowth in which all tissues are larger than normal without adipose infiltration.[8]

Patients with hemihypertrophy present after birth with enlargement of one extremity, or one side of the body. The hands usually have a flexed wrist with ulnar deviation of the digits and a flexed, adducted thumb. The muscle–tendon groups do not have normal excursion and progressive contractures are seen with growth of the limb.[8]

Klippel–Trénaunay syndrome is associated with a slow-flow vascular lesion that contains capillaries, veins, and/or lymphatic components, with enlarged hands or extremities due to skeletal, adipose, and vascular growth.[8]

CLOVE syndrome includes capillary malformations, lipomatous overgrowth, vascular malformations, epidermal nevi, and skeletal distortions with central nervous system components.

Other syndromes including Maffucci syndrome and Ollier disease show enlargements due to vascular malformations and enchondromas.[8]

To delineate these overlapping overgrowth disorders associated with similar genetic mutations, Keppler-Noreuil *et al.* reported the collaboration of several clinicians that outlined specific characterization of disease for management and prognosis.[6] All cases of *PIK3CA*-related overgrowth spectrum (PROS) are sporadic, with mosaic distribution of involved tissues. The condition may be evident at birth or may be detected in early childhood presentation. Children may either have isolated findings or a spectrum of features. Most, but not all, are progressive. The authors stress that although these are distinct clinical disorders, there is still much overlap in PROS.[6]

Macrodactyly

Macrodactyly describes the overgrowth of bony and fibroadipose tissue, often in a pattern that mimics a local nerve. Muscular overgrowth may be associated with macrodactyly.[9,10] Macrodactyly is sporadic unilateral 90% of the time, and not associated with malignant transformation.[10] Rios *et al.*[10] genetically sequenced and histologically examined specimens from macrodactylous tissue (n=6) and confirmed mutations in the *PI3K* gene. The rate of growth, location, and the severity should be evaluated on an individual patient basis.[11] Four types of macrodactyly have been defined by Upton (Table 29.1).[12]

Table 29.1 Types of macrodactyly

Type	Description
I	Macrodactyly with lipofibromatosis of a nerve, static or progressive
II	Macrodactyly associated with neurofibromatosis
III	Macrodactyly associated hyperostosis
IV	Macrodactyly associated hemihypertrophy

(Reproduced with permission from Upton J. Mathes SJ, Hentz VR (eds). Failure of Differentiation and Overgrowth. In: *Plastic Surgery*, 2nd edn. Philadelphia, PA: Saunders; 2005.)

The clinical presentation varies with each patient. The hand may show overgrowth with excessive adipose formation. Affected digits often deviate away from each other due to asymmetric over growth in the adjacent sides of adjacent digits (Fig. 29.1). Overgrowth in the palm and forearm is often apparent as well as fat deposits extending up to the axilla and chest wall.[8] Excessive adipose tissue, commonly seen along the median nerve in the hand (nerve territory-oriented macrodactyly)[9] usually requires multiple debulking surgical procedures, epiphysiodesis of the phalanges, osteotomy, arthrodesis, and/or amputation of hypertrophic digits. Neural elements are often enlarged along the palmar aspect of the hand.[9] In contrast, the vessels are usually of normal or smaller size.[10]

Macrodactyly can be static or progressive. The static type shows enlargement at birth with proportional growth as the child grows. *Macrodystrophia lipomatosa* refers to the progressive form of macrodactyly with associated osseous and

Fig. 29.1 This pediatric patient with macrodactyly shows an enlarged middle and slightly enlarged index finger with middle finger deviation away from the index finger. *(Courtesy of OrthoCarolina Hand Fellowship Teaching File.)*

Fig. 29.2 A 14-month-old male patient with congenital, progressive macrodactyly.

adipose overgrowth. Occasionally, the overgrowth appears static in the distal aspect of the extremity but progresses proximally. This progression may follow surgical debulking or partial amputation.[9] Timing of surgery differs between the two types. Reduction surgeries and epiphysiodesis are performed later in the static type and outcomes are more predictable. Patients with the progressive form may require earlier and repeat surgeries, while patients with unrestricted, progressive growth may require amputations of large bulky parts (Figs. 29.2 & 29.3A–E).[8]

Skeletal components can demonstrate increase in length, width, and girth. Involved epiphyses can show asymmetry and accelerated growth. Premature osteoarthritis is common in the affected by the third decade.[8] Standard radiographs of macrodystrophia lipomatosa show osseous and soft-tissue overgrowth with splayed, broad, elongated phalanges and secondary degenerative joint disease.[9,13,14]

Magnetic resonance imaging of the affected area may show deposits of fat within the nerve sheath, bone marrow, periosteum, muscles, and subcutaneous tissues, with fatty tissue masses and proportional enlargement of mesenchymal tissues.[13,15] The fatty masses are hyperintense on T1 images and have a lower signal on T2 images.

Though reports vary, there appears to be a relationship between fibrolipomatous hamartoma of nerve and macrodystrophia lipomatosa.[16,17] Histological analysis shows abnormal fatty tissue interspersed with nerve bundles with endoneural and perineural fibrosis.[16,18] The perineurium in macrodactyly is thickened and the number of myelinated axons is reduced.[10] Swollen, dissociated Schwann cells, interstitial fat, and dense endoneural connective tissue are frequent findings.[10] Because the nerves in the palm are enlarged compressive neuropathies are common. If this compressive neuropathy is unrecognized the patient may develop altered sensory function.[8]

Treatment

Treatment of patients with overgrowth conditions is patient specific and attempts to address both function and appearance. Surgical planning should consider patient age, clinical syndrome, severity, progression, deformity, function, range of motion, and the expectations of the patient and family

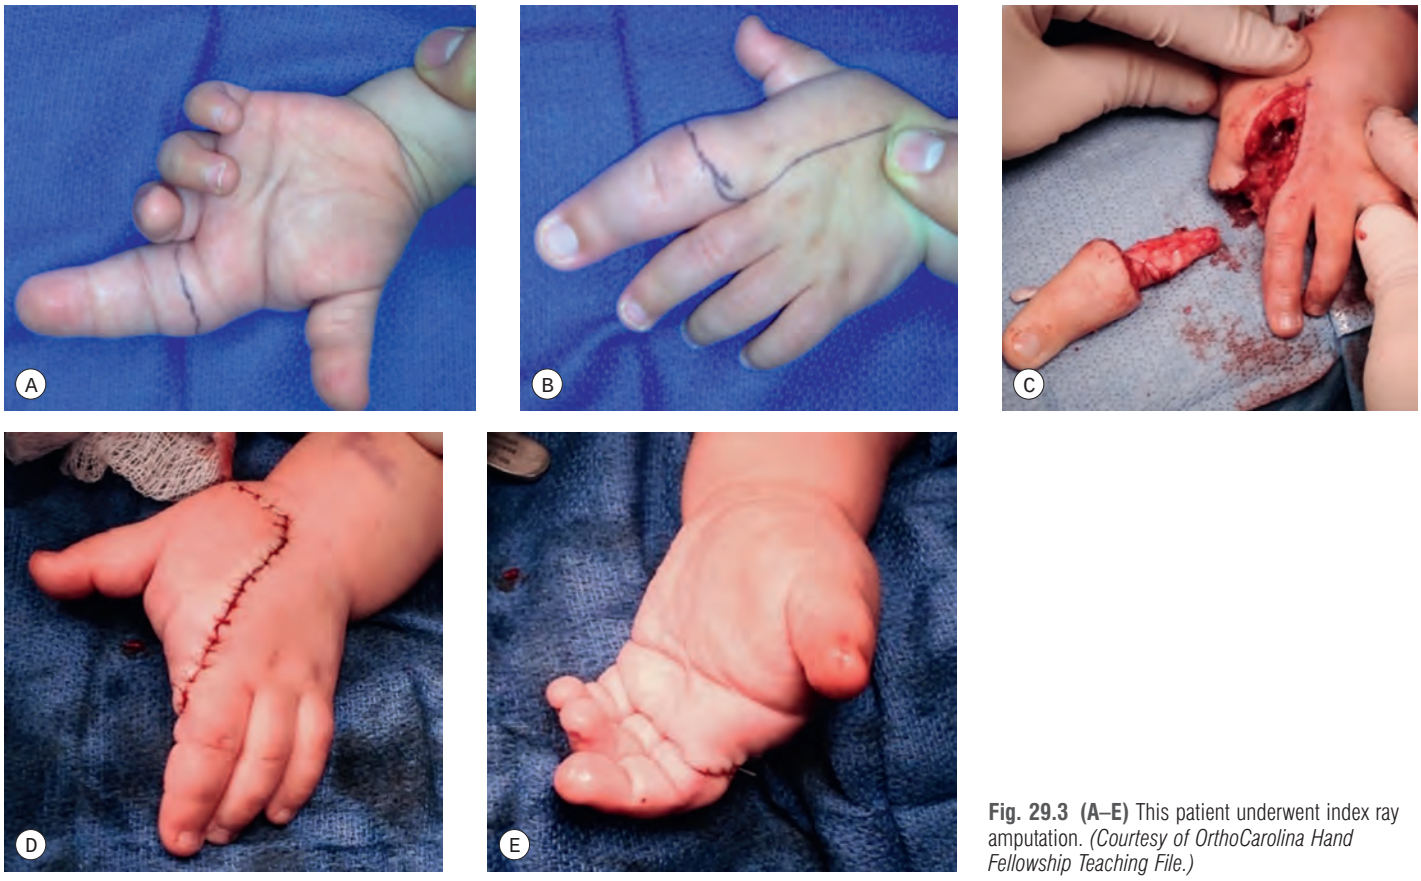

Fig. 29.3 (A–E) This patient underwent index ray amputation. *(Courtesy of OrthoCarolina Hand Fellowship Teaching File.)*

members. Discussions with the family should include arthritis and stiffness, recurrence, and the possibility of multiple procedures. Serial radiographs demonstrate the extent of deformity and progression while magnetic resonance imaging (MRI) scans demonstrate other abnormalities that may be present. Timing for procedures is patient specific. Epiphysiolysis should be considered when the digit or hand reaches the size of one of the adult parents. Other surgeries include debulking, osteotomies, and neuroplasty. Amputation is considered early in very aggressive cases or when reconstruction may not provide optimal outcomes.[8]

Surgical incision placement is important, as volar scars can lead to hypertrophy and contracture. Midaxial incisions are preferable as they can be used at revision surgeries. Palmar incisions distal to the carpal tunnel should be in zig-zag configuration. Only one side of a digit should be worked on at a time for the prevention of vascular compromise. Arterial segments can be reconstructed with vein grafts as needed to preserve blood flow. Care should be taken to preserve sensation, especially on the ulnar thumb and radial index finger for pinch.[8]

Digit salvage may be possible through soft-tissue and skeletal reduction surgeries. Growth arrest will halt longitudinal growth of the digit and can be accomplished through use of a drill, an osteotome, or a burr to destroy the physis. Physeal stapling is potentially reversible and in selected instances may allow gradual correction of angular deformity. Soft-tissue debulking should be thorough with preservation of digital arteries and at least two dorsal veins per digit. Precise surgical techniques are important for salvage of vincular branches to the flexor tendons and to perform neuroplasty and pulp reduction. The remaining skin will be reinnervated from the remaining digital nerve[8] (Figs. 29.4–29.10).

Historically, a number of strategies have been advocated for the surgical management of macrodactyly. Barsky reduced the longitudinal axis through resection of the distal portion of the middle phalanx, distal interphalangeal joint (DIP) and distal phalangeal physis with sacrifice of the often relatively stiff DIP joint motion.[19] The author also described stapling or wiring of the epiphyseal plate and concluded that results from surgery are not entirely satisfactory. Tsuge described resection of all three physes of the phalanges combined with tip-plasty.[20] Hoshi shortened the digit through resection of the DIP joint with fusion and unilateral longitudinal soft-tissue wedge resection. Millesi described a resection of the distal phalanx of the thumb with shortening of the proximal phalanx through an oblique shortening osteotomy.[21] Ogino described a resection osteotomy of the proximal phalanx, osteotomy with fusion of the DIP joint and tip and unilateral soft-tissue resection.[22] Bertelli performed longitudinal resection osteotomies of the distal, middle, and proximal phalanges with tip and unilateral soft-tissue resection.[23]

Outcomes

Cerrato *et al.*[11] evaluated 21 patients with isolated macrodactyly of one or more digits. Right hand involvement was seen in 67%, progressive overgrowth in 67%, and nerve-territory orientation in 57% (the others with lipomatous forms). The territory affected in 10 out of the 12 nerve-territory orientation patients was in the median nerve distribution. Enlarged nerves were seen intraoperatively in all nerve-oriented and lipomatous patients. The most common finger involved was the middle finger (67%) followed by the index finger (47%). Those with progressive overgrowth underwent more surgeries: 4.1 versus 1.8 per patient. Nearly all patients (19/21) underwent soft-tissue debulking, with other procedures including closing wedge osteotomies (11 patients), partial amputation/ostectomy (9 patients), epiphysiodesis (7 patients), and ray amputations (6 patients). Other associated procedures included neuroplasties of median, ulnar, and radial nerves and syndactyly release. Closing wedge osteotomy was employed for angulation greater than 30° or for correction

of digital scissoring. The authors recommend epiphysiodesis when the affected digits reached the adult length of their parents' hands.

Hardwicke *et al.*[24] reviewed 32 patients with macrodactyly, 20 affecting the upper limb. There was a slight male predominance in their series (male:female = 1:0.66). The authors found the middle ray affected most frequently with an average of 2.5 digits affected, usually adjacent. Six of 20 cases were progressive; 16 of the 20 cases were treated surgically. Patients underwent an average of 2.5 surgeries with static disease requiring fewer surgeries.

Overview

Overgrowth conditions can be associated with syndromes or can be isolated, as in macrodactyly. Patients have varied presentations and should have an individual approach for treatment options. Progressive overgrowth requires a more aggressive approach and will require more surgeries than static conditions.

Clinical tips

Overgrowth

- Macrodactyly may be associated with an overgrowth syndrome.
- Can be static or progressive – each patient needs an individual treatment approach.
- Progressive types require a more aggressive approach and more surgeries than static types.

Undergrowth

Introduction

Congenital upper limb anomalies occur in approximately 5.25 per 10 000 live births. Among these anomalies, undergrowth anomalies occur approximately 1.19 per 10 000 live births.[25] Undergrowth conditions are classified as malformations in the OMT classification and are subclassified as either under the entire limb or hand plate only along the proximal–distal axis.[3]

Brachydactyly

Brachydactyly, Greek for "short finger", is a condition isolated to the hand plate that presents with shortened digits. Some types show autosomal-dominant inheritance patterns.[26] Brachydactyly may occur in isolation but more commonly it is associated with other hand malformations.[27] The index and small fingers are the most commonly involved digits while the middle phalanx is the most commonly affected bone. Brachymetacarpia refers to brachydactyly isolated to the metacarpals.[5]

Bell[28] defined subgroup types of brachydactyly (Table 29.2). Brachydactyly has also been associated with hereditary multiple exostosis.[29]

Treatment

Treatment of brachydactyly depends on the severity of shortening. Typically, function is preserved and surgical intervention usually focuses upon aesthetic concerns.[27] In brachymetacarpia, the patient will often present with one knuckle that is not apparent when the patient makes a fist. This abnormality usually does not limit the patient's function, unless the thumb or index fingers are involved.[30] The metacarpal physis usually closes prematurely and the resultant metacarpophalangeal joint demonstrates limited flexion (Fig. 29.11A,B). To address the loss of length, one may consider distraction lengthening of the affected bone. In cases of severe ray shortening or in cases in which multiple digits are affected, hand function can be compromised. Options for treatment of such cases include webspace deepening, osteotomy and bone grafting, non-vascularized toe phalanx transfer, distraction lengthening, and microsurgical toe to hand transfers.[31]

Although brachydactyly, symbrachydactyly, and transverse deficiency primarily affect the hand plate, others can also affect the entire upper limb.[3]

Table 29.2 Groups of brachydactyly

Type	Description
A	Shortened middle phalanges
B	Short or absent middle or distal phalanges with deformed thumbs and great toes
C	Deformity of the middle and proximal phalanges of the index and middle fingers with shortening of the metacarpals
D	Short and broad distal phalanx of the thumb and great toes
E	Shortening of one or more of the metacarpals

Clinical tips

Brachydactyly

- Brachydactyly can affect the entire finger or individual bones of the finger.
- Treatment is usually observation, but surgical options include: phalangeal and metacarpal lengthening, osteotomy, and web deepening.

Symbrachydactyly

Symbrachydactyly, is a rare upper limb anomaly seen in approximately 0.6 per 10000 live births. It most commonly affects males (73%) and is typically unilateral (left side 67%, right side 27%). Between 1% and 7% of patients have bilateral presentation. Only 7% have associated anomalies or a positive family history.[32]

Surgeon classification of the different manifestations of symbrachydactyly is inconsistent. The previous IFSSH classification system categorized symbrachydactyly under categories I, II, and V; or failure of formation, differentiation, and undergrowth, respectively.[33] The OMT classifies the condition as a malformation in the failure of axis formation/differentiation of the entire limb and/or hand plate.[2,4] Blauth and Gekler subdivided symbrachydactyly into four types (Table 29.3).[34]

Symbrachydactyly is divided into four types: (1) short finger type; (2) oligodactylic, atypical cleft hand; (3) monodactylic; and (4) peromelic. Symbrachydactyly presents with a hand or entire limb that is shorter and smaller than the uninvolved upper limb. The digits are short, underdeveloped and often have incomplete syndactyly.[35] Since the mesoderm is primarily affected, the fingernails and distal phalangeal tufts (ectodermal elements) are often preserved.[36] The central digits and middle phalanges are usually more severely affected.[36] Patients may present with small nubbins that have nails present. Digital amputations due to constriction bands are distinguishable by the presence of other bands elsewhere on the body and absent distal finger and nail. Anatomic structures proximal to the hand are often hypoplastic in symbrachydactyly, while proximal structures are usually normal in hands affected by constriction ring syndrome.[35,36]

Poland association (PA) is the association of symbrachydactyly with unilateral absence or hypoplasia of the sternocostal head of the pectoralis major muscle. There is no known genetic etiology. In contrast to symbrachydactyly without PA, PA is seen more commonly on the right side.[37] It has been suggested that the cause is disruption of the subclavian artery during growth and development causing underdevelopment of the limb.[38] Catena *et al.*[37] demonstrated that 57.7% of PA patients had associated upper limb anomalies including hypoplastic hand without functional or morphologic anomalies (8%), symbrachydactyly with five functioning fingers (20.6%), symbrachydactyly and some functioning fingers (14.9%), and symbrachydactyly with absent or non-functioning fingers (4.6%).

Table 29.3 Subdivisions of symbrachydactyly

Symbrachydactyly type	Description
Short finger (brachymesophalangia)	All four fingers are short and incompletely formed with a relatively normal thumb; middle phalanges may be missing with incomplete syndactyly
Oligodactylic (atypical cleft hand):	The central portion of the hand is aplastic, whereas the borders digits are less severely affected
Monodactylic	The fingers are absent or aplastic, whereas the thumb is present
Peromelic	Pesembles a transverse amputation at the metacarpophalangeal joint level, may have nubbins with or without nail remnants

(Reproduced with permission from Julie C. Woodside, MD,* Terry R. Light, MD* Symbrachydactyly — Diagnosis, Function, and Treatment. *J Hand Surg Am.* Vol. 41, January 2016).

Treatment

The individual presentation of each hand provides a guide for treatment. Treatment should aim to increase the child's functional capability. An untreated aplastic hand without digits can serve as a helping hand and can be fitted with a prosthesis. A monodactylous hand usually has a functioning thumb and a palm width with hypoplastic or normal metacarpals. Bimanual tasks with thumb and palm grip/pinch and pressing or hooking with one finger are possible. With a bidactylous hand, usually a thumb and an ulnar digit, two-finger pinch is possible but grip is usually weak.[35,39] These children have difficulty with cylindrical pinch, or wrapping their finger around a larger object with the thumb underneath. If the child has three functioning digits, then tip, palm, and cylindrical grip are possible, although they will still lack full-power grip.[5] With four or five digits, power grip is increased, although the fingers may have unstable interphalangeal joints; these children may be capable of single-hand prehension.[2]

Treatment of these hands may include excision of nubbins, syndactyly release, webspace deepening, joint stabilization, bone transfer, and microvascular second toe transfer.[35] Since many manual skills are developed by the age of 3 years,[40,41] early reconstruction can help in the development of grasp and pinch.[42]

Hypoplastic nubbins, which may have rudimentary, difficult to care for nails, may occasionally block the prehensile function of adjacent digits. These small digits can be excised if the family wishes and if they have extrinsic tendons, these can be used for toe-to-hand transfer or free phalanx toe transfer.[35]

Often the interphalangeal joints that are present in hypoplastic digits are unstable to pinch. In older skeletally immature children, these joints may benefit from physis-preserving interphalangeal arthrodesis. The phalangeal condyle is denuded of articular cartilage and is fused to the secondary ossification center of the more distal phalanx.[35] Distraction lengthening of the digit can be performed and combined with other procedures.[43] Digits with distal webs or syndactyly should undergo web deepening or syndactyly release with or without full-thickness skin grafting.[35]

Non-vascularized toe phalanx transfer can add osseous stability to digits if an adequate soft-tissue sleeve is present. The proximal phalanx of the third or fourth toe is harvested extraperiosteally with its proximal collateral ligaments and plantar plate. The soft tissues are sutured to the metacarpal head creating a stable articulation. Harvesting the graft extraperiosteally and preserving the distal articular surface prevents resorption.[31] Goldberg and Watson[44] found 91%

radiolucent physes and 83–100% growth of the contralateral phalanx if the patient was between 6 and 18 months old at the time of surgery. As the patient's age at surgery increased, the percentage of open physes decreased (67% if between 18 months and 5 years; 50% if older than 5 years), but the percentage of growth remained the same. Over time, patients have reported donor site morbidity in the residual foot. Concerns have been related to the appearance of the foot and footwear issues related to abnormal toe position. Donor toes may be short, floppy and unstable. Deformity is sometimes noted in adjacent toes.[45] Donor toe deformity may be minimized by iliac crest bone graft placed at the donor site.[46]

Distraction lengthening of a short phalanx or metacarpal can be accomplished with or without intercalary bone grafting. The technique expands the osseous and soft-tissue length of the digit and does not require neurovascular reconstruction.[47] Kessler *et al.*[47] in 1977 applied osteotomy and distraction lengthening of one or more metacarpals in 11 children between 5 and 11 years of age, achieving 2.5–4 cm of length. Each patient underwent a second procedure for interposition of bone graft to encourage earlier healing. Arslan[30] reviewed six patients who underwent distraction osteogenesis without grafting for brachydactyly. Indications were decreased pinch and cosmesis. A proximal metaphyseal osteotomy and external fixator were used in all but one patient who had a diaphyseal osteotomy. After a 6-day resting period, lengthening was accomplished at 0.25 mm/day until desired length and the fixator was then left in place until consolidation (average 12.25 weeks). Pinch improved in the patients with thumb (n=2) and index finger (n=2) lengthening, but those performed for cosmesis of ring finger (n=2) brachymetacarpia were dissatisfied with the scar tissue appearance from the pin sites.

Thumb and first webspace abnormalities are common. The supinated thumb can lie in the plane of the hand, with limited grasp and pinch.[48] The thumb may be adducted and retropulsed. Metacarpal rotational osteotomy can better position the thumb for pinch. Deepening the first web with release of tight fascia and contracted muscle can be done at the same surgery. A dorsal rotational flap, dorsal and palmar triangular flaps, or a four-flap Z-plasty can be used to widen the first webspace.[49] Langer *et al.*[48] combined first webspace deepening with an abduction–rotational osteotomy of the thumb metacarpal in 14 patients. The average palmar abduction of the metacarpal was 73° with pronation of 60–90° for pulp-to-pulp pinch. In some patients, Huber transfer for opposition, metacarpal lengthening, interphalangeal joint arthrodesis, long finger metacarpal lengthening, and syndactyly release were performed in conjunction with the thumb reconstruction. Patients underwent an average of four surgeries per hand. Because of recurrent deformity, three of 14 patients underwent revision osteotomy, while eight of 14 underwent repeat first web deepening. All patients were ultimately able to perform key pinch, lateral pinch, and experienced subjective improvement in function and appearance. Five patients were unable to oppose the thumb to any digit.

Adding sensate digits to a hand can increase a child's prehension, pinch, grasp, and function. Microsurgical toe transfers are useful for a child with an absent thumb distal to the carpometacarpal joint, absent digits except an ulnar finger, and for an adactylous hand.[42] The adactylous hand will require one mobile digit and at least a stable post or another mobile digit to achieve prehension. Survival rates are generally greater than 95%.[50] The procedure was first described by Cobbett[51] and Buncke[52] as a single-stage second toe transfer to the hand. When transfer of two toes is recommended, it may be accomplished in one or two stages, harvesting the second toe from each foot. Surgery is usually delayed until ages 2–5 years to allow the vessels the be of adequate size.[50] The symbrachydactyly hand presents challenges different from those following traumatic amputation or in a child with constriction ring syndrome, since the hand with symbrachydactyly often has hypoplastic or absent musculotendinous units, nerves, and arteries.[53,54] Often, the common extensor and flexor mass are used as motors for the transfer. The median nerve is occasionally absent, requiring that other nerves such as the dorsal sensory branches of the radial nerve are used to achieve volar reinnervation.[55]

Jones *et al.*[50] reported a microvascular success rate of greater than 97% with micro-anastomosis re-exploration required in 8.5% of 82 digits. Vilkki[39] reported that 14 of 17 patients undergoing toe transfer achieved the ability to actively pinch. Although most re-operations are performed because of limited digital motion, tenolysis has not been shown to improve motion. Transferred digits function primarily as a post.[53,56] In a series of 28 second toe transfers in 14 patients, Van Holder *et al.*[57] found a mean extension deficit of 20° and total active flexion of 80°. In contrast, in a series of 65 second toe transfers in 58 patients, Foucher *et al.*[58] reported an average extensor lag of 25° but total active motion of only 38°.

The long-term outcomes of microsurgical toe transfers have been reported by Kaplan and Jones[42] using the Pediatric Outcomes Data Collection Instrument (PODCI). In 12 patients with an average follow-up of 7.6 years post-surgery, two re-operations were performed: a tenolysis with arthrodesis and a sural nerve grafting with a rotational osteotomy. The parents reported lower scores for upper extremity function, sports and physical function, and global function, and levels of happiness similar to general population while the patients reported lower than normal scores in upper extremity function and transfer and mobility but levels of happiness higher than the normal population.

Kay *et al.*[56] reported the psychological outcomes after toe-to-hand transfers in 17 patients with symbrachydactyly. Both the parents and patients had a high level of satisfaction for appearance, function, reaction of others, well-being, and donor site. The authors also found lengths of up to 100% of the contralateral toe with normal growth (Figs. 29.12–29.16).

Clinical tips

Symbrachydactyly

- Symbrachydactyly patients can be evaluated based on number of functioning digits.
- This can be used to strategize a treatment plan to advance their function.
- Conservative observation as well as surgical procedures from nubbin removal, web deepening, to toe transfer are available treatment options.

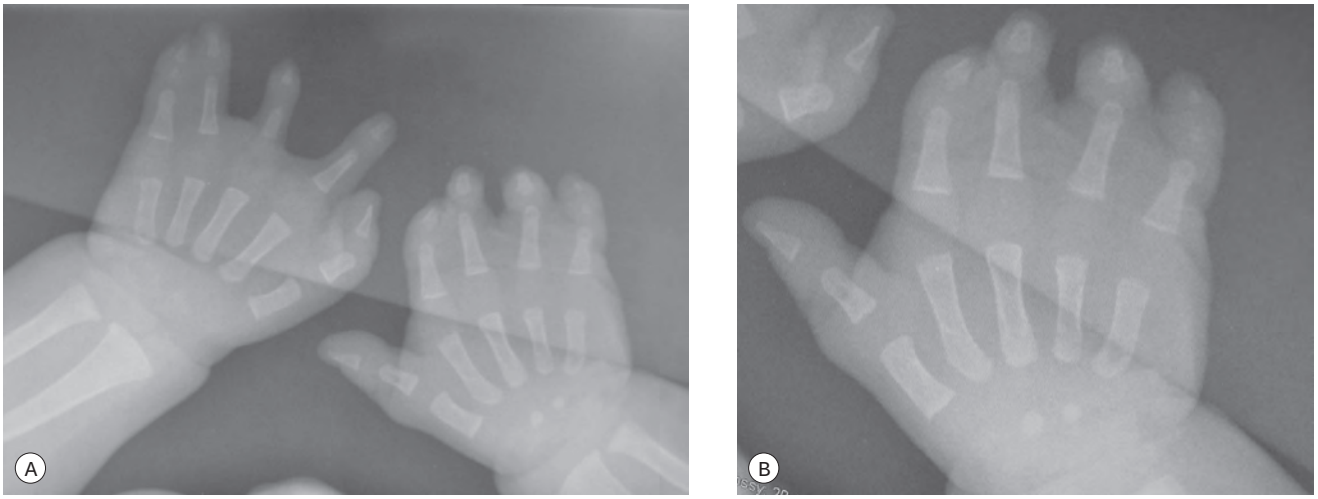

Fig. 29.12 (A) A comparison bilateral anterior–posterior (AP) X-ray of a 9-month-old male with bilateral symbrachydactyly and **(B)** an AP X-ray of just the right hand. These show shortened digits with absent middle phalanges and retained proximal and distal phalanges.

The left hand underwent separation with full-thickness skin grafting of the ring and small fingers. The right hand underwent webspace deepening of the ring–small and index–middle fingers.

Skeletal abnormalities

Introduction

Generalized skeletal abnormalities include multiple hereditary osteochondromas, Maffucci syndrome, and Ollier disease.

Multiple hereditary osteochondromatosis

Multiple hereditary osteochondromatosis (MHO) is a skeletal dysplasia that affects bones that develop through endochondral ossification. It is inherited through an autosomal-dominant pattern and is also referred to as *multiple hereditary exostoses* and *multiple exostoses*.[59] Osteochondromas are common, benign bone tumors that usually form in the metaphysis of long tubular bones. Upper limb osteochondromas are commonly noted in the proximal humerus, distal radius and ulna, and metacarpals and phalanges.[60–62] They are evident in skeletally immature children, growing over the first decade of life and usually decrease in growth and stop growing at skeletal maturity.[62] They are cartilage-capped exostoses that can be solitary or associated with a skeletal dysplasia as in MHO (Figs. 29.17 and 29.18).

MHO usually shows full penetrance and is usually associated with a defect in either the *EXT1* (chromosome 8) or *EXT2* (chromosome 11). These genes have a role in regulating chondrocyte maturation and differentiation, which, in turn, affects endochondral ossification.[63] Reports suggest that between 30% and 60%[59,61,64] have forearm involvement while between 30% and 79%[62,63,65–67] demonstrate hand involvement.

Osteochondromas in the hand are usually asymptomatic but can cause bone shortening and angulation. If a distal phalangeal osteochondroma is subungual, the lesion may distort nail growth. In patients with multiple lesions, operative intervention may be necessary for large lesions or to address deformity.[63] Woodside *et al.*[62] reviewed 83 hands of patients with an average age of 11 years at initial presentation

Fig. 29.16 The patient from Figs. 29.12–29.15: dorsal view of the right hand following webspace deepening.

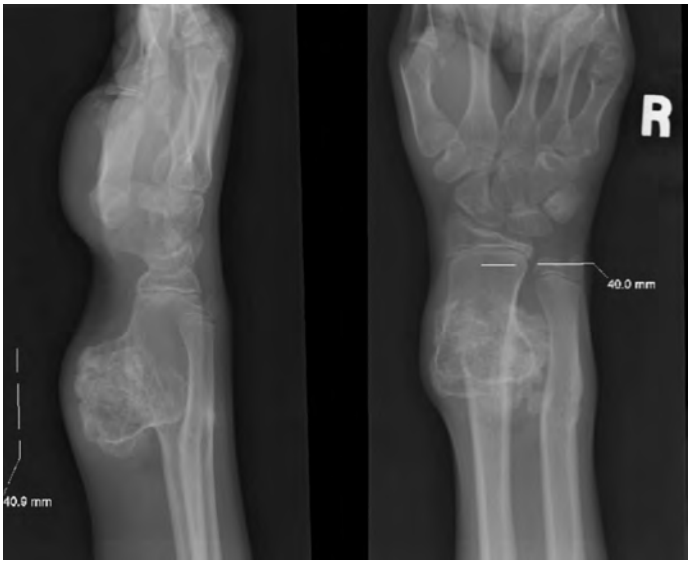

Fig. 29.17 X-ray of a 16-year-old male with familial multiple hereditary osteochondromas (MHO) with a large osteochondroma of the volar aspect of the radial.

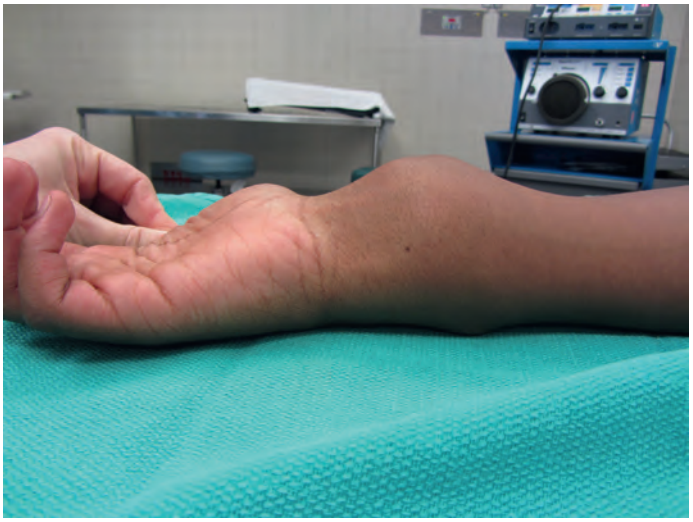

Fig. 29.18 A clinic photograph of the prominence, the patient hand median neuropathy with a Tinel's sign over the mass.

and found the small finger was the most often affected and the thumb the least often affected. Most of the lesions were sessile, smaller tumors with <50% of the bone affected. Patients had an average of 13.1 tumors per hand and the involvement of five bones per hand. An average of two bones per hand had angulation and shortening. The metacarpals of the small and index finger were the most commonly affected bone and the metacarpals on the ulnar side of the hand tended to have the most shortening and angulation. At follow-up (average 4.6 years), an increase of 2.7 lesions per hand in the number of detected tumors was evident. Spontaneous regression of eight tumors was noted in one hand while an increase of 16 tumors was noted in another hand. Patients of 7–10 years of age demonstrated the most tumors. The largest increase over time was seen in children age 2–6 years at initial presentation, likely reflecting rapid skeletal growth. As the patients reached skeletal maturity, the tumors stabilized and little change was seen. Cates *et al.*[29] and Wood *et al.*[68] also found increased involvement of the small finger and metacarpophalangeal joints of the ring and small finger, with sessile lesions the most common.

MHO of the forearm can cause bowing of the radius, shortening of the ulna with disruption of the radioulnar joint, ulnar deviation of the wrist, and radial head dislocation.[59,61,69,70] Solomon theorized that the radius either bowed or dislocated at the radiocapitellar joint in response to relative shortening of the ulna.[67] Burgess and Cates[60] reviewed 35 patients and 65 forearms (average: 11-year follow-up) using defined radiographic measurements and using normal values from Gindhart[71] (Table 29.4). The results did not show a correlation of the radial articular deformity with the degree of negative ulnar variance, which does not support a theory of ulnar tethering causing the distal radial deformity. There was a strong correlation between radial and ulnar growth deficits, with the ulna occurring at a more rapid rate. Wood[72] and Cates[60] observed isolated distal radius metaphyseal exostosis did not affect forearm length. Ulnar shortening of more than 8% was significantly correlated with radial head dislocation. The authors also found that carpal slip was not related to any other measurements or to the severity of the disease process.[60]

Gottschalk *et al.*[59] reviewed 48 patients with 76 affected forearms, initial average age of 12 years, with 7-year follow-up to determine the natural history of the forearm deformity seen in MHO patients. Forearms are classified according to osteochondroma location: (1) in distal ulna only; (2) distal radius and ulna; (3) distal radius only; (4) diaphysis of radius or ulna; and (5) proximal radius or ulna. The authors measured radial articular angle, percent ulnar variance, radial bow, radial length, and ulnar length on radiographs as

Table 29.4 **Measurements for forearm multiple hereditary osteochondromatosis**

Measurement	Definition
Ulnar variance (UV)	Shortening of the ulnar relative to the radius
Percent ulnar variance (PUV)	Ulnar variance/length of the linear axis of the forearm
Radial articular angle (RAA)	Angle of inclination of the distal articular surface of the radius from the linear axis of the forearm
Radial bow (RB)	Greatest distance the radial diaphysis deviates from the linear axis of the forearm divided by the length of the linear axis
Percent carpal slip (PCS)	Percentage of the lunate unsupported by the radius
Radial length (RL)	Center of proximal physis to center of distal physis
Radial shortening (RS)	Mean radial length of controls* minus the radial length of the patient
Radial z-score (R-z)	Radial shortening corrected for the standard deviation of the radial length of controls* [patient's length (mm) – normal length]/one standard deviation = ratio is the deviation of the length of the radius from that controls*
Ulnar shortening (US)	Predicted length of the linear axis minus ulnar length
Ulnar z-score (U-z)	Ulnar shortening/standard deviation

*Based on Gindhart PS. Growth standards for the tibia and radius in children aged one month through eighteen years. *Am J Phys Anthropol.* 1973;39:41-8. (Measurements from radiographs as described by Burgess RC, Cates H. Deformities of the forearm in patients who have multiple cartilaginous exostosis. *J Bone Joint Surg Am.* 1993;75:13-8.)

described by Burgess.[60] The authors did not find any significant differences in radiographic measurements with regards to the forearm classification. The smallest radial z-scores (R-z) and ulnar z-scores (U-z), indicating more severe shortening, were found in type 1 forearms that presented with a dislocated radial head. Type 4 had the largest R-z and U-z scores, or the least radial and ulnar shortening. Twelve of the 13 forearms with radial head dislocations were type 1. When type 1 forearms retained a reduced radiocapitellar joint, significant differences were seen in radial shortening (–2.2 cm vs. –3.8 cm), ulnar shortening (–3.2 cm vs. –5.2 cm), and percent ulnar variance (7% vs. 10%). The authors conclude that the results support the ulnar tether theory for radial head dislocation.[73] When followed longitudinally, patients with an osteochondroma of the distal ulna have a normal-appearing radius that gradually deforms with increased shortening of the ulna that can lead to eventual dislocation of the radial head. This suggests a tether around the distal radioulnar joint that impedes longitudinal radial growth, and with more severe ulnar shortening, increased radial shortening and deformity (bowing, articular surface tilting, and radial head dislocation) can be seen.[59]

Treatment

Treatment remains controversial and varies from conservative observation to aggressive surgical intervention. Peterson[69] recommends intervention to prevent radial head dislocation for at-risk forearms. Surgical treatment includes excision of osteochondroma when it interferes with growth or function or causes pain, ulnar lengthening with osteotomy to prevent further radial deformity, ulnar tether release, hemiepiphyseal stapling of the radius, and osteotomy of the radius.[59,69,72,74] Diligent radiographic monitoring of these patients is necessary.

Ollier disease and Maffucci syndrome

Ollier disease is a rare (estimated 1/100 000) congenital, nonhereditary condition that affects cartilage ossification. Involved patients form enchondromas at the metaphyseal ends of bones.[75] Enchondromas are intraosseous cartilaginous tumors. They are usually benign and can be solitary lesions or multiple. Multiple enchondromas in a region are termed Ollier disease.[75] When multiple regional enchondromas are associated with soft-tissue and visceral hemangioma malformations, the disease is termed Maffucci syndrome.[76] The metacarpals and phalanges are the common sites of hand involvement.[75,77]

Patients present with palpable bony masses on the finger or hand and usually unilateral asymmetry of the extremity. The lesions in the metacarpals or phalanges expand the cortex and cause palpable lesions. The affected bones are often short and deformed. Radiographs can demonstrate calcifications with stippled appearance and metaphyseal widening. Initially enchondromas are adjacent to the growth plate cartilage; with growth, enchondromas migrate away from the physis.[75] Tomlinson *et al.*[77] reviewed 22 hands in 11 patients at an average age of 17 years. Tomlinson found an average of 8.1 bones affected per hand, with the most common bones being the proximal phalanges of the middle, ring, and small fingers on the left, and proximal and middle phalanges of the middle finger and middle phalanx of the ring finger on the right. The index finger and thumb were the least commonly affected bones (Fig. 29.19A–C).

Malignant transformation is possible within enchondromas. The malignant lesions show cortical erosions, extension of tumor into soft tissues, and irregularity of the surface of the tumor, while enchondromas demonstrate uniform mineralization.[75] Chondrosarcomas are less well circumscribed and show poor demarcation. Maffucci syndrome is associated

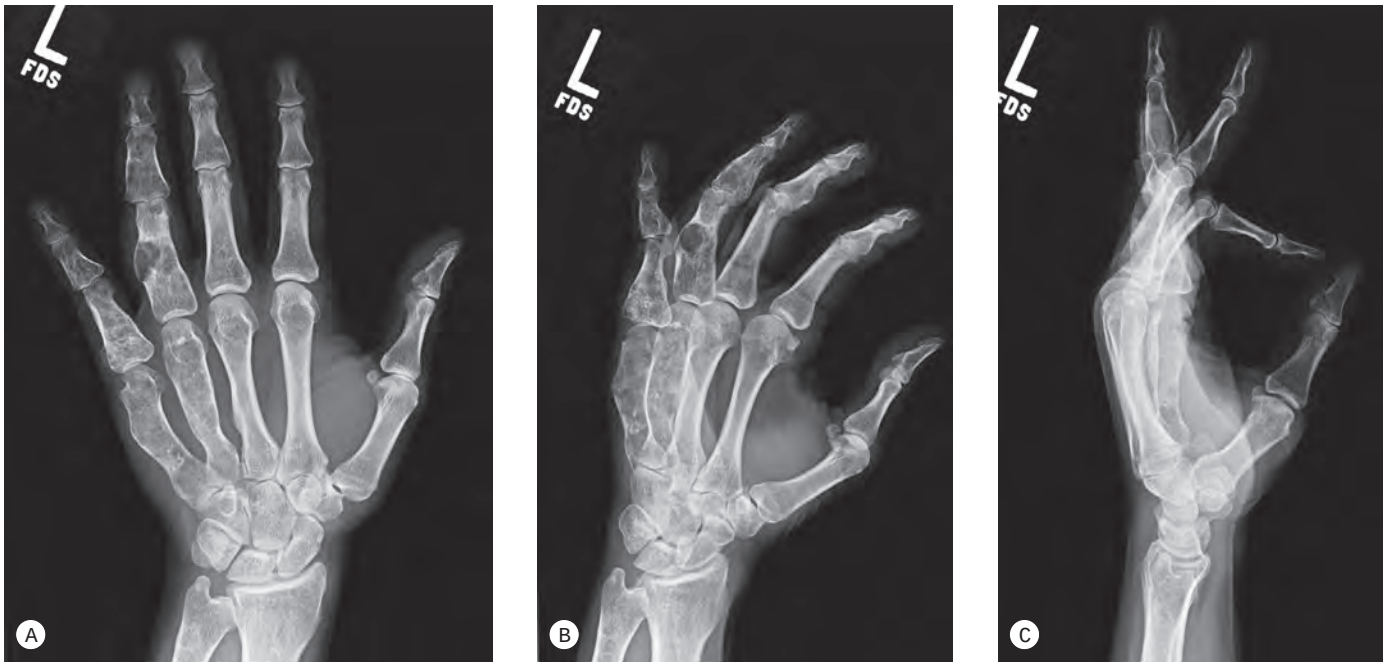

Fig. 29.19 (A–C) Anterior–posterior , oblique, and lateral X-rays of a skeletally mature patient with Ollier disease and multiple enchondromas in the ring and small fingers.

with a high risk of malignant transformation, generally quoted as being between 17% and 50%. One study has suggested that there is up to 100% chance of malignancy with very long-term follow-up. Ollier disease has a smaller risk (25–30%) of malignancy than does Maffucci syndrome.[76,78,79]

Most multiple enchondroma patients do not have functional limitations from hand tumors, some may experience shortening, limitations from tumor size, and problems with hand appearance.[80] Kim *et al.*[80] reviewed three patients on whom six procedures were performed on 30 bones for cosmesis. All enchondromas showed thinned and bulging cortices. A flap of this expanded cortex was raised, the lesion curetted and some of the bone flaps were trimmed to reduce the volume of the bulging cortex. Some lesions were filled with bone substitute. The authors noted bony union in all patients with improvement in hand appearance without compromising finger range of motion. Seventy-four percent had at least a 30% reduction in bulging on radiographs. Thirty-seven percent had greater than 40% reduction.

Sassoon *et al.*[81] reviewed 80 patients surgically treated with solitary and multiple enchondromas of the hand and found that the ring and small fingers were the most commonly affected and the thumb was the least frequently affected. The majority of lesions were monocentric with cortical expansion, and centralized within the bone. Patients in Sassoon's series with multiple enchondromas showed full healing after surgery with new bone formation in 61%, restoration of full motion in 86%, recurrence in 21%, and one case of malignant transformation. The malignant transformation occurred in a 55-year-old female with Maffucci syndrome who underwent amputation through the small finger metacarpophalangeal joint.

Clinical tips

Osteochondromas

- MHO shows multiple osteochondromas in the skeleton and can affect the hand and upper extremity.
- These osteochondromas can be associated with bone shortening, angulation, and blocking motion of joints.
- Treatment of multiple osteochondromas involves observation or surgical excision.
- Ollier disease is a condition of multiple enchondromas, while Maffucci syndrome has these and hemangiomas. Maffucci syndrome has a higher malignant transformation rate.

Future directions

Research involving the *PIK3CA*-related overgrowth spectrum and advances in genetic testing and gene therapy will greatly advance our understanding of the disease and help to possibly provide different treatment options. Current ongoing research in functional capabilities in children with symbrachydactyly will help advance the physician's understanding and allow better treatment selections to help improve that function. Registries that track these more rare conditions can allow cooperative studies of larger populations of patients with congenital hand anomalies and, with the addition of a new classification system, future research will be more streamlined from physician to physician.

Growth considerations in pediatric upper extremity trauma and reconstruction

Marco Innocenti and Carla Baldrighi

Access video and video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Skeletal growth is possible because of the presence of an active physis.
- The physis is a temporary anatomical structure physiologically regulated by several factors. It can be hindered by congenital conditions (chondrodysplasias), direct damage, or interruption of its blood supply.
- Regardless of its etiology, when the physis and or the epiphysis are damaged in a skeletally immature individual, three main issues must be addressed: restoration of longitudinal growth, restoration of joint congruency and function, and replacement of the osseous defect.
- Therapeutic options include completion of epiphyseal arrest, resection of physeal bar, and epiphyseal distraction.
- Where there is involvement of the whole epiphysis, autologous epiphyseal transfer may achieve the dual goals of restoring joint function and growth potential. The longer the period of time between the epiphyseal insult and the expected end of growth, the stronger the indication for surgical treatment.

Introduction

- The growth plate is a temporary anatomical entity, which allows axial growth in long bones. Once skeletal maturity is approached, the function of the growth plate gradually decreases and eventually stops.
- Trauma, infection, irradiation, thermal injury, tumors, and congenital disorders may affect the growth plate and interfere with the growth process.
- Any damage to the growth plate in a skeletally immature individual leads to growth disturbance with deformity and/or length discrepancy.
- Goals of the surgical treatment should be restoration of the physiological growth, prevention of angular deformities, and correction of established deviation of bones and joints.

Basic science/disease process

Anatomy and physiology of the epiphyseal growth plate

The physis (also known as growth plate, epiphyseal plate, epiphyseal growth plate, epiphyseal cartilage) is a highly specialized and organized cartilaginous structure derived from the mesoderm. It develops in the bone bud, secondary to the primary ossification centers (metaphysis) and is responsible for longitudinal and circumferential bone growth.[1] The physis must be distinguished from the epiphysis, or secondary ossification center (Fig. 30.1).

The physis consists of proliferating chondrocytes surrounded by synthesized extracellular matrix. The extracellular matrix is composed of water, collagen fibrils (mainly types II, IX, X, and XI) and proteoglycans (aggrecan, decorin, annexin II, V, and VI) arranged to form a sort of sponge with very small pores.[2] This arrangement confers peculiar mechanical properties that permit the physis to be "hard" when an axial load is applied rapidly (a jumping child) or "soft" when deformed slowly (when chondrocytes secrete new extracellular matrix).[3]

The physis is traditionally divided into horizontal zones of chondrocytes at different stages of maturation (see Fig. 30.1). The resting zone (reserve zone or germinal matrix), immediately adjacent to the epiphysis, contains small, uniform, irregularly scattered chondrocytes, also referred to as stem cells, with low rates of proliferation but rich in storage materials (lipids and cytoplasmic vacuoles) for later growth.[4,5] The resting zone is responsible for protein synthesis and for maintaining a germinal structure. Injury to this layer results in cessation of growth.

When chondrocytes enter into the proliferative zone they undergo rapid duplication, increase the synthesis of collagen, in particular types II and XI,[4] and become flat and well organized into longitudinal columns. Mitotic activity is present

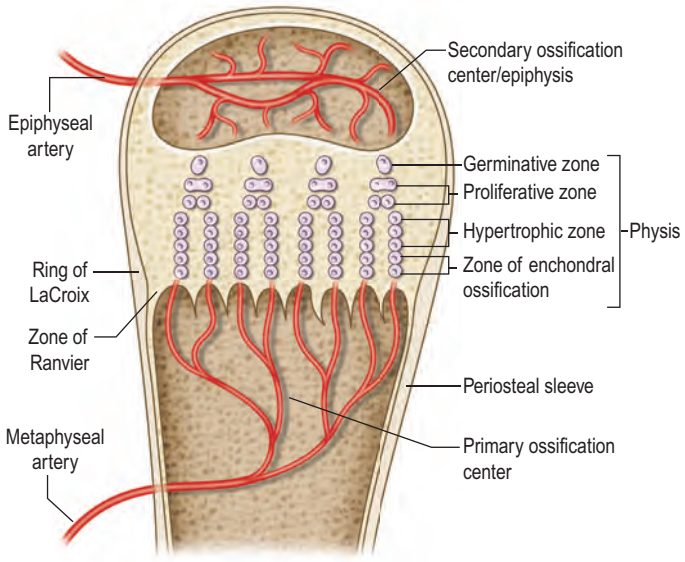

Fig. 30.1 Cross-sectional anatomy of the physis.

only at the base of these columns. This layer is responsible for longitudinal growth of the bone via active cell division. These first two zones have an abundant extracellular matrix that confers a great deal of mechanical strength, in particular in response to shear forces.

Further morphological changes – maturation, degeneration, and provisional calcification – take place in the transformation (or hypertrophic) zone, divided into upper and lower hypertrophic zones.

The presence of provisional calcification[4–6] confers shear resistance to the lower hypertrophic zone. In contrast, the upper hypertrophic zone containing scant extracellular matrix is the weakest portion of the physis and it is here that most injury or alteration to the physis occurs.[7–9]

In continuity with the metaphysis is the zone of endochondral calcification where the mineralization process of the matrix becomes more intensive.

The periphysis is a fibrochondroosseous structure that surrounds the physis of tubular bones and plays an important role in skeletal development[10] (see Fig. 30.1): (1) it allows gradual circumferential growth of the physis; (2) it continues to maintain its transverse diameter[11]; and (3) it is critical to the overall stability of the growth plate and to support for the physis bone–cartilage junction.[11–13]

The part of the periphysis adjacent to the epiphysis is a wedge-shaped group of germinal cells known as the zone of Ranvier, while the part adjacent to the metaphysis is known as the ring of LaCroix. Histologically, the Ranvier and LaCroix zones are a single structure (see Fig. 30.1).

Chondrocyte proliferation and differentiation in the physis, and therefore longitudinal skeletal growth, are regulated at both a systemic and local level.[14] A number of endocrine, paracrine, and autocrine factors and their respective receptors are involved in this process. Amongst these, the parathyroid hormone-related protein (PTHrP) and the Indian hedgehog (Ihh) play a prominent role in skeletal maturation.[1,15–18] There is also mechanical control of growth, which is important in pediatric orthopedic surgery because it is the basis of the widely used epiphysiodesis and epiphyseal distraction procedures.[3]

Vascular anatomy of the growth plate

The epiphyseal and physeal cartilage vascular anatomy in newborn and early postnatal life is integral to long-bone development and differs from later postnatal periods. In late fetal and early postnatal life, epiphyseal cartilage canals (or transphyseal vessels) are seen passing through the physeal cartilage and communicating with the metaphyseal marrow. Such vessels play an active role in forming the secondary ossification centers[18–20] but their primary earlier function is to provide nutrition by diffusion to epiphyseal chondrocytes.

The transphyseal vessels are constantly obliterated several months after birth. Once the obliteration has occurred, the physeal cartilage becomes an avascular structure supplied by the epiphyseal vessels by diffusion, and by the metaphyseal vessels invading the lowermost regions of the hypertrophic zone.[21,22]

The main vascular supply to the germinal zone is from the epiphyseal vessels. Two types of epiphyseal vascularization are described.[23] Type A epiphyses are almost entirely covered by articular cartilage, and the epiphyseal vessels enter the epiphysis after traversing the perichondrium. With this anatomical configuration, the blood supply to the epiphysis, and consequently to the germinal zone, is susceptible to damage if the epiphysis is separated from metaphysis. Type B epiphyses are only partially covered by articular cartilage. Their blood supply enters from the epiphyseal side and is protected from vascular injury during separation. The proximal femur and proximal radius are the only two examples of type A epiphyses.

Growth plate closure and skeletal age assessment during puberty

It is generally assumed that long bone physes close at 14 years of skeletal age in females and at 16 years in males while the axial skeleton completes its development later.[24–26] In 50% of normal children and adolescents, skeletal age does not differ from chronological age.[27] Prediction of limb length discrepancy and final standing height, as well as decisions regarding when to perform an epiphysiodesis, are first subjected to determination of skeletal age.

A complication unique to physeal injuries is growth disturbance. Once damage to the physis has occurred, the predicted amount of growth remaining from that specific physis must be determined to plan the treatment. This can be accomplished by determining the skeletal age of the patient and then using information on physeal growth rates and patterns assembled by Green and Anderson.[28–32]

Treatment decisions are often made during puberty. Puberty is the period of time in the growing individual characterized by a significant increase in growth rate.[33,34] In girls, puberty starts at 11 years and ends at 13 years of skeletal age; in boys, it starts and ends 2 years later (13 years and 15 years of skeletal age).[27] Peak height growth and Tanner stage 2[35] signal the beginning of puberty. The 2 years of pubertal growth spurt are known as acceleration phase followed by a deceleration phase that continues until skeletal maturity.

The radiographic markers currently used to assess skeletal age are all based on the appearance of ossification centers in specific skeletal segments at specific times. Several age assessment methods are based on the use of anteroposterior

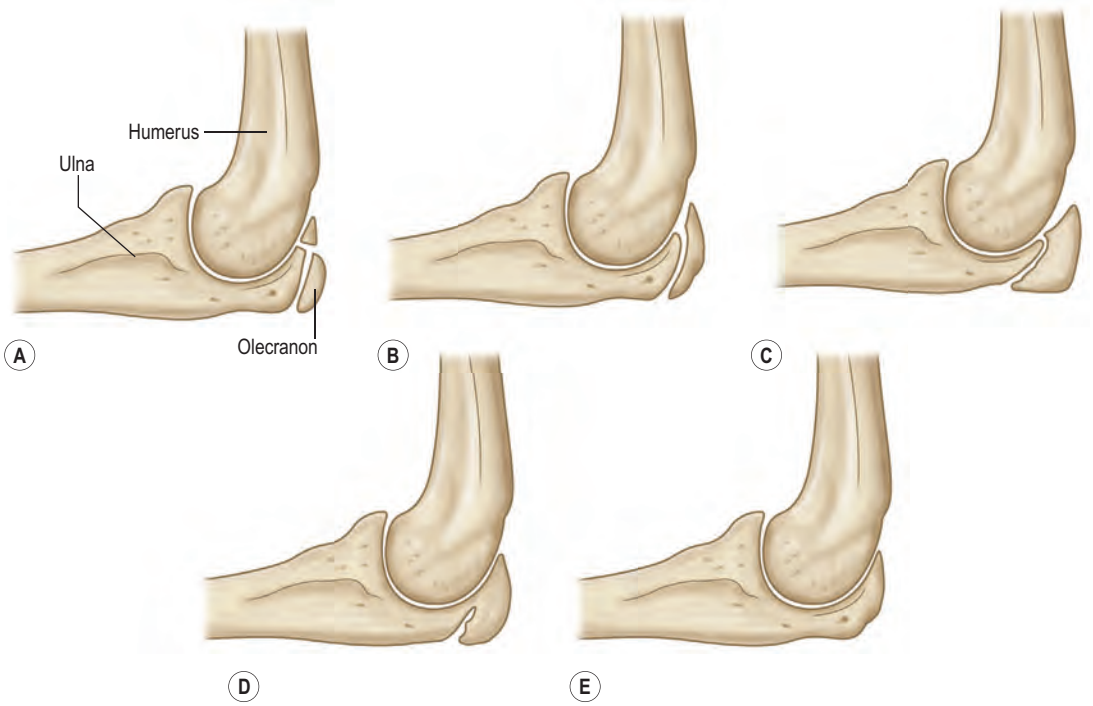

Fig. 30.2 Olecranon maturation according to Dimeglio *et al.*,[35] with significant changes occurring every 6 months. **(A)** two ossification centers (girls 11 years; boys 13 years); **(B)** half-moon shape (girls 11.5 years; boys 13.5 years); **(C)** rectangular shape (girls 12 years; boys 14 years); **(D)** beginning of fusion (girls 12.5 years; boys 14.5 years); and **(E)** complete fusion (girls 13 years; boys 15 years).

radiographs of the left hand and wrist.[36–39] Other methods use left elbow radiographs.[27,40] The axial skeleton can also be used to determine the skeletal age: Risser sign[41] is based on the appearance of the left iliac apophysis of the pelvis. However, other radiographs can be used to assess skeletal age.[27]

Different assessment methods become helpful at different ages. The Greulich and Pyle atlas[36] is probably the most common and widely used method to assess skeletal age. This technique, however, has some limitations, especially during puberty because it does not make it possible to assess skeletal age at 6-month intervals during the 2 years of peak growth rate.[27] On the other hand, during the pubertal acceleration phase, the elbow, at the level of the distal epiphysis ossification centers and the olecranon apophysis, undergoes peculiar and identifiable morphological changes every 6 months[27,40] (Figs. 30.2 & 30.3). Elbow ossification centers always appear in a determined sequence (the mnemonic is CRITOE: capitellum, radial head, internal (medial) epicondyle, trochlea, olecranon, external (lateral) epicondyle). The ages of appearance, as a general guide, are 1–3–5–7–9–11 years.

During the acceleration phase, the skeletal age is best assessed with X-rays of the left hand and left elbow.[42–45] In the deceleration phase, the growth rate decreases significantly. The remaining growth in both boys and girls is around 6 cm, of which 4.5 cm belong to the trunk and skull. During this phase, the most useful tools for skeletal age assessment are again the left hand and the Risser stage.

Regardless of the assessment method used, skeletal age alone is not enough and it should be related to other clinical and radiological findings such as standing and sitting height, Tanner stage, and annual growth rate.

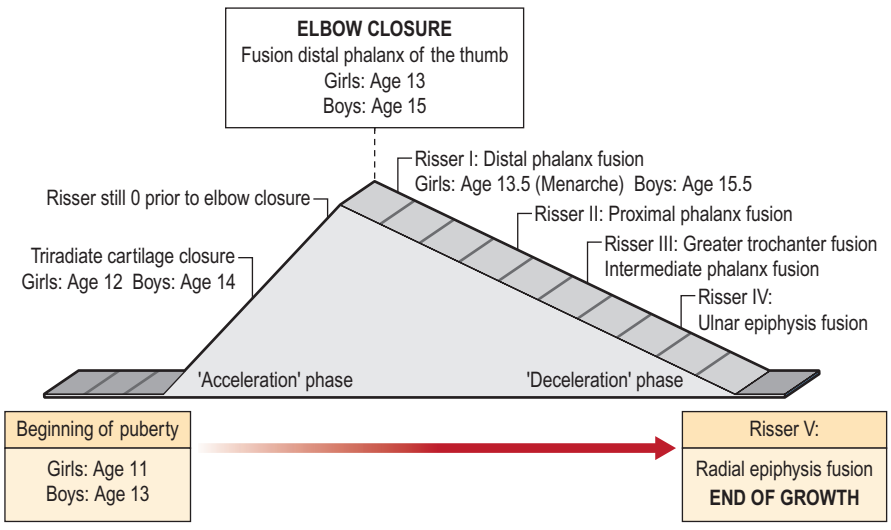

Fig. 30.3 Pubertal diagram. Acceleration phase, between skeletal age of 11 and 13 years in girls and 13 and 15 years in boys; Risser sign is 0. End of the acceleration phase, complete elbow and distal phalanx of the thumb closure; Risser sign is still 0.

Diagnosis/patient presentation

Conditions affecting the growth plate

A complication unique to physeal injuries is growth disturbance. Trauma is the most common cause of physeal injury and growth disturbance, but physeal growth arrest may as well occur after infection, tumor, irradiation, thermal injury, laser beam exposure, and sequelae of Blount's disease (growth disorder with bowing of the tibia).[46–49]

Trauma

Incidence and distribution in the upper extremity

Physeal injuries represent 15–30% of all fractures in children[50–54] and frequently involve the upper extremities.[53,55] The incidence varies with age, with a peak in adolescence.[53,55,56] The upper hypertrophic zone, just above the area of provisional calcification, is the weakest layer of the physis and where most injuries to the physis occur.[7–9] This observation implies that, after most injuries, the germinal layer of the physis remains intact and attached to the epiphysis. Consequent normal growth should resume unless insult to the blood supply of the germinal layer or development of a "bony bridge" across the injured physis occurs.[57]

Classification of physeal fractures

Several classification systems for physeal injuries have been described.[58–64] The Salter and Harris classification (Fig. 30.4)[65] is by far the most widely used system. This classification helps to distinguish different types of fractures and provides prognostic information as well. In Salter–Harris type I (see Fig. 30.4), the injury is a separation of the epiphysis from the metaphysis. It occurs entirely through the physis and therefore the surrounding bone is not involved. It is rare and tends to be seen in infants or pathologic fractures, such those secondary to rickets or scurvy. Because the germinal layer remains with the epiphysis, growth is not hindered unless blood supply is interrupted (traumatic separation of the proximal femoral epiphysis). Often, X-rays of a child with a type I Salter–Harris fracture will appear normal. Healing of type I fractures tends to be rapid, and complications are rare.

In Salter–Harris type II injury (see Fig. 30.4), the fracture extends along the hypertrophic zone of the physis but then it continues and exits through the metaphysis. This is the most common type of growth plate fracture, and tends to occur in older children. The epiphyseal fragment contains the entire germinal layer as well as a metaphyseal fragment, known as Thurston Holland's sign. The periosteum on the side of the metaphyseal fragment is usually intact and provides stability after reduction. Growth disturbance is uncommon because the germinal layer remains intact.

In Salter–Harris type III injury (see Fig. 30.4), the fracture starts through the hypertrophic zone and exits through the epiphysis. These injuries also tend to affect older children. By definition, type III fractures cross the germinal layer and are usually intra-articular. Consequently, they raise concerns about growth and, when displaced, they require anatomic, and often open, reduction.

In Salter–Harris type IV injury (see Fig. 30.4), the fracture starts from the metaphysis and then extends through the physis and into the epiphysis. By definition these fractures disturb the germinal layer and are usually intra-articular. Consequently, these injuries may impair normal growth and affect articular congruency. In type IV injuries, an anatomic reduction is mandatory in order to prevent osseous bridging across the physis and to restore the articular surface.

A Salter–Harris type V injury (see Fig. 30.4) occurs when the physis is crushed from a pure compression force. It is so rare that some authors question whether such an injury exists.[66] For those authors who have reported on this injury,[65,67] it carries the most concerning prognosis as the growth disturbance is almost a rule. It often requires later surgical treatment to restore limb length and alignment.

Despite being widely used, the Salter–Harris classification excludes a few physeal injuries: the Rang's type VI epiphyseal injury,[62,63] which represents an injury to the perichondral ring, and two additional injuries described in the Peterson classification system (Fig. 30.5),[56] which is very similar to the Salter–Harris scheme. The Peterson type I fracture is a transverse fracture of the metaphysis that extends longitudinally into the physis. Clinically, this type of fracture is commonly seen in the distal radius. The Peterson VI fracture is an open injury associated with loss of the physis.

Treatment of physeal fractures

Growth plate injuries that are less severe, and occur closer to the time of closure of the growth plate, carry the best prognosis. More severe injuries occurring in younger patients require observation and possibly treatment to prevent problems. The principles of treatment of physeal fractures are the same as those involved in the treatment of all fractures, with a few important considerations.

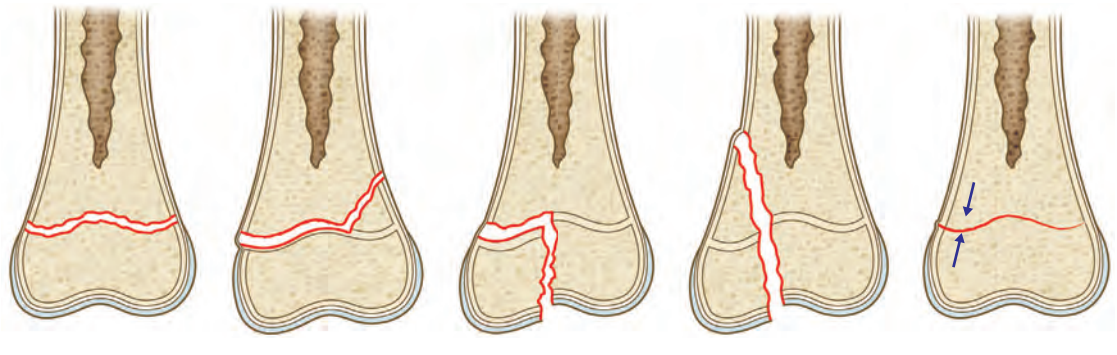

Fig. 30.4 Salter–Harris classification of physeal fractures. *(Redrawn after Salter RB, Harris R. Injuries involving the epiphyseal plate.* J Bone Joint Surg Am. *1963;45:587–621.)*

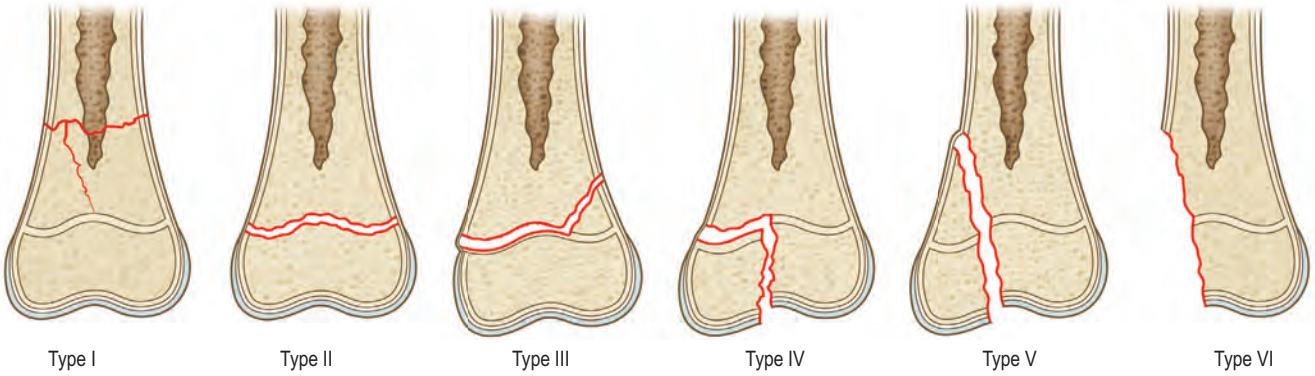

Fig. 30.5 Peterson classification of physeal fractures. Type VI injuries are open and associated with loss of the physis. *(Redrawn after Peterson HA. Physeal fractures: part 3. Classification.* J Pediatr. Orthop. *1994;14:439.)*

The goal in the treatment of physeal injuries is to obtain and maintain an acceptable reduction while avoiding any further damage to the germinal layer of the physis during reduction. Thus the most important goal, and the most subjective one, is to establish the limits of acceptable reduction.

The age of the patient, the location and displacement of the fracture, and the time elapsed since the injury must be all taken into consideration when assessing a non-anatomic reduction. Although animal studies have not shown that delay in reduction produces a growth disturbance,[68] the recommendation is to accept any displacement in type I and II injuries after 7–10 days[9,69] and rather plan an osteotomy later. As a general rule, the remodeling potential is inversely proportionate to the age of the patient and is also related to the location and type of injury. Consequently, a greater deformity can be accepted in younger children.

Because type III and IV injuries are by definition intra-articular, the focus must be on achieving an anatomic reduction regardless of the age of the patient and the time that has elapsed since the injury. Once the physeal fracture has been reduced, the reduction can be maintained with cast, pins, internal fixation, or combinations of these three.

Tumor

Bone sarcoma involving the epiphysis

Most of the common primary malignant bone tumors occur in patients aged under 30 years.[70] Typically, osteosarcoma and Ewing sarcoma are found in adolescents and young adults, but they may also be diagnosed during infancy. The current approach to systemic therapy[70] includes preoperative (neoadjuvant) chemotherapy and postoperative (adjuvant) chemotherapy for both osteosarcoma and Ewing sarcoma. Radiotherapy is indicated only in Ewing sarcoma and it may be the only local treatment in cases of tumor in unfavorable locations, such as spine and pelvis, and in all cases where radical surgery is unlikely to be successful. Postoperative radiotherapy is indicated in all cases of intralesional resections with the aim of reducing the risk of local recurrence.

With advances in bone reconstruction, the role of surgery has become predominant in the treatment of primary bone tumors, and the percentage of limb salvage versus amputation has significantly increased. In the upper limb, bone sarcomas are more frequently located in the distal radius and proximal humerus. Although the tumor is usually initially located at the metaphyseal level, the growth plate and the physis are always to be considered as a possible target of sarcoma invasion. From a functional standpoint, it is critical to know whether the surgical resection may spare the epiphysis or not.

In the past, the growth plate was thought to be a biologic barrier to bone tumor invasion[71–73]; unfortunately this theory has not proven to be valid[74–76] (Fig. 30.6). The current view is that invasion of the physis must always be suspected when

Fig. 30.6 Osteosarcoma involving the proximal epiphysis and the adjoining diaphysis in a 6-year-old child.

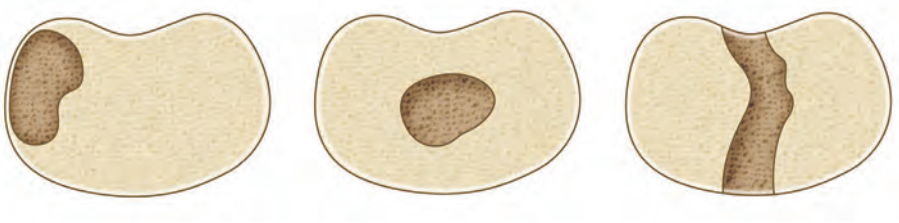

Fig. 30.7 Classification of physeal bars. Type A, peripheral; type B, central, surrounded by normal physis; type C, central, traversing the physis.

the tumor is located in the proximity of the growth plate and all patients should be investigated with magnetic resonance imaging (MRI). In the event of epiphyseal involvement, the oncological resection must include the epiphysis and the only possible reconstructive option for such a defect in the pediatric age group is autologous epiphyseal transplant.

Congenital chondrodysplasia

Chondrocyte proliferation and differentiation in the physis, and therefore skeletal growth, are regulated by various endocrine, paracrine, and autocrine factors. Any disturbance of the epiphyseal growth plate physiology and development results in various skeletal abnormalities known as dysplasia or chondrodysplasia. These cases may also require reconstruction to maintain growth.

Patient selection

When the physis is damaged and deformity results or is foreseen, several treatment options are available. The best treatment for a growth plate injury depends on the individual situation. Although physeal injuries are common, problems arising are rare, occurring in only 1–10% of all physeal fractures.[9,53,56] Comminuted fractures, high-energy injuries, and physeal injuries that cross the germinal layer are more prone to result in physeal arrest with subsequent growth disturbance. Physeal injuries are most common in adolescents close to skeletal maturity. In these individuals, the remaining growth is limited.[9,53,56] Consequently, even when it occurs, physeal arrest will produce minimal or no length discrepancy or angular deviation and will seldom require treatment.

Growth disturbance resulting from a physeal fracture is usually evident 2–6 months after the injury, but it may take up to a year to manifest.[9] This information is important both to warn the parents about possible complications and to anticipate close long-term follow-up. In fact, the management of a post-traumatic growth disturbance is easier when directed exclusively towards treating the arrest rather than tackling both the arrest and the acquired deformity.

Growth disturbance is usually a consequence of the development of a bony bridge, or bar, across the physis.[57] However, when the injury only reduces rather than stops the growth rate of a portion of the physis, it may still produce asymmetric growth and angular deformity with no development of bony bridge.[77] If the bony bar involves a large portion of the physis, it may stop the physeal growth completely. However, in most cases, the bony bar is confined to a rather small portion of the physis and the growth stops only at that point. The remaining healthy physis continues to grow, creating a tethering effect, which may produce either a shortening or a progressive significant angular deformity, or both.

The extent and location of the bar, the skeletal age of the patient, and the amount of growth remaining from the physis must all be determined to plan the treatment of a physeal bar appropriately. Plain radiography, tomography, computed tomography (CT), or MRI[46,78–81] may all be used to assess the anatomy of a physeal bar. MRI is by far the preferred method currently used to investigate physeal anatomy.[82–85] In particular, fat-suppressed, 3D, gradient-recalled echo sequences can provide an accurate 3D reconstruction of the physis and estimate the percentage of physeal arrest.[85] The classification of partial physeal arrests is based on their location within the physis (Fig. 30.7): peripheral (type A) or central (type B or C). In type B, the bar develops in the center of the physis and is surrounded by a perimeter of healthy physis. This may create a tethering effect that "tents" the epiphysis, leading to joint deformity. In type C (central) the bar traverses the entire physis (front to back or side to side) while the physis on both sides of the bar is normal.

Treatment/surgical technique

Treatment of physeal arrest

Different treatment options are available for the management of physeal arrests. These options include observation, completion of a partial physeal arrest, epiphysiodesis, physeal bar resection, or physeal distraction.

Observation

Observation may be the best option when the physeal bar involves the entire physis with complete growth arrest if existing limb length inequality and/or angular deformity are acceptable, or if the individual is close to skeletal maturity with little longitudinal growth remaining.

Completion of a partial physeal arrest and epiphysiodesis

Completion of a partial physeal arrest may be indicated if there is an acceptable existing angular deformity that may become clinically unacceptable if left untreated. To avoid significant limb shortening of the upper extremity, the surgeon must evaluate the predicted remaining growth and foresee a lengthening procedure if necessary. In the upper extremity limb, length discrepancy is a relative issue but the asynchronous rate of longitudinal growth between two bones in an anatomic region where the two bones are paired in close longitudinal relationship, as in the forearm, or asynchronous growth in an anatomic region where the harmonic activity of

several physes contributes to the final size and shape of the bone, such as the distal humerus, might lead to a great risk of anatomic distortion. If the likelihood of length inequality is high, epiphysiodesis of a non-injured physis should be performed at the time of completion of the physeal arrest.

Epiphysiodesis is an established method of limb length equalization or angular deformity correction in children and adolescents with projected limb length discrepancies at maturity as great as 5 or 6 cm. It consists of temporarily stopping or permanently destroying the activity of the whole or just a part (hemiepiphysiodesis) of the growth plate. First introduced by Phemister in 1933,[86] epiphysiodesis has evolved into various reversible or irreversible, open or percutaneous techniques, with and without instrumentation. The ideal tool should be minimally invasive, have minimal morbidity, and be reliably reversible. Pitfalls include errors in the prediction of growth and planning of the surgery. In particular, with non-reversible techniques, timing must be precise. Overcompensation for limb length discrepancy or creation of an opposite angular deformity can be very distressing for the patient, family, and surgeon. Although many different techniques have proven their efficacy, percutaneous epiphysiodesis using transphyseal screws combines the minimal invasiveness of a percutaneous technique with reversibility.[87]

Physeal distraction

Physeal distraction is an alternative treatment for partial physeal arrest. Physeal distraction uses the growth plate as a zone of least resistance. It involves the damaged physis and therefore acts at the site of the deformity. It requires a force to be applied longitudinally across the physis, permitting both lengthening and angular correction on multiple planes, with external control of the correction until consolidation. Prior resection of the bony bar is not necessary.

A distinction must be made between distractional epiphysiolysis and chondrodiastasis,[88,89] chondrodiatasis,[90] and hemichondrodiatasis.[91]

The chondrodiastasis technique employs large forces or rapid rate of distraction (>1 mm/day) or both.[92] This provokes a distraction and opening of the physis that provides a rapid *in situ* correction from the bony bar without prior bar resection, but almost invariably it produces a premature physeal fusion.[93,94] This notion limits the indications to patients nearing skeletal maturity and preventive lengthening according to predicted limb length discrepancy.[94,95] In the literature, physeal distraction techniques are mostly reported for the treatment of lower limb deformities and little is known about their application in the upper limb.

Bar resection

If a portion of the physis has prematurely closed, but the reminder of the physis is healthy and there is substantial growth remaining, resection of the physeal bar and insertion of interposition materials are indicated. This technique in fact preserves longitudinal bone growth ability.[96,97] The procedure was first introduced by Langenskiöld and has been documented in both human and animal models.[47,79,96,98–101]

The surgical technique of bar resection consists in removing the bone bridge along with the neighboring portions of metaphysis and epiphysis and filling the cavity with an inert material that will prevent recurrence of physeal bar formation (Fig. 30.8).

Type A peripheral bars can be removed under direct vision, taking care to resect a wide cuff of periosteum. Type B and C central bars need to be approached through a window in the metaphysis or through an osteotomy (see Fig. 30.8A–C). Their resection may be facilitated by the use of fluoroscopy, fiber optic lighting, and dental mirrors, as well as magnifying loupes (see Fig. 30.8D).

Physeal bar resection is recommended when all the following conditions are present: the remaining physis must be undamaged and must be large enough to permit growth to continue; and there should be a significant amount of growth remaining in that physis before physiologic physeal closure. Bars involving more than 50% of the physeal surface are unlikely to respond to surgical treatment.[48,62,79,96–98,100] Despite the acceptance that younger patients, with higher growth potential, will benefit from physeal bar resection, there is still no agreement in quantifying the amount of this growth potential.[79,98,101]

According to Bright,[102] indications for a bone bridge resection are as follows: there must be more than 50% of remaining healthy physis; the expected physeal growth must last for 2 years or more; there must be good soft-tissue coverage of the lesion; and, in the case of growth arrest due to infection, the infection must have been absent for more than 1 year.

Once the bar is completely resected, various interpositional materials can be used to fill the void and prevent transphyseal bone bridge formation.[62,79,98] Of the interposition materials described, fat is the most commonly used.[96,103] It has the advantage of being autologous and immediately available.

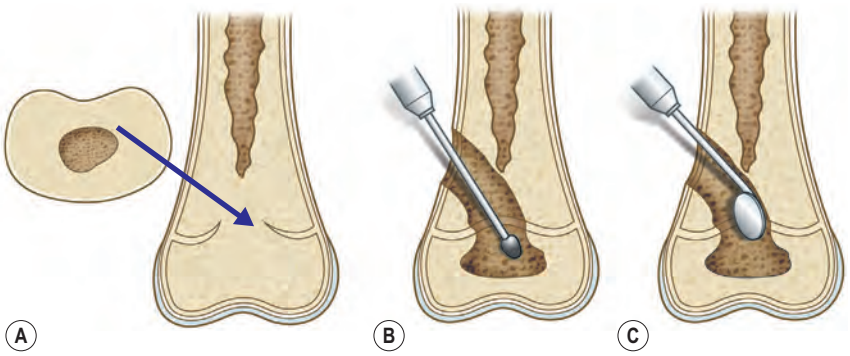

Fig. 30.8 **(A)** Central bar. **(B)** Bar resection through metaphyseal approach. **(C)** Assessing the resection.

Failure to prevent re-formation of the physeal bridge[104,105] may be due to the fact that fat may not provide adequate hemostasis of the cavity and may migrate.[97,106]

Silicone (Silastic) has been experimentally used in both human and animal studies with good results,[102,107] but Silastic has been withdrawn from the market.[99] Methylmethacrylate, commercially known as Cranioplastic, is a material used to fill partial defects of the skull, is radiolucent, and is thermally non-conductive. The advantage as interposition material[97] is that its solid structure may help to support an epiphysis if a large metaphyseal defect has been created.[106] It may, however, damage the healthy physis because of heat produced by the exothermic reaction during the solidifying phase.[108] It may also be problematic to remove if further reconstructive procedures are required. Rarely, it can migrate from the physis into the diaphysis, and cause a pathological fracture.[109]

Expanded polytetrafluoroethylene (EPTFE) membrane (Gore-Tex dura substitute; WL Gore, Flagstaff, AZ, USA) is generally used as an artificial dura substitute. The advantages of EPTFE membrane are that it is inert, non-reactive, unaffected by long-term exposure within the body,[110] easy to handle, and provides good hemostasis. The disadvantage is that, being a soft material, it does not provide sufficient mechanical support and it is therefore only recommended when the resected area is at most 30% of the cross-section of the physis.[111]

Bone wax is readily available and commonly used in medical applications to control bleeding. It has been successfully used as interposition material with the advantages of being inexpensive and permitting good hemostasis. It is not associated with excessive complications.[112] The disadvantage is that it does not offer a good mechanical support to the physis after bar resection.

Regardless of which interposition material is selected, the purpose is to fill the cavity created in the physis with the material so that bar formation is prevented. After bar resection, radiographic markers should be placed on each side of the physis to assess growth resumption.

Results after bar resection are variable. Even with appropriate patient selection and standardized operative technique, failure may result. Graft dislocation out of the cavity is one of the causes of failure.[113] It is therefore recommended that the interposition material be anchored so that it will not dislodge, allowing bleeding into the cavity.[97] It is important that, even when growth resumes, premature closure of the physis is to be expected.[56,79,98,106,113]

Physeal bar resection with interposition of certain materials plays a role in the treatment of partial physeal arrest; however, its results are relatively modest.

Corrective osteotomies, lengthening or shortening

Epiphysiodesis and resection of the bone bridge with the insertion of interposition materials[96,97] are the two main methods to treat partial physeal arrest that also prevent further progression of angular deformity. In addition, for mild deformities of less than 20°, we can expect spontaneous remodeling after bar resection,[96,97,114] although this has not been universally reported.[77] When an angular deformity is already evident, corrective osteotomy is indicated because remodeling sufficient to correct the deformity cannot be expected. Corrective osteotomy should be considered for any angular deformity that is judged to be "clinically unacceptable".[79,98,97,106]

It is well known that the physeal growth rate responds to the force applied on the physis itself: growth is stimulated by both mild tension and mild compression.[115] However, according to the Hueter–Volkmann principle,[116] when compression on the growth plate exceeds a certain level, growth is indeed suppressed.[115] If the compression is applied only on one side of the physis, worsening of the deformity may ensue. Improved alignment may therefore facilitate more normal growth.

Bone lengthening involves the principle of distraction-induced osteogenesis and the use of an external fixator. Because of the non-weight-bearing status of the upper extremity, limb length discrepancy of the upper limbs is better tolerated and of less functional and cosmetic significance than their counterparts in the lower extremity. For these reasons, along with the incumbent risks associated with the surgery, indications for bone-lengthening procedures in the upper extremities are confined to selected cases.[104,117–128]

Reported complications of upper limb lengthening include pin tract infections, complications related to callus stability and formation (callus deformities after fixator removal, re-fractures, and malunions), diminished range of motion, elbow flexion contractures, pin-related nerve injuries, temporary radial nerve paresis as a complication of humeral lengthening, and sympathetic dystrophy.[129–133] Considerable morbidity results from nerve injury secondary to the transfixing wires.[132,133] In addition, in distraction lengthening of the upper limb, the bone formation takes longer compared to the lower limb because of the lack of weight-bearing. Therefore the external fixator must be kept on for several months. The length of treatment further decreases patient compliance and can be a major issue in young children and adolescents.

Epiphyseal transfer of the proximal fibular epiphysis

Access the Historical Perspective section online at http://www.expertconsult.com

Indications

The main indications for epiphyseal reconstruction are loss of an epiphysis following trauma, tumor resection, or infection in children. Vascularized epiphyseal transfer is a procedure that can simultaneously achieve the double goal of reconstructing a lost joint and maintaining growth potential. Because of its biological and morphological characteristics, the proximal fibula is by far the best donor site for reconstruction of large bone defects of the upper extremity. In fact, unlike other bone segments suggested for vascularized epiphyseal reconstruction,[158,159] the proximal end of the fibula contains a true epiphysis with a growth plate that, if properly revascularized, maintains its growth potential at the recipient site. In addition, the fibula is a tubular bone with a long expendable diaphysis that is perfectly suited for upper limb reconstruction, allowing safe and stable bone fixation.

The two most common locations of bone sarcomas of the upper extremity in the pediatric age group are the distal

Historical perspective

The first reports of free non-vascularized epiphyseal transplant date back to the end of the 19th century.[134–136] All attempts in the pre-microsurgical era had discouraging results in terms of graft survival and growth. Early revascularization of the growth plate was identified as the crucial condition in determining success.[137] In the past 30 years, advancements in microvascular surgery led to experimental research with several studies proving the feasibility of vascularized epiphyseal transfer in animal models.[138–146]

In the 1980s, this procedure was successfully introduced into clinical practice.[147–149] These first encouraging results convinced the scientific community to refine further the technique and expand its indications. During the past 15 years, an increasing number of papers have successfully reported on limited series of reconstruction of either the proximal humerus or the distal radius and ulna with this technique.[150–157]

metaepiphysis of the radius and the proximal humerus, with a slightly higher incidence for the latter. Due to morphological and dimensional similarities, the proximal fibula is ideal for distal radius reconstruction.[154] In addition, under the influence of a new biomechanical environment, the plasticity of the immature bone allows remarkable remodeling of the epiphysis after its transfer into the new anatomic location. Since the forearm is a two-bone segment and severe wrist deformity may result from asymmetrical growth of radius and ulna, the younger the patient, the greater is the indication for epiphyseal transfer in this location.

Case study

Resection of the entire radius for sarcoma

Sometimes the extension of the sarcoma is so wide that resection of the entire radius is required (Fig. 30.9). In such case, the reconstruction with proximal fibular epiphysis is particularly demanding. It is actually impossible to restore the entire length of the radius and, in addition, the absence of interosseous membrane would lead to unacceptable instability and proximal migration of the graft.

In the two cases of our series, we performed a bone fixation of the fibula to the midshaft of the ulna in a neutral pronation/supination (Fig. 30.10A). This is a sort of radioulnar synostosis, which provides a stable neoradius with the only drawback of abolishing pronation and supination.

The only conceptual concern that may be related to this choice is the risk to have a divergent growth of the two bones, because the ulna is straight and the new radius has an angle of about 45° with the longitudinal axis of the forearm.

However, in our experience, a longitudinal remodeling occurred and over the years the distal portion of the new radius migrated medially toward the ulna (see Fig. 30.10B), thus improving the stability of the joint and its function (Fig. 30.11).

Despite the anatomic mismatch between the fibular head and the glenoid fossa and the difference in transverse diameter of the shafts between the humerus and the fibula,[151] autologous proximal fibular transplant remains the best option for

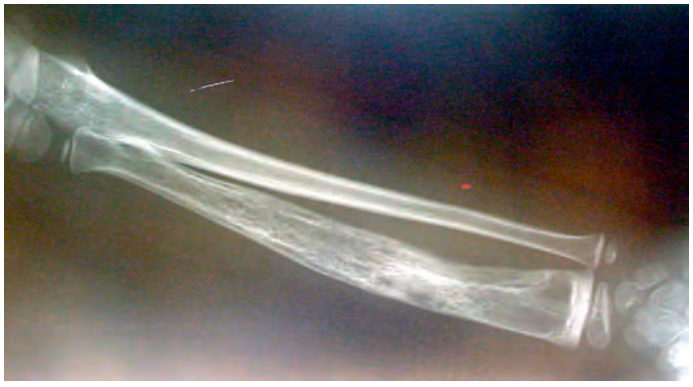

Fig. 30.9 Sarcoma involving extensively the radius. Resection of the entire bone is required.

Fig. 30.10 **(A)** Bone fixation of the fibula to the midshaft of the remaining ulna. Radioulnar synostosis in neutral pronation/supination position is created, providing a stable neoradius but eliminating pronation and supination. **(B)** Longitudinal remodeling of the physis occurred over the years.

Fig. 30.11 Long-term clinical outcome: functional flexion–extension of the wrist and wrist stability are restored after surgery.

autogenous reconstruction of the proximal humerus (Fig. 30.12). Over time, the fibular diaphysis undergoes hypertrophy, which minimizes the size discrepancy. Moreover, remodeling of the fibular head, although less impressive than in distal radius reconstruction, is expected, leading to more than acceptable shoulder joint stability and function (Fig. 30.13).

Proximal fibula epiphyseal transfer has proven to be an excellent option in limb salvage surgery in pediatric oncologic cases. Congenital differences of the upper limb, such as radial dysplasia, may also benefit from this surgical procedure. These cases, though, raise a few concerns and considerations: the new radius may be expected to grow more than the native ulna, which usually is hypoplastic, thus developing wrist instability and ulnar deviation. Limited literature is available at the moment on epiphyseal transfer for radial dysplasia with encouraging results reported by Yang *et al.*,[160] only on Bayne and Klug type III radial longitudinal deficiency. There is no report on long-term outcomes that could help to validate the technique.[149,153,161]

Vascularized epiphyseal transplant based on the anterior tibial vascular system is a long and demanding procedure with high rate of complications, although transient, at the donor site. For these reasons, the cost–effectiveness ratio should be carefully evaluated. From personal experience of 30 cases, we have concluded that distal radius reconstruction is indicated up to 13 years of age because the radius and ulna require symmetrical growth until skeletal maturity. On the other hand, the humerus tolerates well a length discrepancy from both functional and cosmetic standpoints, setting the age limit for such a procedure at around 10 years of age.[162]

Vascular supply of the proximal fibular epiphysis

In the past 30 years, the vascular anatomy of the proximal fibular epiphysis has been extensively investigated in order to define the best pedicle supplying both the epiphysis and the diaphysis of such a graft. There is general agreement that the proximal epiphysis of the fibula is supplied by two vascular sources: (1) the lateral inferior genicular artery; and (2) the recurrent branches of the anterior tibial artery. The role of the two systems is differently emphasized according to different authors,[163–167] but the majority of reports confirm that the anterior tibial artery provides the major contribution to the blood supply of the proximal fibular growth plate. Summarizing the data available in the literature, the lateral inferior geniculate artery mostly supplies the capsule of the proximal tibiofibular joint, the anterior and posterior recurrent branches of the anterior tibial artery supply the epiphysis, and the peroneal artery supplies the fibular shaft. It has also been experimentally demonstrated[165,166] that the anterior tibial artery is able to vascularize the proximal two-thirds of the fibular diaphysis through tiny musculoperiosteal perforators that distribute to the periosteum of the shaft.

Almost all possible vascular pedicle combinations have been described in use in clinical practice. Pho *et al.* reported on 3 cases[148] where the peroneal artery was used as the pedicle, postulating that the presence of intercommunicating branches between the metaphyseal and epiphyseal systems allowed for

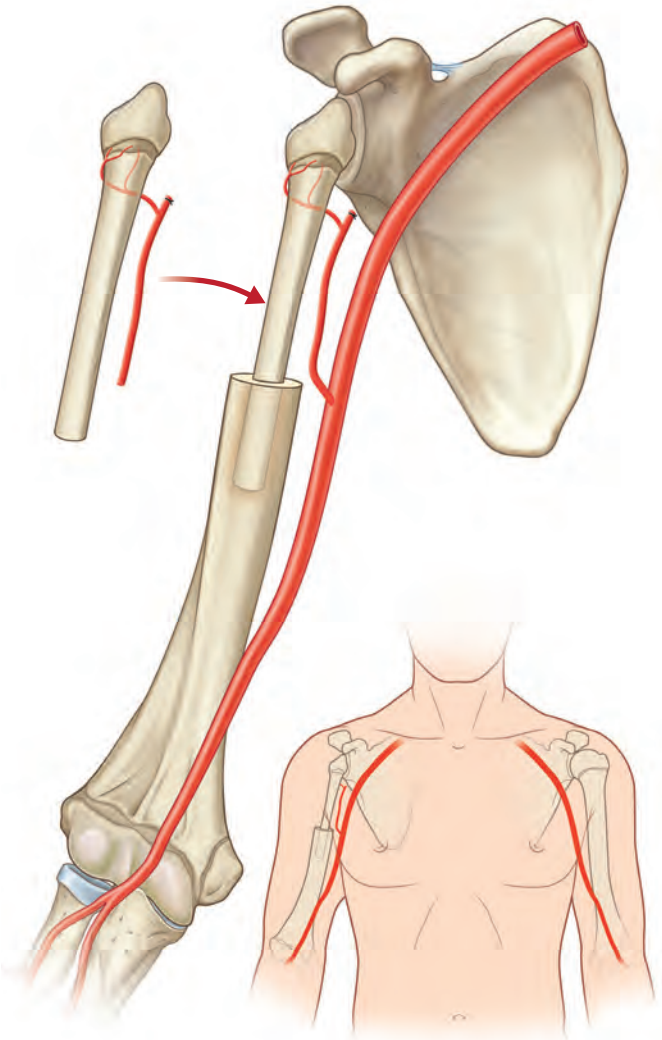

Fig. 30.12 In proximal humerus reconstruction, the smaller fibula is usually inserted inside the humeral medullar canal with a periosteal flap overlapping the bony junction. This type of assemblage improves stability and ability to heal. Vascular anastomoses are usually performed end-to-end to the deep humeral vessels.

Fig. 30.13 Reconstruction of the proximal humerus at 5-year follow-up. The transferred proximal fibula underwent significant remodeling and hypertrophy as well as enough longitudinal growth to prevent limb length discrepancy.

acceptable blood supply to the growth plate based solely on the peroneal artery. Although this is probably anatomically possible if enough soft tissue is left around the fibular neck, further experiences[151,156] have had disappointing results on the growth rate of grafts supplied by the peroneal artery alone.

The use of a bipedicled graft has been suggested,[147,149,151] with the purpose of providing two separate blood supplies to the epiphysis and the diaphysis. This option, however, is technically demanding, time-consuming, and requires two anastomoses at the recipient site. In addition, the physis is very susceptible to ischemia, and normal growth can be expected only if ischemia time is less than 3 h.[168] For these reasons, a single-pedicled graft is definitely a better choice.

The anterior tibial system has proven to be adequate in supplying both the epiphysis and the shaft and it is therefore the preferred pedicle for such a graft (Fig. 30.14). A potential disadvantage to the use of the anterior tibial vascular system is that the pedicle is very short (the distance between the division of the popliteal artery and the origin of the recurrent branch at the fibular neck). To overcome this issue, it has been suggested to use a reverse-flow pedicle.[151,154,161] In this way, long vessels are provided, allowing comfortable anastomosis at the recipient site.

Harvest technique of the proximal fibula based on the tibialis anterior artery (Video 30.1)

The flap includes the proximal fibular epiphysis and a variable amount of the adjoining diaphysis. The epiphyseal articular surface is oriented upward and medially to form the proximal tibiofibular joint. The biceps femoris tendon and the lateral collateral ligament are inserted in the lateral and proximal aspect of the epiphysis, which is also where the origins of the peroneus longus and extensor digitorum longus muscles are located. The common peroneal nerve crosses the fibular neck, moving toward the anterior compartment of the leg. The superficial branch is located in the space between the extensor digitorum longus and peroneus longus muscles, while the deep branch reaches the interosseous membrane and joins the anterior tibial vessels, giving several motor branches to the surrounding muscles. Proceeding proximally, the dissection of the vascular pedicle with preservation of the motor branches becomes increasingly demanding because of the increasing number of motor branches surrounding the vessels.

The harvest technique (Video 30.1) has been refined over the years and has been finally described in detail[169,170] with the purpose of standardizing it and making it reproducible. The aim of the procedure is to harvest the proximal

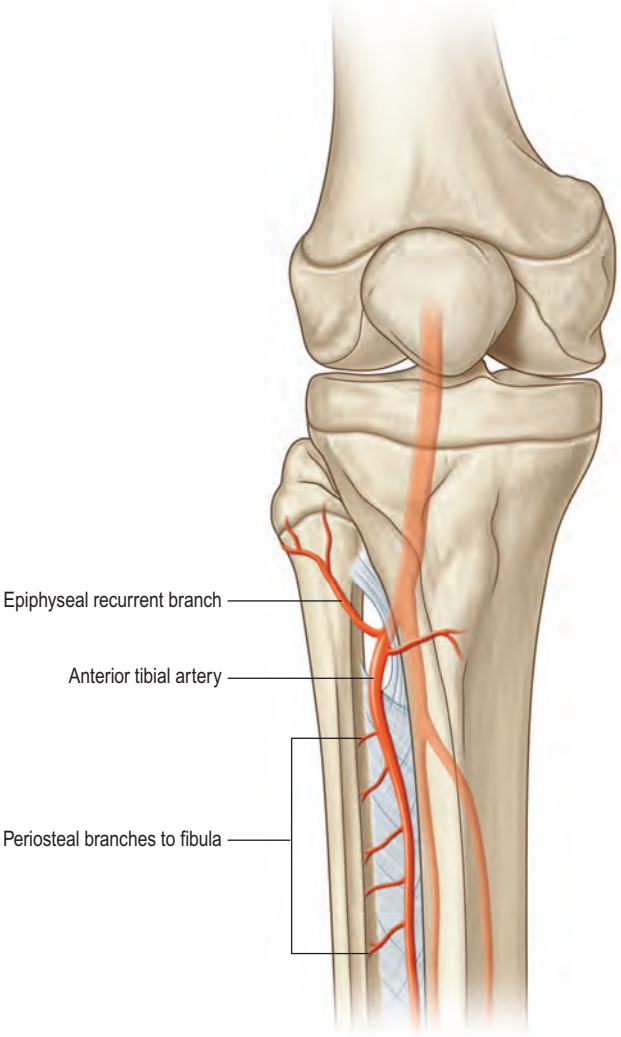

Fig. 30.14 The anterior tibial artery supplies the growth plate and proximal epiphysis by means of a recurrent epiphyseal branch and the proximal two-thirds of the diaphysis by means of musculoperiosteal perforator branches.

fibula, preserving the blood supply to both the epiphysis and diaphysis with the least possible local morbidity. The following step-by-step description is the optimal surgical sequence according to the experience of the senior author (Video 30.1 ▶).

Skin incision

The surgical approach is developed in the plane between tibialis anterior and extensor digitorum longus muscles because this allows for direct visualization of the neurovascular bundle. The skin incision is therefore located in the anterolateral aspect of the leg and is extended proximally up to the neck of the fibula where it proceeds posteriorly and proximally over the biceps femoris tendon (Fig. 30.15).

Exposure of the anterior tibial pedicle

The anterior tibial artery and veins lie on the interosseous membrane. The peroneal nerve surrounds the vessel according to a very intricate tridimensional pattern and delivers several motor branches to the muscles of the anterior compartment of the leg (Fig. 30.16). These motor branches are more numerous in the proximal part of the leg and it is therefore recommended to start the dissection distally and proceed proximally, maintaining the same plane to the fibular neck. Great care should be taken not only in dissecting the nerve from the vessels but also in preserving the small perforator branches of the anterior tibial artery that pierce the extensor digitorum longus and peroneus longus muscles, interposed between the vascular pedicle and the fibular shaft, supplying the periosteum of the proximal two-thirds of the diaphysis.

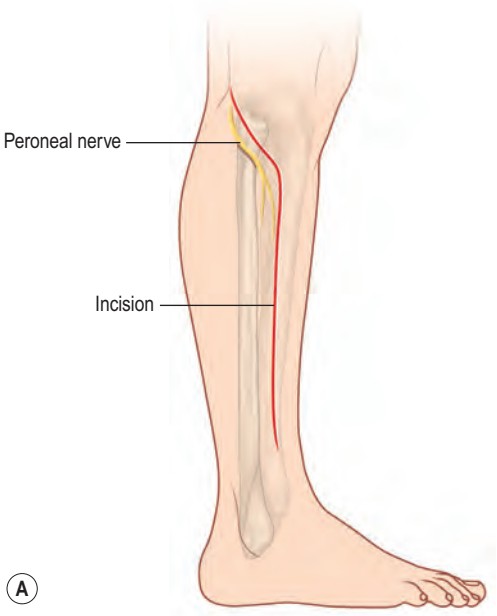

Fig. 30.15 (A,B) An anterolateral approach is used for the harvest of the proximal fibula based on the anterior tibial vascular system. The skin incision is on the projection of the intermuscular space between the tibialis anterior and extensor digitorum longus muscles. The incision is prolonged proximally and posteriorly over the tendon of biceps femoris muscle.

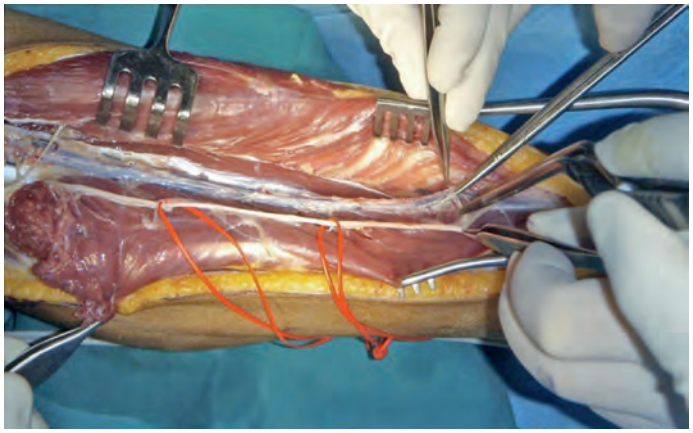

Fig. 30.16 During the diaphyseal dissection of the pedicle, great care must be paid to isolating the peroneal nerve and its motor branches to the muscles of the anterior compartment.

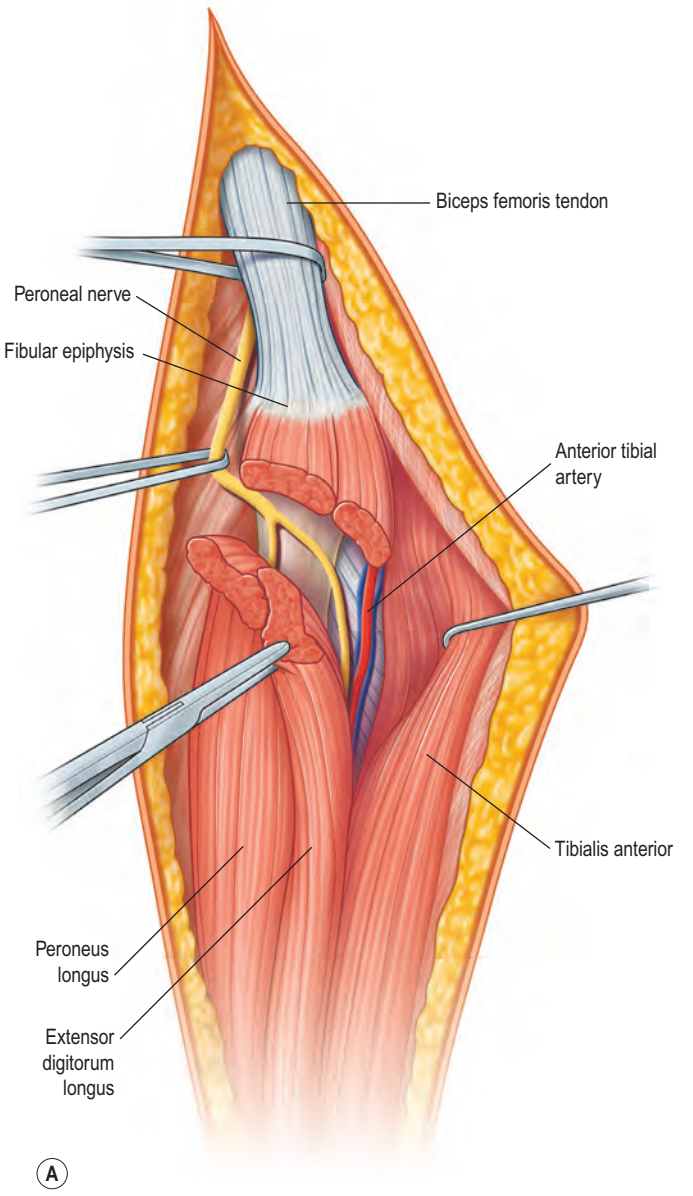
Dissection of the peroneal nerve at the fibular neck

The point where the peroneal nerve approaches the fibular neck is an important anatomic landmark. The nerve is in close contact with the bone and is covered by the proximal portion of extensor digitorum longus and peroneus longus muscles, which must be sharply divided in order to expose and protect the nerve and its motor branches (Fig. 30.17). Medially, at the same level, the recurrent epiphyseal branch of the anterior tibial artery rises from the main artery and pierces the muscular cuff and feeds the epiphysis. Its direct dissection is unnecessary and potentially dangerous; it is therefore recommended to preserve the proximal insertion of the muscles attached to the proximal epiphysis in order to protect the fragile epiphyseal vascular network.

Section of the interosseous membrane and distal osteotomy

The interosseous membrane must be sharply detached from the tibia, and all the soft tissue interposed between it and the vascular bundle must be carefully protected (Fig. 30.18). The perforator vessels to the shaft of the fibula branches off laterally and pierces the of extensor digitorum longus and peroneus longus muscle bellies. In order to maintain the vascular connection between the artery and bone, a longitudinal strip of muscle approximately 1 cm wide should be preserved around the harvested fibula (Fig. 30.19). The fibula is cut distally at the desired length, and an extra portion of periosteum is left in order improve healing capacity at the recipient site. The anterior tibial artery and veins are ligated as distally as possible to obtain a long reverse-flow pedicle.



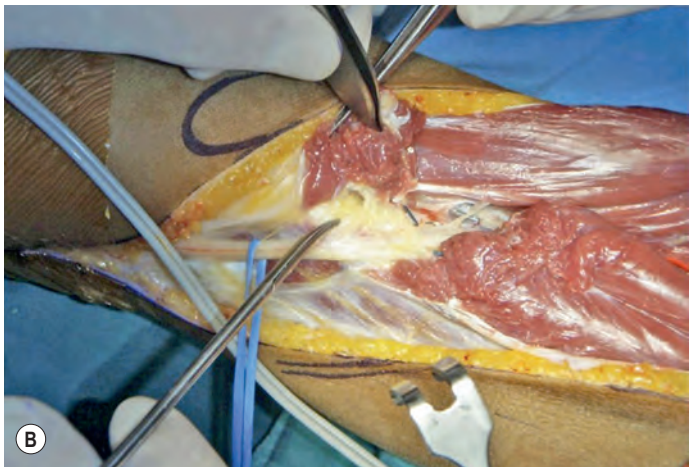


Fig. 30.17 (A,B) The peroneal nerve is an important landmark in proximal dissection. The nerve is exposed in its intramuscular portion by means of sharp section of the extensor digitorum longus and peroneus longus muscles. The muscular cuff proximal to the section must be left intact because it protects the recurrent branch to the growth plate of the anterior tibial artery.

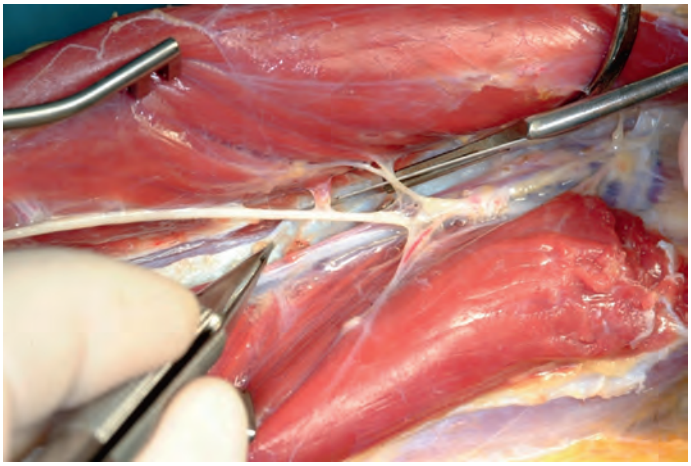

Fig. 30.18 Sharp detachment of the interosseous membrane from the tibia. Note the location of the vascular pedicle and its relationship to the peroneal nerve.

Harvest of the biceps femoris tendon and capsulotomy of the proximal tibiofibular joint

The insertions of the biceps femoris tendon and the lateral collateral ligaments are almost at the same point at the apex of the fibula. The tendon should be divided in two strips (Fig. 30.20): the posterior portion is harvested with the fibula to provide additional soft tissue useful for stabilization of the recipient joint; the anterior half is used to reinforce the lateral collateral ligament after its reinsertion on the lateral aspect of tibial metaphysis by means of staples or transosseous sutures. Gentle external rotation of the fibula allows for the division of the medial and posterior capsule of the proximal tibiofibular joint after coagulation of the lateral inferior genicular artery.

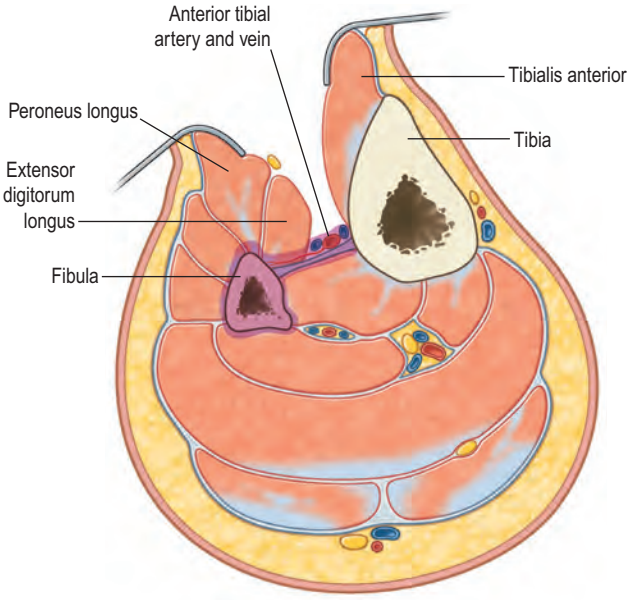

Fig. 30.19 The perforator branches to the diaphysis are too small and fragile to allow a direct intramuscular dissection. It is therefore suggested that a strip of muscle containing the perforators be left intact between the vascular pedicle and the bone.

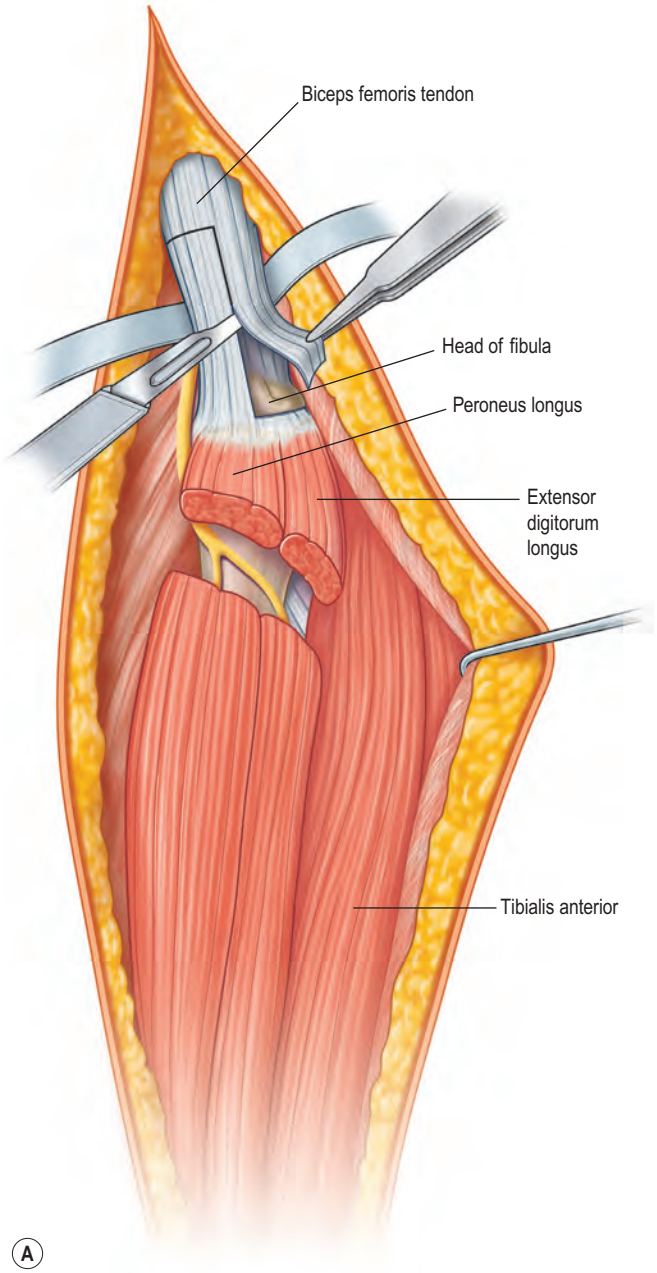

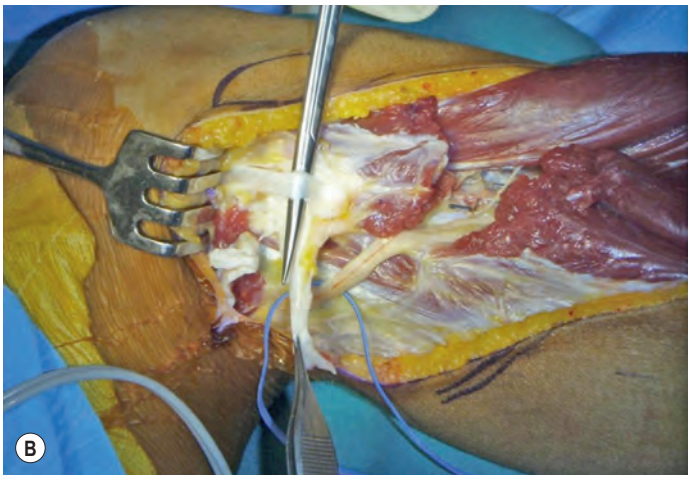

Fig. 30.20 (A,B) The biceps femoris tendon is longitudinally divided in two strips. One is harvested with the bone flap and may be used to improve the stability of the joint after the transfer. The second one is fixed to the lateral aspect of the tibia to reinforce the lateral collateral ligament.

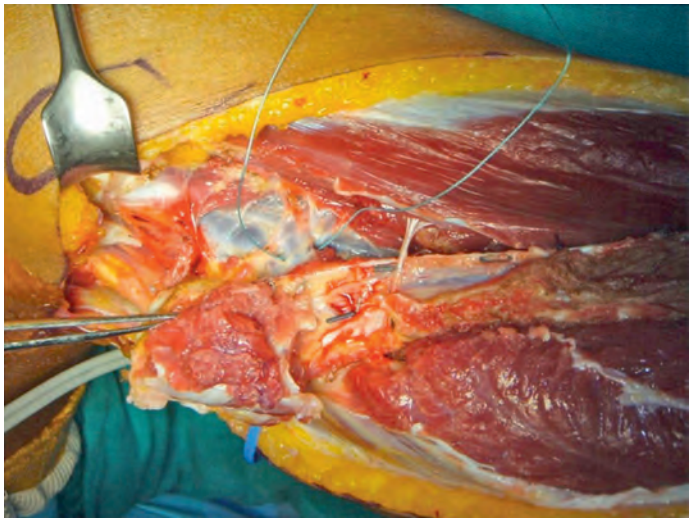

Fig. 30.21 After release of tourniquet and 20–30 min of reperfusion of the flap, the tibialis anterior artery is ligated and severed just distal to its emergence from the popliteal artery.

Final dissection of the proximal portion of the vascular pedicle

The anterior tibial artery should be dissected up to the division of the popliteal artery (Fig. 30.21). The recurrent branch rises from the anterior tibial artery approximately 2 cm distal to its origin, and is often difficult to identify. For this reason, it is advisable to preserve all the small vessels, which pierce the muscular cuff toward the fibular epiphysis. After release of the tourniquet, the muscular cuff surrounding the epiphysis, the diaphyseal periosteum, and the medullary canal are carefully inspected. After a few seconds, bleeding should be observed at the three levels, confirming the successful harvest of the proximal fibula, based on the anterior tibial artery pedicle (Fig. 30.22). Due to low tolerance to ischemia, it is suggested to wait 20–30 min before clipping and dividing the proximal pedicle.

Details regarding the selection of flap vena comitans is given in Box 30.1; osteosynthesis in Box 30.2; and selection of recipient vessels in Box 30.3.

Postoperative care

Donor site

In order to protect the reconstructed lateral collateral ligament, a cast at 30° flexion of knee and neutral ankle position is applied. In children below the age of 8 years, the cast is maintained for 4 weeks; in older and compliant children, the cast may be substituted after 2 weeks with a brace of appropriate size, for a total of 4 weeks of immobilization. The rehabilitation program is started at 1 month postoperatively with the aim of recovering full motion of the knee without compromising stability (Box 30.4).

Recipient site

A long spica cast or a shoulder brace is applied for 4 weeks, respectively, after distal radius and proximal humerus

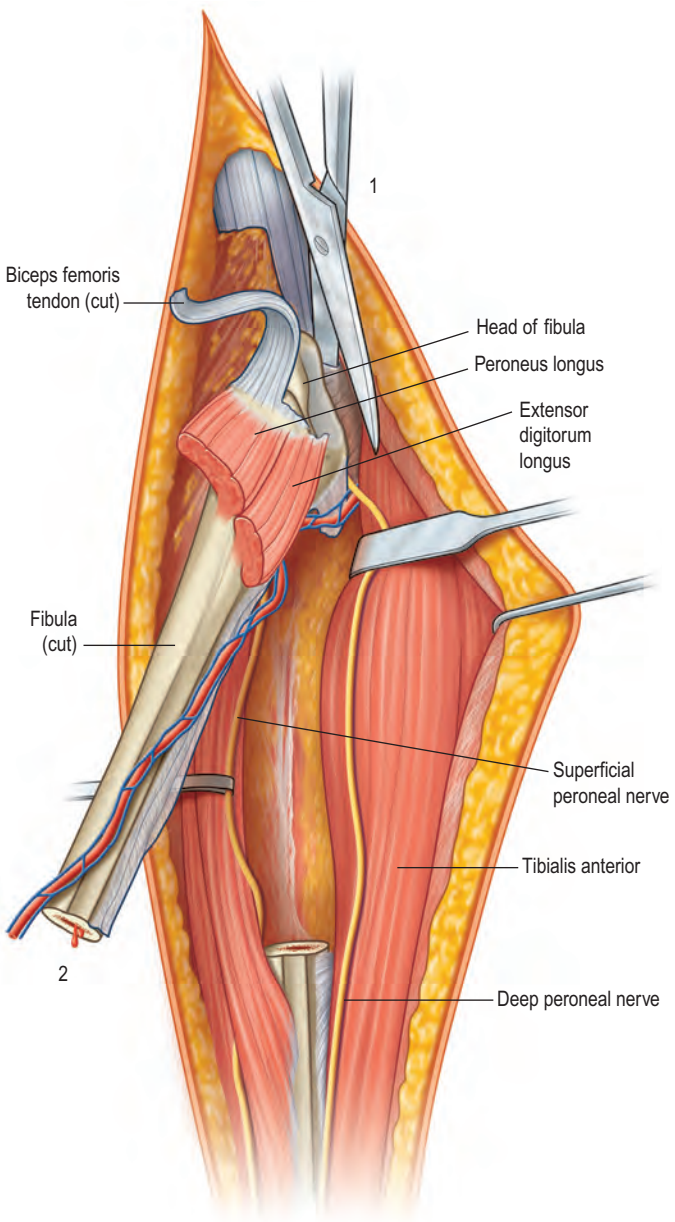

Fig. 30.22 At the end of the dissection, before severing the vascular pedicle, the tourniquet is released to reset the ischemia time. Bleeding should be observed from both the epiphysis and the medullar canal after a few minutes. 1, posterior articular capsule is severed; 2, bleeding from the bone is observed.

BOX 30.1 **Selection of flap vena comitans**

The proximal epiphyseal fibular transfer based on the anterior tibial artery is a reverse-flow flap; however, an adequate venous return is guaranteed by the presence of several small shunts that interconnect the two venae comitantes, allowing the reverse venous flow to bypass the valves. Due to this intricate pattern of valves and shunts, usually, only one of the two venae comitantes has adequate return flow: it is instrumental, for a good outcome, to identify which one is.

After 20–30 min with the tourniquet down, the two venae comitantes are ligated and divided proximally leaving intact the flow through the artery. Within a couple of minutes, the venous flow is inverted and bleeding is evident from one of the two venae comitantes. The bleeding vein is tagged to be anastomosed at the recipient site. (Fig. 30.23).

During the dissection of the vascular bundle care must be taken not to interrupt these delicate venous shunts.

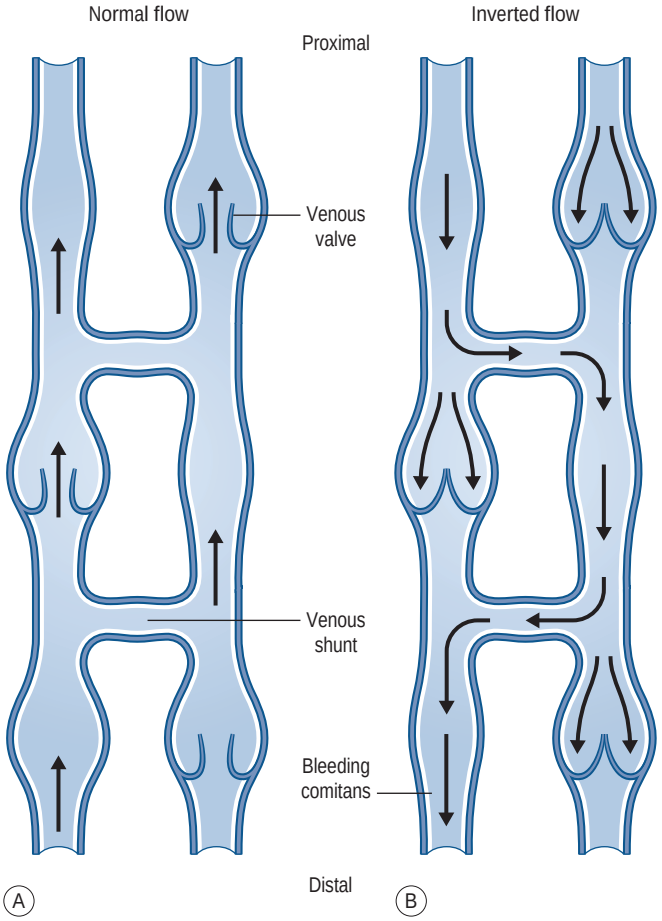

Fig. 30.23 **(A)** Pattern of valves and shunts of venae comitantes. **(B)** When the flow is inverted, bleeding is usually evident from one of the two venae comitantes.

BOX 30.2 **Osteosynthesis**

Humerus reconstruction

The arm is a single bone segment with a high mechanical stress, particularly in case of rotation against resistance. For this reason, a stable bone fixation must be provided; long plates are therefore preferred over less invasive options such as K-wires and screws. However, the implant cannot be too stiff for risk of fracture at the level of the most proximal screw, which is the weakest point of the implant (Fig. 30.24A). In order to provide a more elastic and less invasive bone fixation, we advocate the use of locking compression plates (LCP). The fibula is usually placed for a couple of centimeters in the medullary canal of the distal stump of the humerus and a periosteal flap is wrapped around the bony junction. Then a long LCP plate is placed. Three bicortical screws are used in the humeral portion while few unicortical screws are used in the fibular portion (see Fig. 30.24B). This type of assemblage provides a very stable bone fixation at the junction between fibula and humerus and a minimally invasive and elastic fixation in the fibular segment.

Radius reconstruction

Similarities in size and shape between the radius and the fibula facilitates osteosynthesis in the forearm. Also in this case, LCP plates are the preferred method of bone fixation. As an alternative, lag screws and step-cut osteotomy may be used. The wrist joint is temporarily stabilized with a K-wire which is usually removed 1 month after surgery, in addition the strip of biceps femoris tendon is woven in the residual capsule in order to provide additional stability to the joint. By contrast, the distal radioulnar joint is intentionally left lax without any type of stabilization in order to maintain full range of pronation and supination.

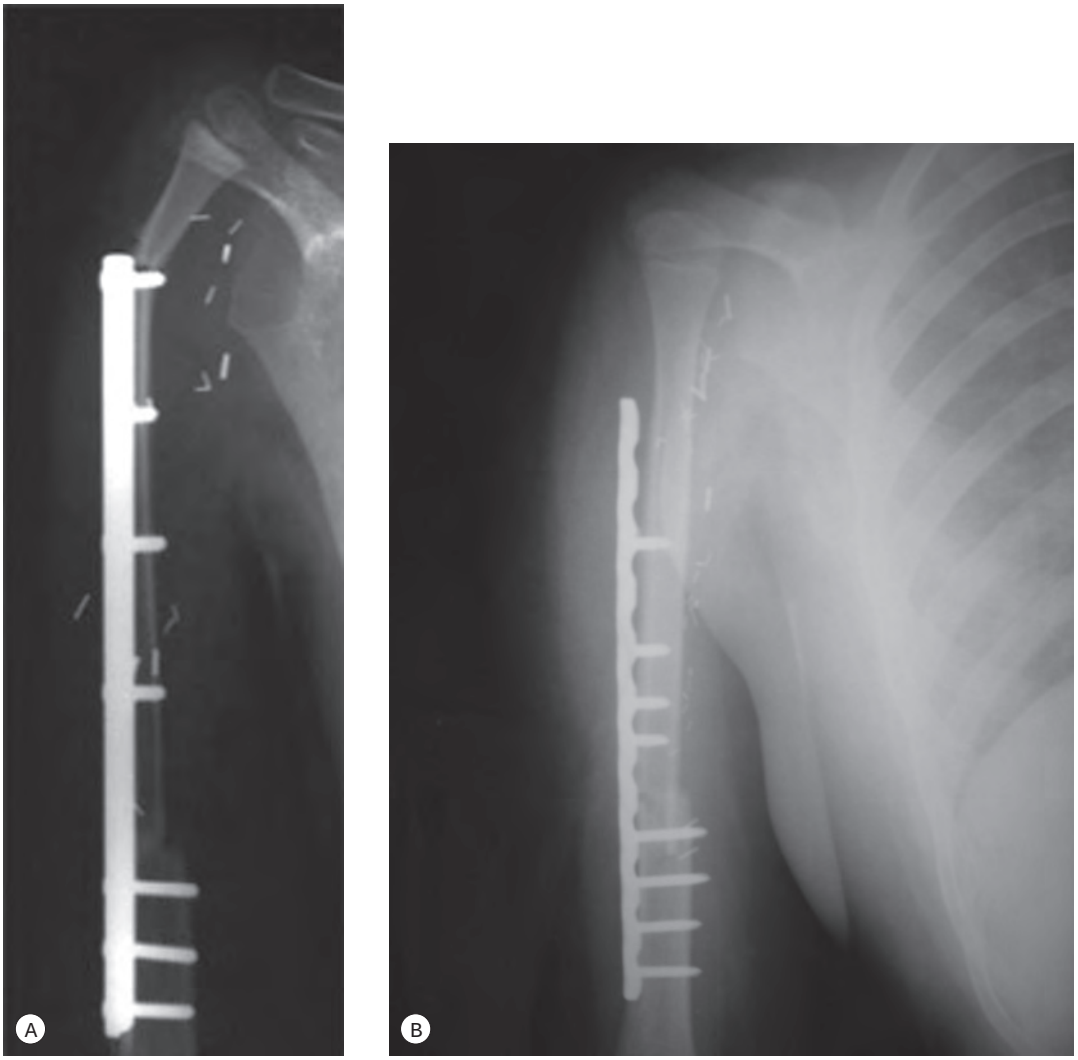

Fig. 30.24 **(A)** Humerus implant: the weakest portion of the implant is at the passage between the hardware and the bone, with higher risk of fracture at these levels especially in case of rigid implants. **(B)** More elastic and less invasive bone fixation.

BOX 30.3 **Selection of recipient vessels**

The harvest of the fibula based on a reverse-flow anterior tibial artery pedicle allows for a long distal pedicle, which may be easily anastomosed to the recipient vessels.

In humeral reconstruction, the deep brachial artery, satellite of the radial nerve, is usually preferred for end-to-end anastomosis with the fibular vessels. If the venae comitantes are too small, the cephalic vein or one of the venae comitantes of the brachial artery may be chosen for venous anastomosis.

In case of radius reconstruction, there are more choices. When the radial artery is resected together with radius, the proximal stump can be easily anastomosed with the fibular pedicle end to end: Alternatively, the anterior interosseous artery may be used end to end because its sacrifice has a negligible impact on hand blood supply.

BOX 30.4 **Postoperative rehabilitation: donor site**

- After 4 weeks of immobilization, the cast or the splint are removed and passive range of motion of knee and ankle is initiated.
- The use of crutches is virtually impossible because of the surgery involving the upper limb and is therefore avoided.
- During the therapy sessions, the child is also helped to get acquainted with the upright position standing only on the non-operated leg.
- The splint is repositioned only at night for 4 more weeks.
- A transient palsy of the peroneal nerve occurs in almost all cases. Great care is taken to avoid equinus deformity of the foot with Achilles tendon retraction. A Codivilla spring is used routinely in all cases of peroneal palsy and maintained until complete recovery. Passive mobilization of the ankle is taught to parents and performed 3–5 times per day.
- Full weight-bearing is usually possible at 2 months after surgery.
- The rehabilitation program is eventually tailored to each patient considering their clinical condition and the necessity of adjuvant chemotherapy.

reconstruction. The rehabilitation program follows the immobilization period and must take into account different variables such as type and stability of bone fixation, amount of muscles excised during the resection, and age and compliance of the patient.

Outcomes, prognosis, and complications

Analysis of the results takes into account the survival of the grafts, as well as their consolidation, longitudinal growth, and remodeling. In a personal series of 27 cases of upper limb skeletal reconstruction after bone sarcoma resection with epiphyseal transplant, all the transferred bones except one survived and healed with the recipient bone in a period of time ranging from 1 to 2 months. This variability depended on the age of the child and the length of the reconstructed segment. In some cases, the viability of the transplant was confirmed by bone scan.

Significant axial growth, calculated by the progressive increase in the distance between the tip of the metal plate used for bone fixation and the apex of the epiphysis of the transferred fibula, has been observed in approximately 70% of cases monitored. Its extent was variable depending on factors that are only partially known, amongst which the patient's age was predominant. The annual growth trend varied between 0.7 and 1.35 cm (Fig. 30.25), and in all cases there was prevention of future length discrepancy with the opposite limb. As far as the radius is concerned, symmetrical growth was observed in the neoradius in all cases, not only with respect to the opposite limb, but also to the adjacent ulna, which confirms the integration of the fibula into its new anatomical site. The average flexion of the wrist was 75°, while the average extension was 63°. The overall range of movement was equal to on average 70% of the opposite hand, which allowed for excellent functional recovery. The prosupination range was also restored.

Fig. 30.25 Postoperative radiograph and 4-year follow-up of one case of distal radius reconstruction. In this case, the average growth per year was 0.9 cm.

In cases of humeral reconstruction, the functional outcomes were not as positive. The morphological and dimensional discrepancy between the fibular head and the glenoid fossa may lead to proximal migration of the fibular epiphysis and, in some cases, subacromial displacement. Moreover, the extent of soft tissue involved in the neoplasia and consequently removed further hinders functional recovery. In all monitored cases, however, shoulder abduction between 70° and 100° was observed.

Premature ossification of the growth plate and consequent end of growth were observed in five cases of humeral reconstruction. Two of these transplants were based on peroneal vessels, which, in our opinion, are not as reliable in ensuring correct epiphyseal perfusion. In the other three cases, the epiphyseal artery was probably damaged during stabilization in the glenohumeral joint. Five fractures of the neohumerus and two of the neoradius were observed. All the fractures but one healed conservatively in due time. Replacement of an inadequate fixation was performed in one case.

In four cases of proximal humerus reconstruction, incorrect alignment between the fibula head and glenoid fossa was observed. In these cases, the epiphysis migrated subacromially. The reasons for this complication are the anatomical mismatching between fibular head and glenoid fossa and the extensive oncological excision of muscles and ligaments with consequent joint stability. All the four cases, however, recovered an acceptable range of motion.

With transosseous suture of the lateral collateral ligament at the donor site, no residual instability of the knee was ever observed. Neuropraxia of the peroneal nerve occurred in approximately two-thirds of cases. This was probably caused by stretching of small motor branches during the dissection. This deficit resolved spontaneously within 1 year in all but two cases. One of the patients had a permanent residual paralysis of the tibialis anterior and one of the extensor digitorum longus muscles.

Secondary procedures

Secondary procedures may be necessary at both the donor and the recipient site.

Donor site

In case of permanent palsy of the peroneal nerve, a tendon transfer is indicated to restore the function of the tibialis anterior muscle. In our series, we observed no cases of knee joint instability.

Recipient site

A feared complication is the total loss of the graft due to failure to restore its blood supply. We did not observe this complication but its treatment would require the use of a massive frozen allograft as salvage procedure. In the majority of cases, the fate of an osteoarticular allograft in the medium/long term is a massive resorption of the articular cartilage, which should be treated with a prosthetic replacement of the allogenic humeral head.

In our experience, we have observed premature growth arrest, probably due to vascular damage to the physis, in five cases of proximal humerus reconstruction. Despite the limb

length discrepancy, all patients have an acceptable function and no further surgery was required.

A relatively frequent complication is graft fracture in proximal humerus reconstruction. In our series, this event was usually successfully treated conservatively with immobilization in a cast. Nonetheless, revision of the hardware and cancellous bone grafting may be considered in cases of displaced fractures.

Future directions

Although epiphyseal transfer proved to be a reliable and effective reconstructive option in case of skeletal disorders involving an immature epiphysis, this procedure is not widely used yet. The technique is well standardized, and several papers are now available in the literature reporting, in the vast majority of cases, either the reconstruction of the proximal humerus or the distal radius. In the future, new recipient sites might be added to the classic ones, taking advantage of the high remodeling potential of the immature fibular head. We have recently used this technique for mandible reconstruction on a child affected by osteoblastoma of the mandibular condyle, with encouraging results. In selected cases, other joints might benefit from reconstruction with vascularized proximal epiphyseal transfer.

Congenital differences at the wrist level, such as radial and ulnar dysplasia, are now successfully treated with this procedure. A few cases of radial dysplasia have been, indeed, reported recently with good results.[160] These cases, though, need a longer follow-up to evaluate the growth rate. These initial results are very encouraging, and epiphyseal transfer of the proximal fibula may be a valid alternative to the procedure described by Vilkki,[171] which is, at present, the only alternative to the conventional techniques.

Vascular anomalies of the upper extremity

Joseph Upton III and Amir Taghinia

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Vascular anomalies of the upper limb are divided into tumors (including hemangiomas) and malformations.
- Hemangiomas have a biphasic growth phase consisting of proliferation and spontaneous involution; malformations tend to expand slowly throughout life.
- Hemangiomas are usually treated conservatively, whereas vascular malformations can be managed by observation, sclerotherapy, embolization, and/or surgical resection.
- Surgical resections can be predictably performed if basic principles are followed; venous malformations, lymphatic malformations, and combined lesions are most amenable. Many technical refinements have made these operations safer and more predictable.
- Fast-flow lesions with or without fistulae comprise the most difficult group of lesions; their natural history is one of gradual progression.
- New discoveries in the biochemical pathways responsible for these lesions hold promise for future medical therapy.

Introduction

During the past five decades, there has been a steady, almost exponential increase in our knowledge of vascular anomalies. A biological classification system has evolved and is under constant refinement.[1] A careful physical examination augmented with advanced imaging will yield an accurate diagnosis from the vast myriad of possibilities. A multidisciplinary team can offer individualized treatment with some degree of predictability. Improvements in minimally invasive radiological procedures have dramatically transformed treatment of these lesions. With discovery of biochemical agents and pathways responsible for these lesions, widening application of medical therapies show promising outcomes. However, in many patients, surgical treatment is often the best remedy and should not be viewed as the last resort. A carefully planned and well-orchestrated procedure and rehabilitation can yield remarkable outcomes.[2]

Clinical tip

Vascular anomalies are complex problems and are best approached by a multidisciplinary team. In our center, we have a weekly conference and a separate weekly clinic where the team meets to discuss individual patients. Representatives from radiology, general (pediatric) surgery, hematology, anesthesiology, plastic surgery, dermatology, and scientists from the laboratory all attend. Other specialists such as neurosurgeons, orthopedic surgeons, oral surgeons, ophthalmologists, endocrinologists, and head and neck surgeons are called as needed. Thus, a comprehensive approach to patient care can be undertaken, with immediate availability of ultrasound imaging and expert opinion. This approach has been monumental in the correct diagnosis and treatment of hundreds of patients.

Classification and Overview

The etiology of vascular birthmarks has long stimulated the fertile imagination of humans. Historically, classification systems have reflected a balance between folklore and science. Well into the 19th century, the doctrine of maternal impressions dictated that a gravid mother's craving for strawberries, sight of an accident, or emotional longing could imprint a vascular blemish, a *naevus maternus*, on her unborn child.[3,4] With the development of the microscope, a vast number of histological terms have been introduced. Despite these academic advances, most lesions are still inaccurately labeled as hemangiomas. Study of the histopathology and natural history of these lesions spawned intriguing embryological classifications,[5,6] which seemed logical at the time but failed to distinguish involuting from non-involuting lesions and offered little guidance in management. In the late 1970s, Mulliken and Folkman proposed a working hypothesis that these cells could be distinguished by their cellular characteristics and

subsequently surgical specimens were analyzed by selected histological stains, electron microscopy, and autoradiography (uptake of tritiated thymidine into DNA). On the basis of these studies, two types of lesions were present: those that showed endothelial hyperplasia, called *hemangiomas*, and those that did not, called *malformations*. A binary schema based on biologic activity was proposed[1] and accepted by the International Society for the Study of Vascular Anomalies (ISSVA) in 1996.[7] This system has been corroborated by both radiological studies[8,9] and immunohistological staining.[10] However, "no system is carved in stone and must be written on recyclable paper" and is in a constant state of revision. For example, the initial category of "hemangiomas" has been changed to "vascular tumors" to include all vascular tumors in all age groups. A particular vascular lesion may be moved from one category to another or may be discarded completely with expansion of clinical experience and basic science investigation. For the past 30 years, this system has been very helpful to the upper limb surgeon in the proper diagnosis and management of these lesions (Table 31.1). Most frustrating are the large number of eponyms with and without abbreviations, which have been attached to these lesions. These terms are often used indiscriminately without specific reference to cell type, flow characteristics, and growth. Adding to the confusion is the common association of growth disturbances. Both overgrowth and undergrowth with and without dysplastic fat deposition may accompany vascular anomalies. The summary in Table 31.2 helps delineate our present state of knowledge of this nosologic quagmire. The recent discovery that somatic activating mutations in the phosphatidylinositol-3-kinase (PIK3CA)/mammalian target of rapamycin (mTOR) pathway appear to underlie a number of overgrowth phenotypes (termed PIK3CA-related overgrowth spectrum, PROS)[11] promises to provide some degree of molecular differentiation to these disorders.[12–14] Table 31.2 appears online only.

Table 31.1 ISSVA classification of vascular anomalies

Vascular tumors	Vascular malformations
Slow-flow vascular malformations	
Hemangioma:	Capillary malformations (CM):
Infantile hemangioma (IH)	Port-wine stain
Congenital (CH)	Telangiectasias
Non-involuting congenital hemangioma (NICH)	Angiokeratoma
	Venous malformations (VM):
Rapidly involuting congenital hemangioma (RICH)	Common sporadic VM (VM)
	Blue rubber bleb syndrome (BRBS) or Bean syndrome
Hemangiomatosis	Glomuvenous malformation (GVM)
Pyogenic granuloma	Familial cutaneous and mucosal venous malformation (VMCM)
Kaposiform hemangioendothelioma (KHE)	Maffucci syndrome
	Diffuse VM (Bockenheimer)
Rare tumors:	Lymphatic malformations (LM):
Hemangioendothelioma	Common lymphatic malformation (LM)
Infantile fibrosarcoma	Lymphangiomatosis
Hemangiopericytoma	Gorham–Stout syndrome
Giant cell angioblastoma	
Fast-flow vascular malformations	
	Arterial malformation (AM)
	Arteriovenous malformation (AVM)
	Arteriovenous fistula (AVF)
	Complex-combined vascular malformations
	CVM, CLM, LVM, CLVM (Klippel–Trénaunay),
	CM-AVM (Parkes Weber), AVM-LM
	Proteus, hemihypertrophy, capillary–lymphatic–overgrowth–vascular–epidermal nevus (CLOVE)

ISSVA, International Society for the Study of Vascular Anomalies.

A correct diagnosis impacts directly upon appropriate treatment and an incorrect diagnosis may result in unnecessary or harmful remedies. Most upper limb surgeons designate all fast-flow anomalies with or without arteriovenous fistulae as Parkes Weber syndrome (PWS). However, PWS patients comprise a very small percentage of the fast-flow group, which comprises about 15% of upper extremity fast-flow malformations.[15] Not all slow-flow combined malformations should be called Klippel–Trénaunay syndrome (KTS), an eponym we reserve for combined capillary–lymphaticovenous malformation (CLVM) lesions. The venous malformation (VMs) collectively comprise the largest clinical group of patients evaluated by the hand surgeon. The majority are small lesions involving all portions of the upper limb and/or ipsilateral chest wall. Other subgroups have emerged. The diffuse VMs involving all structures within the upper limb including bone have been designated Bockenheimer lesions,[16] originally described as "diffuse genuine phlebectasias", and are not amenable to surgery with the exception of pathologic fractures and localized areas of symptomatic thromboses. Maffucci patients commonly get skeletal enchondromas but many of the skeletal lucencies may be clusters of VMs, which are also found in abundance within the soft-tissue planes.[17,18] The glomuvenous (GVM) lesions occur in clusters with a characteristic appearance, are painful, have been localized to chromosome 1p21–22, and in the past were called glomus tumors or glomangiomas.[19] They have been renamed to stress the fact that they are malformations and not tumors (as suggested by the suffix "oma"). The VMs seen in the blue rubber bleb nevus syndrome (BRBNS) also have a characteristic cutaneous appearance, are also familial and often confused with GVM, Maffucci and capillary malformations–venous malformations (CM–VM).[20] The associated gastrointestinal lesions, often localized to the small bowel, are often the cause of anemia and iron deficiencies (see Table 31.7).

Lymphatic malformations (LMs) often occur in combination with other vascular elements but the most common varieties are either isolated or diffuse LMs, which may involve any portion of the upper limb and/or ipsilateral chest wall.[15] Lymphangiomatosis conditions are not of primary concern to the upper limb surgeon as they involve visceral organs and/or the lungs and in the long run are life endangering. Nevertheless, a microsurgical approach to treatment of central lymphatic conduction anomalies may be of some utility.[21] LMs in the Gorham–Stout syndrome involve skeletal structure including the humerus, radius, ulna and tubular bones of the hand.[22] Pathologic fractures can occur.

Table 31.2 **Diagnostic work-up of vascular anomalies**

	Klippel–Trénaunay (KT)	Parkes Weber (PW)	Lipomatous	CLOVES	Hemihypertrophy	Proteus	Maffucci
Capillary stain	Present, deep purple	Present, pink, often diffuse	Rare	Present, pink, diffuse, truncal	Uncommon	Present, pink, often diffuse	Absent (rarely reported)
Progressive overgrowth	Present	Present	Present, symmetrical	Present, often extensive	Either overgrowth or undergrowth	Absent at birth, haphazard, unrelenting, disproportional	Secondary to enchondroma growth, moderate to massive
Hemodynamics	Slow flow	Fast flow	Slow flow	Slow flow	Slow flow	Slow flow	Slow flow
Vascular anomalies	VM, LVM	AVM, AVFs	Absent	VM, LVM, LM	Absent	VM, LM, CM	VM including within bone, hand common
Associated anomalies	Common: GI, GU, genitalia Hypoplastic lymphatics Deep venous anomalies	Rare, Cobb syndrome	Absent	No visceral	Skin, CNS, heart, GU, dental, others	Cerebriform soles/palms, linear nevi, dysregulated fat, lung cysts, neoplasm, facial phenotype	None
Limb enlargement	Moderate, disproportionate digits and toes common	Arm, leg length discrepancy	Moderate, nerve-territory oriented	Moderate	Macrodactyly, syndactyly, polydactyly, club feet	Major, asymmetrical	Disproportionate
Limb affected	Upper 5%, lower 95%	Upper 23%, lower 77%	Equal	Equal	Arms, hands equally	Arms/legs, hands/feet equal	All
Skeletal changes	Unusual, can occur with large lesions	Common, direct involvement, demineralization	Common, symmetrical	Marked scoliosis, lower limb	Hip dysplasia, scoliosis, increased bone age	Skull hyperostosis, vertebral megaspondylodysplasia	Gross distortion, asymmetry, limb length discrepancy, phalanges common scoliosis, short stature, fractures
Macrodactyly	Diffuse enlargement	Minimal to moderate	Moderate to gigantic	Diffuse or longer with flexion contractures	Digits longer with flexion or extension contractures	Asymmetrical, moderate to gigantic	Digits longer with asymmetrical masses, increased size due to tumors
Dysregulated fat	Present within malformation	Present	Common, entire limb and axilla	Present	Multiple lipomas	Lipomas, regional fat absence	Present occasionally
Nerve involvement	Absent	Absent	Intermittent	Intermittent	Absent, compression neuropathies with contractures	Absent	Absent

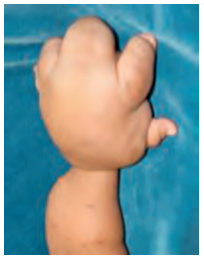
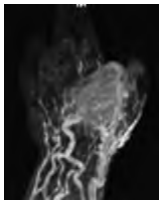
Table 31.2 **Diagnostic work-up of vascular anomalies—cont'd**

	Klippel–Trénaunay (KT)	Parkes Weber (PW)	Lipomatous	CLOVES	Hemihypertrophy	Proteus	Maffucci
Muscle anomalies	Displaced by VM, LVM	Displaced by malformation	Absent	Absent	Common, atavistic intrinsic and extrinsic muscles	Absent	None
Associated neoplasms	Absent	Absent	Absent	Absent	Renal, adrenal and CNS	Ovarian, parotid	Chondrosarcoma (17.5–30%), many others less frequently, ovarian, CNS
Coagulopathy	Present	Normal	Normal	Normal	Normal	Normal	None
Increased cardiac output, CHF	No	Yes	No	No	No	No	No
Clinical prognosis	Stable	Often progressive deterioration Steal phenomenon Worse with CHF or amputations	Good, related to size and weight of limb	Progressive deterioration with extensive limb involvement	Progressive contractures (flexion or extension, intrinsic)	Progressive growth of affected regions	Good with local Rx; Ollier's patients increased problems
Risks	DVT, risk increased postoperatively	Infection, CHF, gangrene	Secondary arthritis	Scoliosis, pulmonary compromise	Neoplasms: pheochromocytoma, Wilms, hepatoblastoma	Neoplasms, PE, depression	Pathologic fractures
Genetics	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown
		 					





AVF, Arteriovenous fistula; AVM, arteriovenous malformation; CHF, congestive heart failure; CLOVES, congenital lipomatous overgrowth with vascular malformations, epidermal nevi, and skeletal anomalies; CM, capillary malformation; CNS, central nervous system; DVT, deep vein thrombosis; GI, gastrointestinal; GU, genitourinary; LM, lymphatic malformation; LVM, lymphatico-venous malformation; PE, pulmonary embolism; Rx, treatment; VM, venous malformation.

There are many conditions in which vascular anomalies, *overgrowth* or *undergrowth* coexist and with our present state of knowledge, it is difficult to draw clear lines due to the increasing amounts of growth factors found in the omnipresent dysplastic fat tissue within these extremities. Often at their vascular clinic reviews, the authors encounter lesions that do not fit into any specific category and are designated as "PUVA", for *provisionally unique vascular anomalies*. With time, this large group of "unknowns" will become more precisely defined. Several examples of recent breakthroughs in clinical diagnosis and biochemical markers include: discovery of PIK3CA[12,13,23] in overgrowth conditions, and the identification of CLOVES syndrome (congenital lipomatous overgrowth with vascular malformations, epidermal nevi, and skeletal anomalies) as well as fibro-adipose vascular anomaly (FAVA).[24]

Children with CLOVES present with large extremity and truncal CMs, moderate to marked overgrowth, large fatty tumors, either LMs or VMs, and epidermal nevi.[25,26] They have characteristic upper extremity anomalies including macrodactyly, syndactyly, joint contractures, wide spade-like hands, with hyperextension/hyperabduction of the thumb. Previously, most of these cases had been called "macrodactylies", "gigantism", or Proteus and did not fit the criteria for the Proteus syndrome (see Table 31.2 ◍).[27,28]

FAVA was recently described as an entity similar to but distinct from venous malformation.[24] This lesion is dense and does not contain large vascular channels amenable to traditional sclerotherapy or steroid injections. It usually affects muscles in the extremities. Pain is the hallmark symptom and surgical resection the only known effective treatment.

Another group of confusing lesions can be found in the fast-flow group, where all lesions should not be called Parkes Weber (PWS) anomalies. Most fast-flow lesions are easily diagnosed by their clinical characteristics, palpable bruits, shunts, and progressive growth. A small group of these children seen by the extremity surgeon may have mild hypotonia, fast-flow deeper lesions and frontal bossing. Males have a nevus on the glans of the penis. In the past they were placed in the Bannayan–Riley–Ruvalcaba syndrome (BRRS) or the Cowden syndrome. Genetic testing is diagnostic and they are now called the PTEN hamartoma-tumor syndrome (PHTS) (see Table 31.8).[29,30] The hand surgeon may also see the capillary malformation–arteriovenous malformation (CM–AVM) syndrome, which initially appears to be an innocent CM, which are pinkish red and surrounded by a small halo. One-third of these patients may have an existing AVM and 12% may evolve into a PWS and intracranial AVMs should be considered. This condition is hereditary and is caused by a mutation in *RASA1*.[31,32] The PWS describes a diffuse AVM of an overgrown extremity with an overlying CM.[33] In contrast to lesions with direct arterial–venous shunting (AVMs with arteriovenous fistulas [AVFs]), PWS lesions show diffuse involvement of all soft-tissue structures with fast-flow arterioles in the initial absence of large draining veins. Large shunts develop secondarily. The lower extremity is involved much more frequently than the upper limb.

Diagnosis/patient presentation

Evaluation begins with a detailed history and physical examination. In contrast to the rapid growth and slow involution that characterize infantile hemangioma (IH), vascular malformations usually continue to grow. Although vascular malformations are by definition present at birth, many are inconspicuous and some do not appear until late childhood. Dermal ectasias, such as the relatively common capillary malformation ("port-wine stain"), are usually noted in the newborn nursery. Rarely, later in life will it become obvious that some of these capillary stains overlie a slow-flow (venous or lymphatic) anomaly or a fast-flow (arteriovenous) malformation. Venous and lymphatic malformations often coexist and may be quite insidious in their initial presentation. Venous malformations may not manifest until late childhood or adolescence; large lesions are usually obvious within the first 4–8 years of life. Fortunately, the vast majority of vascular malformations are correctly diagnosed by clinical examination alone.[4,15,34,35] It is important to obtain baseline functional data including length and circumference of the affected *and* unaffected limbs early in life and to follow these children as they grow. The clinical characteristics of the more common malformations will be described with the individual case presentations.

The diagnostic work-up varies for each type of vascular anomaly (Table 31.3). Ultrasonography is the "go-to" initial radiological test for these lesions, and can easily confirm the initial distinction between a vascular tumor and vascular malformation.[36] In our center, the ultrasound is typically done in the clinic room with a portable machine. This diagnostic tool not only pinpoints the location of the lesion but also enables its identification as either slow-flow or fast-flow. Expensive diagnostic studies are unnecessary in the case of a diffuse or localized, asymptomatic slow-flow malformation or a small fast-flow lesion amenable to simple excision and closure. When a patient is symptomatic or if an operation is being considered for a large vascular anomaly, one should learn as much as possible about the size, extent, depth, and three-dimensional (3D) characteristics of the lesion. Magnetic resonance imaging (MRI) with contrast (gadolinium) is the "gold standard". Fat-suppressed T1-weighted sequences with contrast will differentiate between a vascular tumor and malformation.[37] MRI can also help distinguish between lesions similar to VM such as FAVA[24] or intramuscular hemangioma (Enzinger type).[38]

Computed tomography (CT) can be used to detect interosseous involvement or skeletal distortion caused by a vascular malformation and help delineate soft-tissue planes. Large cystic cavities in an LM are clearly depicted. New 3D rendering of both fast-flow and slow-flow malformations using CT technology provides very impressive views of the entire malformation and its relationship to neighboring soft tissue and skeletal structures. Three-dimensional rendering of computed tomography angiography (CTA) can be invaluable preoperatively. Plain radiology of the affected region provides very little information other than showing the presence of phleboliths and interosseous involvement or other skeletal distortions. Angiography has very little use in the diagnosis of slow-flow malformations, although it is indispensable in the diagnosis and assessment of fast-flow lesions.[15] The angioarchitecture and 3D anatomy of the malformation can be precisely determined and the arterial suppliers and draining veins clearly identified. Indirect and direct phlebography techniques are sometimes used for diagnostic and therapeutic purposes for VM in the extremity.

Table 31.3 Vascular anomalies and overgrowth conditions

Diagnostic work-up	Condition		
	Hemangioma	**CM**	**VM**
Physical examination	++++	++++	++++
Ultrasound	+++	–	+

AVM, Arteriovenous malformation; CM, capillary malformation; CT, computed tomography; LM, lymphatic malformation; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; MRV, magnetic resonance venography; VM, venous malformation.

Treatment/surgical technique

The treatment of vascular anomalies has evolved significantly. Although many of these lesions were treated surgically in the past, advanced knowledge and minimally invasive techniques have changed our approach. Now, most of these lesions are best treated by interventional radiologists. As we further elucidate the molecular basis of vascular anomalies, medical therapy continues to improve. Examples include steroids and beta-blockers for infantile hemangioma. Moreover, sirolimus (also known as rapamycin) is being used more frequently to treat large, difficult lesions with promising outcomes.[39] Despite many advancements, however, a subset of these lesions is still best treated with surgery.

Surgical treatment of vascular anomalies is not an endeavor for the timid or the arrogant (Video 31.1 ▶). A well-balanced approach that incorporates calculated risk and cautious execution is necessary – one that can only be cultivated with experience. The surgeon who devotes a practice to the treatment of these lesions is obligated to document meticulously and analyze critically – habits that will serve one well for life-long learning. Most lesions can never be absolutely eradicated. Re-expansion or recurrence is the rule, despite significant

Table 31.4 Principles of management

1. Clear explanation of surgery and complications. Give parents time to make decisions
2. Carefully planned and thorough dissection within a well-defined region
3. Meticulous hemostasis under tourniquet control, bloodless field
4. Fine instruments, magnification, good assistance
5. Judicious incision placement. Avoid dorsum of hand or digit
6. Identification of all structures, preservation tendons, joints, and nerves
7. Dissect no more than half of a digit or limb at a time
8. Avoid vascular compromise. One side at a time. One vessel intact
9. Avoidance intraneural dissections. Neuromas are a nemesis
10. Quick operating rehearsed with assistance if possible
11. Resect marginal skin. Tension free closures. Good tissue coverage
12. Thoughtful, meticulous closures. Subcuticular techniques best
13. Liberal use of drains, tissue sealants, and delayed closures
14. Appropriate early immobilization and subsequent early joint range of motion
15. Aggressive treatment of complications. Amputation of functionless extremities
16. Conscientious, regular follow-up for those with significant malformations
17. A full explanation of potential complications to parents and patients

extirpative operations. This is an important consideration `in preoperative planning, patient counseling, and future interventions.

Surgical principles gain acceptance with time and must be periodically reassessed and refined, particularly in this rapidly advancing field. Principles should not be confused with techniques that change frequently, and are modulated to a great extent by technology. Many of the following surgical principles have evolved from the early operative experience with vascular malformations (especially the fast-flow types), which was punctuated with complications (Table 31.4).[2,3]

1. *Preoperative planning* should include correlation of the size, extent, and involvement of structures with physical examination and imaging. All studies should be reviewed preoperatively; serial studies of growing children are often invaluable in demonstrating the true extent of involvement. A thorough explanation of all potential complications must be given to the patient and/or parents.
2. The surgeon should mentally *outline the extent of the resection and abide by it*. Use of the pneumatic tourniquet and complete exsanguination is necessary to visualize normal and abnormal structures clearly, regardless of the size of the malformation. Once the operative field becomes bloodstained, the identification of nerves, tendons, intrinsic muscles, and other structures is more difficult.
3. *Placement of incisions* is important – particularly in children. A high midaxial incision in the digit is preferred, as it can be used again and is hidden. With growth, palmar scars within or near the palm can lead to contracture. If a palmar approach is chosen, a zigzag incision is preferred, utilizing existing skin creases. If multiple debulking procedures are contemplated in the upper arm or forearm, each incision should be planned carefully to avoid unnecessary scarring. The medial surface of the arm, elbow and forearm is the least conspicuous. Incisions in the weight-bearing plantar surfaces of the foot should be avoided. The placement of incisions in the medial arch, along the borders of the foot, and on the dorsal surfaces is safe. Scars in the webspaces or along eponychial and/or paronychial folds will contract and are likely to become problematic.
4. *Magnification*, either loupe or microscopic, makes a tremendous difference in the identification and preservation of normal neurovascular structures. Small vessels, such as vincular pedicles to the flexor tendons and nutrient vessels to the carpal bones, should be saved if uninvolved. Often, vascular anomalies will displace, but not typically invade, neighboring soft tissues.
5. *Avoid vascular compromise*. Only one-half of a digit should be dissected at a time (see Table 31.6). If possible, at least one or two large dorsal veins per finger should be preserved to enhance venous drainage, especially when excising a diffuse lymphatic lesion in the hand or foot. The superficial venous system should not be resected unless a deep system has been identified. When a critical arterial segment to a digit, hand, or foot is removed, this segment should be reconstructed with a vein graft so that at least one digital artery is preserved per digit and one major artery supplies the hand or foot with a functional intact palmar or plantar arch.
6. *Avoid intraneural dissection* whenever possible, despite gross involvement. Although many vascular malformations, particularly VMs and PTEN lesions, are entangled in nerves, dissection often leaves in-continuity neuromas with partial or complete loss of distal sensory or motor function. The symptoms are usually much worse than the initial ones.
7. *Avoid partial dissections within large muscle groups*. Removal of the entire muscle *en bloc* is preferred to avoid a secondary contracture of the entire musculotendinous unit. If more than half of a skeletal muscle is excised piecemeal, a secondary contracture is likely. VMs, mixed CLVMs, capillary malformation-arteriovenous malformation (CM-AVM) and lymphatico-venous malformations (LVMs) are the most problematic lesions. The best treatment for large FAVA lesions appears to be *en bloc* excision of the entire involved muscle.
8. *Replace abnormal or ischemic skin* with a skin graft or a flap. Tissue with questionable viability can be observed and resected later, if necessary. It is usually best to remove and replace skin that is heavily scarred from a previous procedure, chronically infected and ulcerated, populated by lymphatic vesicles or deprived by a proximal steal phenomenon.
9. *Drains* should be used liberally, and delayed primary closure of the wound should be considered. Persistent postoperative bleeding is usually best treated with direct pressure, elevation, and immobilization, rather

than by re-exploration. Baseline coagulation studies should be performed for large/diffuse VMs and LVMs. Liberal use of tissue sealant products is encouraged.

10. *Immobilize the operated extremity* in a young child or adolescent. In the treatment of children with vascular anomalies, the postoperative lack or loss of immobilization is the single most important cause of wound dehiscence, maceration, and chronic infection.
11. The surgeon who has the courage to treat difficult fast-flow lesions should also *be prepared to amputate a symptomatic non-functional or painful digit or extremity* following unsuccessful attempts at palliation. The reconstructive surgeon need not view amputation as a failure.
12. *Follow-up evaluation* should be performed compulsively at yearly intervals. The true extent of the lesion can never be absolutely eradicated short of an amputation. Early childhood, adolescence, and pregnancy are times when change may occur in vascular malformations due to hormonal influences. Malformations may expand dramatically during pregnancy, with use of high-estrogen anti-ovulation medication, or following trauma. Large AVMs, LMs or mixed lesions may be well tolerated as young children only to become burdensome as teenagers due to their expansion, bulk, ulceration, and appearance or steal symptoms.
13. *Give the patient and parents adequate time to make their decision*. The diagnosis and treatment of vascular anomalies is a rapidly changing field. It is important to keep both parents and patients at the appropriate age clearly informed about the natural history of their particular malformation, options for treatment and new types of therapies. These patients and parents often have questions that are not easily answered by their family physician. It is axiomatic that the surgeon provide a *clear explanation of all potential complications* and expected outcomes prior to any surgical treatment.

Clinical tips

In large lesions, it is usually best to do a staged excision. Thorough dissection limited to a specified area should be performed so that subsequent re-entry into a densely scarred bed will be unnecessary. Limited staged (but thorough) excisions are usually better than one extensive dissection that leaves behind abnormal tissue. This way, the surgeon can minimize likelihood of re-entering an area of previous dissection. For example, the digits (including the thumb) should be debulked in stages. We typically debulk one side of a digit through a midlateral incision (half of the dorsal and half of the volar surface), and return several months later to debulk the other side. A single procedure is usually best for the dorsum of the hand, wrist, and palm of the same extremity in a patient with a diffuse LM or VM. In these patients, it usually best to start distal to minimize swelling of involved digits once the more proximal structures are debulked.

Clinical tips

Caveats of palmar dissections

Multiple technical refinements have made these dissections, once considered impossible, both predictable and safe. These are summarized in Table 31.5.

Clinical tips

Caveats of thumb/digital dissections

Surgical approaches to the thumb and digit are similar to those summarized above and have become much safer with microvascular techniques. These are summarized in Table 31.6.

Vascular tumors

Infantile hemangioma (IH)

Basic science/disease process

IH is usually single and involves the upper limb in 15% of cases. The median time of appearance is at age 2 weeks. When dermis is involved, the skin initially appears pink but can evolve to deep red. Deeper lesions may cause a pale, bluish discoloration (Fig. 31.1). This lesion grows very fast during the first 9 months (proliferating phase), begins to shrink by 12 months (involuting phase), and involution is complete by 5 years (involution phase) leaving residual telangiectasias, fibrofatty residuum and redundant, atrophic skin.[34,37,40]

Diagnosis/patient presentation

Some 90% of IH diagnoses are made by history and physical examination. Handheld Doppler demonstrates fast flow. Ultrasonography shows fast flow, elevated resistance and increased venous drainage.[36] On MRI scans, hemangiomas are isointense on T1, hyperintense on T2, and enhance during proliferating phase. Rarely is biopsy needed. Immunostaining for GLUT1, a glucose transporter specific to IH, will differentiate this lesion.[10]

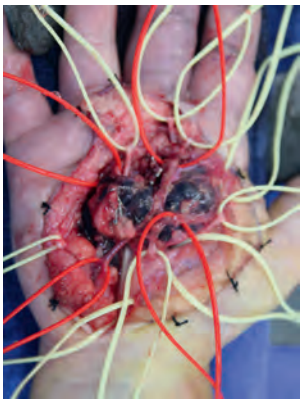
The majority of IH involve the head and neck, lumbosacral region, and liver. The PHACES association includes IH on the face with at least one of the following: posterior fossa brain malformation, hemangioma, arterial cerebrovascular anomaly, coarctation of the aorta and cardiac defects, eye/endocrine abnormalities, and sternal clefting or a supraumbilical raphe. These children need the appropriate specialty consultations.

Treatment/surgical technique

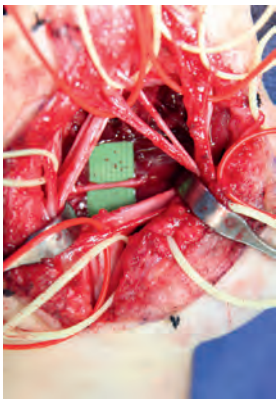
Most IH are managed by observation because 90% are small, localized, and do not impair function. To protect against ulceration and/or maceration during the proliferating phase, topical antibiotic cream and a petrolatum gauze barrier may be used. Ulcerated wounds are treated with local wound care and rarely need biologic coverage such as skin grafts. Those

Table 31.5 **Caveats of palmar dissections**

1. Anatomy complex. Have three-dimensional perspective.
2. Compulsive hemostasis under tourniquet. Avoid inkwell phenomenon.
3. Proximal to distal dissection of nerves. Look for epineural fat and follow epineural connective tissue plane.
4. Identify deep motor branch of ulnar nerve in Guyon's canal and mid-palm.
5. Median and ulnar nerves often involved. Take your time.
6. Although displaced, arterial is anatomy normal. Follow adventitial connective tissue plane. Save palmar arches.
7. Completely resect involved intrinsics to avoid contracture.
8. Try to preserve first dorsal interosseous and adductor pollicis muscles.
9. Simple muscle splitting for localized calcified thrombi.
10. Tissue sealants and drains to avoid bleeding
11. Postoperative compression of thumb and digits easy with Coban
12. Postoperative compression of palm difficult. Wrapping ineffective. Uniform pressure with vacuum-assisted closure device for open wounds or dorsal/palmar splints for closed wounds.
13. Stay within a well-defined region. Tendency to be too aggressive
14. Resect and replace marginal skin.



Diffuse VM palm



Motor branch of the ulnar nerve

Dissection complete

Table 31.6 **Caveats of thumb/digital dissections**

1. Anatomy much easier than palm; outline region to be debulked *before* exsanguination
2. Incisions: midaxial or midlateral, avoid zigzag incisions in glabrous skin to avoid hypertrophic scars; utilize dorsal extension creases if necessary
3. Tourniquet control: digital for distal half and regular proximal digit and thumb
4. Subdermal flap elevation 1st, deeper dissection later
5. Decompress Grayson and Cleland ligaments to identify neurovascular bundle; these structures distorted but always present
6. One side of digit (palmar and dorsal at a time; leave one bundle untouched and do not dissect more than 270° around digit.
7. Identify and dissect along paratenon of extensor; remove malformation between extensor and bone.
8. Preserve vincular vessels at joint space level and dorsal sensory branches of digital nerves: dissect along adventitial planes (arteries) and epineural plane (nerves); keep neurovascular bundle intact.
9. Complete excision of malformation; extend along vincular vessels if necessary.
10. Palmar dissection restricted to ipsilateral side of digit or thumb
11. Palmar pulp dissection: "berry pick" VM, LM, or LVM out of septal pockets and keep nerve attachments to skin intact
12. Extend dissection into palm to level of metacarpophalangeal joint and distal palmar flexion crease.
13. Tissue sealants and drains to avoid bleeding
14. Drape redundant skin over digit and release tourniquet before resection; tension free closure.
15. Postoperative compression dressing held with Coban

Diffuse VM

Ulnar neurovascular bundle

Radial neurovascular bundle

Closure

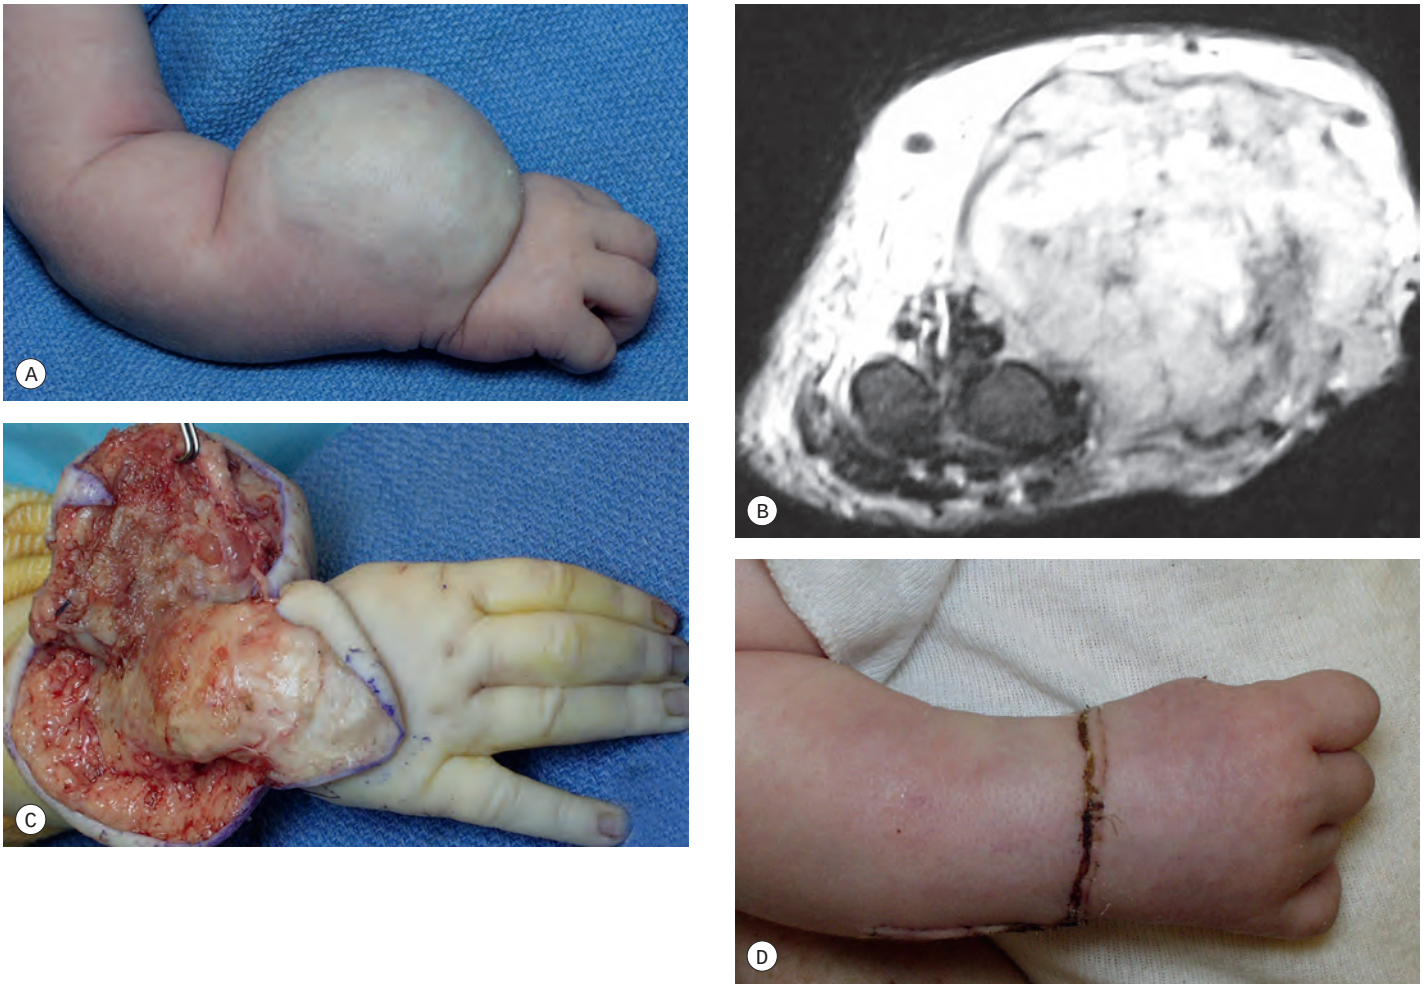


Fig. 31.1 Infantile hemangioma (IH). **(A)** This well-localized, solitary IH on the dorsal forearm has a bluish hue. **(B)** The MRI shows a multilobular, isointense lesion on T2-sequence. **(C)** Excision included extensive dorsal tenosynovectomy. **(D)** Two weeks later active extension is initiated.

that are small but cause functional problems can be injected with steroids.[41]

Problematic lesions too large to treat with intralesional corticosteroid injections are first managed with oral prednisone started at 3 mg/kg per day for 1 month and then tapered until it is discontinued 10–12 months later.[37] Complications of long-term corticosteroid therapy are well known and usually disappear with discontinuation of therapy. Recently, propranolol has been used but its efficacy and safety compared to corticosteroids is debated.[42,43] Atenolol may have a better risk profile than propranolol, and its use is gaining substantial support.[44] Alternatively, the child may be switched to vincristine; interferon is no longer used in those under 12 months of age due to spastic diplegia.

Surgery in the upper limb (during the proliferation phase) is indicated only for problematic ulcerations or large lesions interfering with function. The particular child in Fig. 31.2 has a large, chronically ulcerated lesion that envelopes the neurovascular structures. Excision and neuroplasty through a high midaxial incision both enabled functional use of the digit and avoided secondary contracture of the digit.

After involution, the hemangioma can leave redundant skin with fibrofatty soft tissue. Though these lesions pose no functional problem, they can be unsightly. Small lesions can be excised in one stage, whereas larger ones require a staged approach.

Congenital hemangioma

Basic science/disease process

The upper limb surgeon must be familiar with a variant known as congenital hemangioma (CH).[45] In contrast to infantile hemangioma, congenital hemangioma are rare lesions fully grown at birth that do not exhibit the proliferation and regression so typical of IH. These lesions appear differently with a red-violaceous color, coarse telangiectasias, a central pallor, and a peripheral halo. There are two variations of CH: the rapidly involuting congenital hemangioma (RICH)[46] and the non-involuting congenital hemangioma (NICH)[47] (Fig. 31.3). Both lesions are commonly seen in the extremities and have an equal sex distribution. RICH involutes rapidly after birth; 50% of the lesion is gone by 7 months and involution is complete by 14 months of age. Fibrofatty deposits are not present. NICH does not regress and persists as raised, lumpy, plaque-like lesions with a characteristic peripheral halo. A persistent fast-flow component remains unchanged.

Fig. 31.2 Infantile hemangioma (IH). **(A)** An expanding IH with chronic ulceration and bleeding in a 9-month-old child. **(B)** Excision was performed through a high midaxial incision and normal skin creases.

Diagnosis/patient presentation

Diagnosis is made by physical examination, clinical course and ultrasonography. CH lesions do not stain for GLUT1.

Treatment/surgical technique

RICH does not require operative management early in life, as it undergoes accelerated regression. Only large lesions in other parts of the body may need oral corticosteroid or second-line drug therapy. NICH may require intralesional corticosteroid injection in problematic regions of the upper limb. Large, lumpy masses within the palm of the hand, interdigital webspaces, or those causing muscle or tendon impairment are best excised. Large lesions on the arm, forearm, and within the antecubital fossa are excised later in childhood.

Pyogenic granuloma

Basic science/disease process

Pyogenic granuloma (PG) is a solitary red papule that grows rapidly, forming a stalk. It has been called a lobular capillary hemangioma.[48] It is small with an average diameter of 6.5 mm. The male to female ratio is 2:1. It commonly involves skin and, in the upper extremity, it is most problematic on the glabrous surfaces of the digits, in nail folds (Fig. 31.4), within webspaces and flexion creases. It appears as a red papule growing on the end of a stalk. Persistent bleeding and constant ulceration are common. PG is distributed all over the body including the mucous membranes; cheeks, lips, oral cavity, eyelids and forehead. Histological examination will differentiate PG from hemangioma.[49]

Diagnosis/patient presentation

Diagnosis is made by physical examination because the appearance is classic.

Treatment/surgical technique

Numerous treatments have been described for PG: curettage, shave excision, laser therapy, or excision. Complete excision is preferred in the hand and upper limb. Skin graft coverage may be necessary for large resulting defects.

Vascular malformations

Capillary malformations

Basic science/disease process

CM consists of dilated capillaries in the superficial dermis. CM is most often solitary, but has a wide range in size and may occur in any region of the extremity (Figs. 31.5A,B & 31.5C–F). With time and aging, these pink lesions will often darken and develop some fibrovascular overgrowth. They can be associated with deeper vascular lesions, both slow-flow (Klippel– Trénaunay, CLOVES) and fast-flow (Parkes Weber, CM–AVM, PTEN) (see Tables 31.2 & 31.8) and with skeletal and soft tissue hypertrophy. A CM on the face in one or more of the trigeminal nerve distributions is indicative of

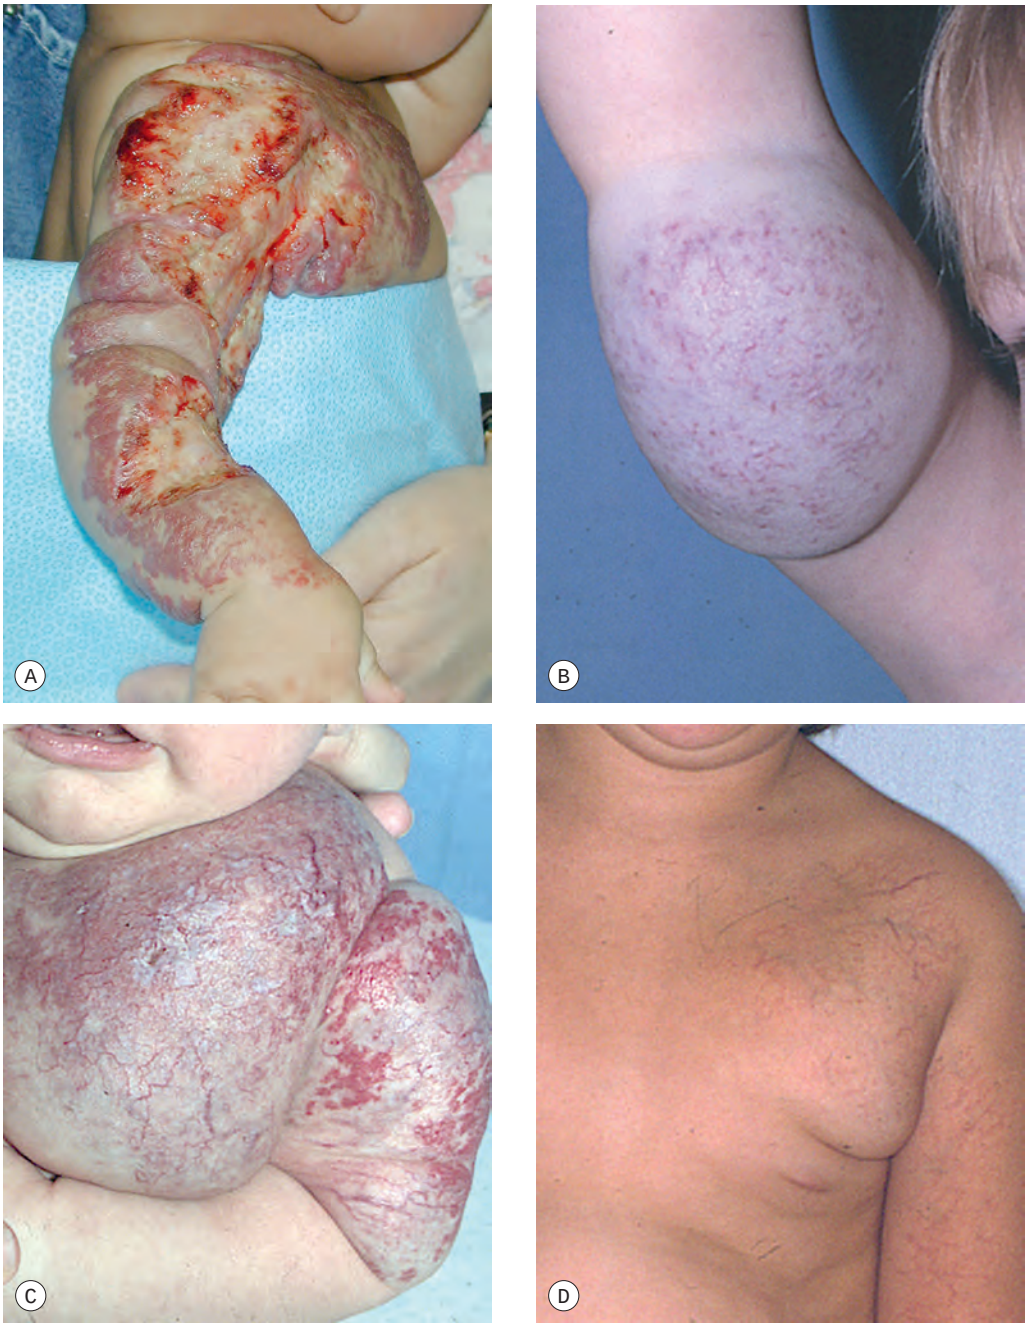

Fig. 31.3 Congenital hemangioma (CH). **(A)** Extensive skin ulceration may occur during proliferation and involution. CH requires local wound care. **(B)** A non-involuting congenital hemangioma (NICH) shows coarse telangiectasias, hard nodules surrounded by a peripheral halo. **(C)** A rapidly involuting congenital hemangioma (RICH) shows typical enlargement and coarse telangiectasias during infancy. **(D)** Several years later with no treatment.

Sturge–Weber syndrome.[50] These patients are at risk for seizures, retinal detachment, glaucoma, and stroke. Fig. 31.5C–F appears online only.

Diagnosis/patient presentation

Diagnosis is made by physical examination. Deeper lesions must be studied with radiographs, scans, and ultrasonography.

Treatment/surgical technique

No treatment is necessary for extremity CMs. Pulsed dye laser (585 nm) can effectively decrease the intensity of the cutaneous blush.[51,52] Patients (including infants) are often treated awake and with topical anesthesia. More dramatic outcomes are obtained in the head and neck region and face than in the trunk and extremities. Multiple treatments are often necessary. Outcomes in younger children are better than adults; results show 90% lightening of lesions, 50–90% improvement, and 20% minimal change. Many will re-darken with time.[53] Occasionally, a dark purple, overgrown extremity CM will be resected or replaced with a graft.

Lymphatic malformations

Basic science/disease process

LM results from an error in the embryonic development of the lymphatic system. Since lymphatic and venous systems have

Fig. 31.4 Pyogenic granuloma (PG). A periungual PG with typical stalk will continue to bleed unless completely removed with curettage or excision. In the young child, this must be differentiated from an unreduced Salter I injury of the distal phalanx (Seymour fracture).

a common origin, combined lymphatico-venous malformations (LVM) occur frequently.[54,55] LM is characterized by the size of the malformed channels: microcystic, macrocystic, or combined. Most lymphatic lesions are noted at birth or within the first 2 years of life. Large macrocystic lesions may be slightly compressible and those with smaller channels are rubbery, a characteristic distinguishing feature. They do not decompress with overhead elevation. Overlying skin may appear normal, have a bluish hue or contain clear or pink vesicles. Dark vesicles are indicative of intralesional bleeding. Dermal involvement often overlies a large lymphatic lesion and this skin may be thick and exhibit cutaneous puckering much like the *peau d'orange* skin seen in lymphedema. Cutaneous vesicles may coalesce, drain clear fluid, bleed, and lead to chronic wounds and sepsis.

LM may be located anywhere within the upper limb and is characteristically macrocystic in the cervicofacial and neck ("cystic hygroma"), mediastinum, and axilla (Figs. 31.6 & 31.7) and microcystic in the distal forearm, wrist, and hand. LMs may be accompanied by increased amounts of dysplastic fat adding to the bulk of the malformation. It is unusual for LMs to directly involve muscle tissue as they are primarily found within the subcutaneous tissue planes. The most problematic regions are within intertriginous skin folds, interdigital webspaces, nail folds and within open wounds caused by vesicle leakage.

There is no characteristic pattern of skeletal involvement with LM. The long and tubular bones of the extremities and joints are rarely affected. The eponym "Gorham disease" is used for skeletal involvement.[56] Extensive LM may be associated with skeletal disuse atrophy. Smaller lesions confined to the distal extremities can present with overgrowth of the hand or foot. LMs and combined lesions containing lymphatic components (CLVM, LVM) can progress to gigantism. Joints are rarely affected but can become severely restricted by the bulky LM (see Table 31.2).

Diagnosis/patient presentation

Some 90% of LMs are diagnosed by history and physical examination. Small, superficial lesions do not require further diagnostic work-up.[34] Large or deep lesions may require MRI scans to confirm the diagnosis, define the 3D characteristics

Fig. 31.5 Capillary malformation (CM) variations. **(A)** Solitary CM over the thenar region in a teenager; stain-darkened during the adolescent growth spurt. **(B)** Localized CM plus large arteriovenous malformation (AVM) with multiple arteriovenous fistulas in a young child with a palpable bruit.

Fig. 31.5, cont'd (C) CM plus overgrowth of thumb, long and ring digits in a child with CLOVES. **(D)** Extensive CM plus lipomatous overgrowth, syndactyly, and no skeletal overgrowth. **(E)** Limb of child with CM–AVM. **(F)** CM in an older man. Note variable effect of laser treatment on the dorsal forearm. CM darkened with cobblestone appearance during the adult years.

Fig. 31.6 Macrocystic axillary lymphatic malformation (LM) in a neonate. **(A)** This extensive LM was diagnosed by prenatal ultrasonography; child born by caesarean section. Constant fluid shifts and intralesional bleeding complicated initial management. **(B)** At 6 months, an aggressive debulking was performed with isolation and preservation of all neurovascular structures. Surgery took 6 h with a blood loss of <100 cc. A dramatic result was obtained with compression wrapping.

of the LM and plan treatment. These scans show characteristic fluid-filled spaces, multiple septations of variable thickness, hyperintense T2-weighted sequences due to water content, and slight rim enhancement following contrast administration. Diffuse enhancement is not present. Direct puncture of macrocystic lesions further delineates the architecture of the lesion prior to sclerotherapy. Large venous channels are often present and bleeding into a large macrocyst is the rule rather than the exception.[57] Ultrasonography (US) shows multiloculated macrocysts with "rim enhancement" and hypo-echoic microcystic lesions with little flow. Histologic confirmation of LM is rarely necessary. LM characteristically shows abnormally walled channels filled with eosinophilic, protein-rich fluid and collections of lymphocytes. Positive immunostaining is seen with lymphatic markers D2-40 and LYVE-1.[58]

Treatment/surgical technique

LM is a benign condition, and intervention for small asymptomatic lesions is not necessary. More aggressive management is reserved for symptomatic lesions that cause pain, infection, compression neuropathies, significant deformity, or functional impairment. An infected LM within the extremity can be controlled with local wound care, oral antibiotics, and occasionally intravenous antimicrobial therapy. The rapidly advancing "wild fire" infections seen in these lesions can cause sepsis but will regress as rapidly as they progressed with appropriate treatment. Sclerotherapy is the first-line management for large, problematic macrocystic LMs. Several sclerosants have been used: doxycycline,[59] sodium tetradecyl sulfate (SDS), ethanol, bleomycin,[60] and OK-432.[61] SDS is the most widely used. Ethanol has the highest complication rate and is particularly toxic to neurovascular structures (see Fig. 31.14). OK-432 is very effective but not widely available. Multiple injection sessions are required for all but the smallest lesions. Swelling, compartment syndromes and skin extravasation are the most common complications encountered in the upper limb. We prefer sclerotherapy for the macrocystic LMs primarily located in the head and neck, axilla, and proximal portions of the upper extremity. Microcystic lesions are best treated surgically.

Resection is reserved for: (1) symptomatic LM causing bleeding or fluid loss, infection, bleeding, pain, or obstruction of function; (2) lesions (microcystic) that cannot be adequately treated with sclerotherapy; and (3) small, well-localized lesions that can be resected for cure. Surgical principles and technical caveats have been outlined. The neonate in Fig. 31.6 presented a good example. Despite sclerotherapy, issues such as bleeding, fluid shifts, and metabolic derangement could not be adequately managed. Resection included a careful identification of all neurovascular structures within and beyond the brachial plexus and excision of large amounts of involved tissue. Characteristically, the LM in this baby was confined to the subcutaneous tissue planes and extended only *between* muscle groups. Staged debulking of large upper extremity LMs is much safer than large radical resections. We often start with the bulkiest chest wall, axillary, and arm regions before extending more distal into the forearm and hand (see Fig. 31.7). Areas of involved skin are preferentially removed and only one side of a forearm, wrist, hand, or digit are debulked at one operation. Flap compromise, wound dehiscence, and infection are early problems and tendon adherence, neuromas, and joint stiffness may be encountered later.

Because of its complex anatomy, the hand is the most difficult region to dissect for an LM or any other type of vascular malformation. There are very few natural fascial planes within the indurated lymphatic tissue, which may have been scarred by previous inflammation. However, smooth, areolar connective tissue planes can usually be found around both nerves and arteries and should be followed meticulously. Of all surgical principles outlined previously, limited and thorough dissection is most important for LM in the hand (see Table 31.4). In contrast to the digits and thumb, postoperative edema is almost impossible to control, and may affect joint mobility and tendon gliding. At this level, all LMs are microcystic and are accompanied by a large amount of adipose tissue, with the consistency ranging from soft to hard rubber (see Fig. 31.8B). Resection in the hand is reserved for those lesions causing functional impairment. These procedures are lengthy

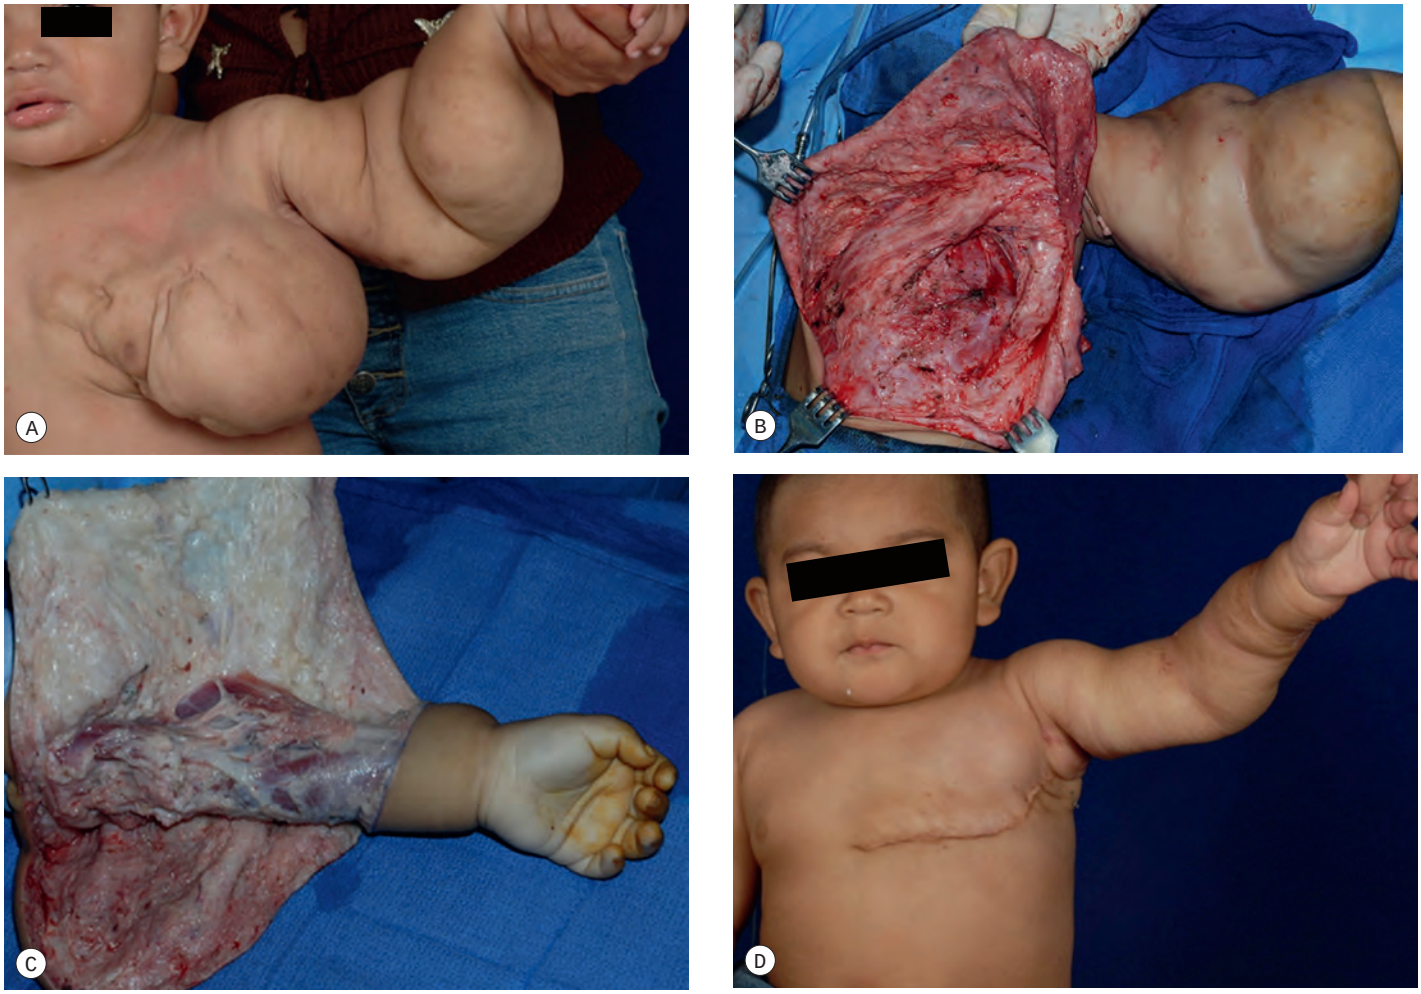

Fig. 31.7 Chest wall and forearm lymphatic malformations (LM). **(A)** A rubbery, hard LM involving the entire arm and chest wall with a normal hand in a 16-month-old child. **(B,C)** Staged resections started with the chest wall where pectoralis major, latissimus dorsi, and serratus anterior muscles have been preserved. The forearm was debulked in two additional stages. **(D)** Three months postoperatively, following three operations.

and tedious. Incisions through glabrous skin must be well designed, as there is a tendency for hypertrophic scar formation, particularly when there is dermal involvement. With dorsal debulking, several large dorsal veins should be preserved in-continuity with the cephalic drainage system of the forearm. Nevertheless, removal of these veins does not predictably cause venous congestion (see Table 31.5).

Dorsal LMs in the thumb and fingers are common and are the easiest in the limbs to debulk (see Table 31.6). Muscle is usually not involved, and the LM usually does not extend below or penetrate through flexor or extensor tendons. The entire dorsal area can be debulked, along with removal of one-half of any involved palmar portion in one procedure. Liposuction, even with ultrasonic technique, is not a good option because of the firm, rubbery consistency of microcystic LM and potential for injury to neurovascular structures. Involved dorsal skin should be excised and replaced by thick split-thickness or full-thickness skin grafts. Multiple digits can be debulked during one operation, and the dorsum of the hand at another stage. Midaxial incisions are preferred (Figs. 31.8 & 31.9A–C). A large dorsal vein in the hand or digit is preserved. Vincular vessels at the joint space level are preserved whenever possible. Incisions through the glabrous surfaces of the palm or digit have a predilection for hypertrophic scarring. Intradigital commissures and webspaces must be closed in their normal configuration. Coban™ effectively controls postoperative edema with circumferential wrapping. Fig. 31.9B,C appears online only.

Outcomes, prognosis, and complications

The degree of functional gain and appearance is proportional to the extent of the malformation. The use of the pneumatic tourniquet in limb surgery significantly decreases the recurrence rate seen in the head and neck region.[62,63] Frequency of complications such as persistent drainage, wound dehiscence, and skin loss is less than 8%; secondary neuromas and hypertrophic scarring are much more common (20%).[15] With appropriate postoperative therapy and splinting, joint stiffness can be minimized. Upper extremities with large, heavy, edematous hands will always be "helping extremities" and digits with limited range of motion will never be normal due to the scar from pervious surgeries and residual LM within the remaining soft tissue. However, extremities with well-localized LM can be expected to function normally following well-planned and executed surgery.

Fig. 31.8 Lymphatic malformation (LM) hand. **(A)** A 4-year-old child presented with an extensive microcystic LM of the entire forearm, wrist, and hand. The dorsum was approached through an ulnar incision with preservation of dorsal venous system, nerves, and extensor tendons. **(B)** The LM along the digits is microcystic, indurated and envelops all structures. Joint spaces are not involved. **(C)** Multiple digits and thumb are debulked during a single stage. **(D)** With continued compression wrapping and exercise, contour and function have been maintained 15 years later.

Venous malformation

Basic science/disease process

VM is the most common vascular anomaly. It is comprised of thin walls and abnormal smooth muscle cells, arranged in clumps instead of in a concentric orientation. VMs show gradual dilatation and expansion with time and growth.[3] Although VMs are present at birth, they are not always obvious. Within the first 5–6 years of life, all but the smallest or deepest lesions will become clinically evident. Less than 10% are clinically indolent until adolescence. Approximately, 40% of all VMs involve the extremities and more than half of these involve deeper structures including muscle, bone, nerve and connective tissue planes. They grow commensurately with the child, and slowly expand during the adolescent growth spurt. VM is typically sporadic and solitary and half have a somatic mutation in the endothelial receptor TIE2.[64]

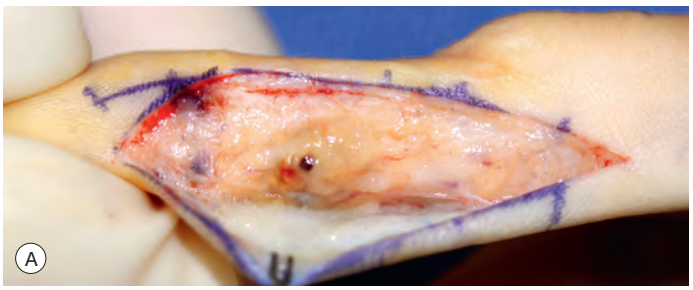

Fig. 31.9 Lymphatic malformation (LM) digit. **(A)** LM along the side of a digit.

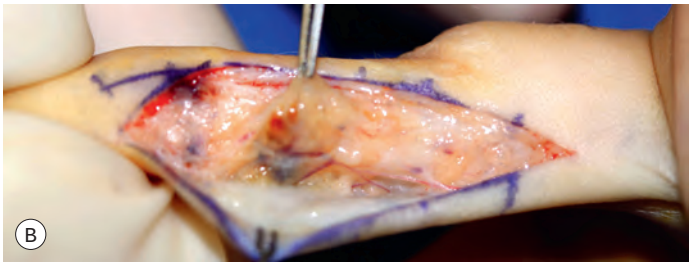
VM may range from small, localized skin lesions to diffuse malformations involving all tissue planes including bones and joints. These lesions become engorged when the limb is in a dependent position and decompress when the limb is held above the level of the heart (Fig. 31.10). Most VMs are located in the subcutaneous plane superficial to the muscular fascia, but in contrast to LM, VM may involve muscles directly.[65] The majority of VMs are solitary and asymptomatic. Often they are multiloculated, incompletely decompressed



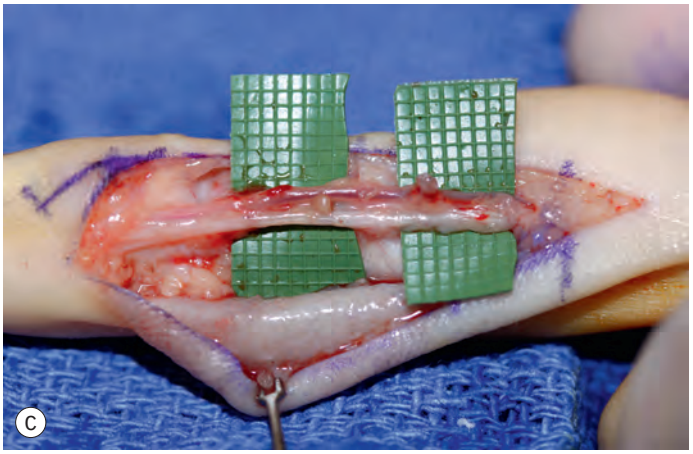


Fig. 31.9, cont'd (B) Lymphatic microcysts and small venous thromboses are studded within dysplastic adipose tissue. **(C)** The neurovascular bundle has been dissected with preservation vincular branches at the joint levels.

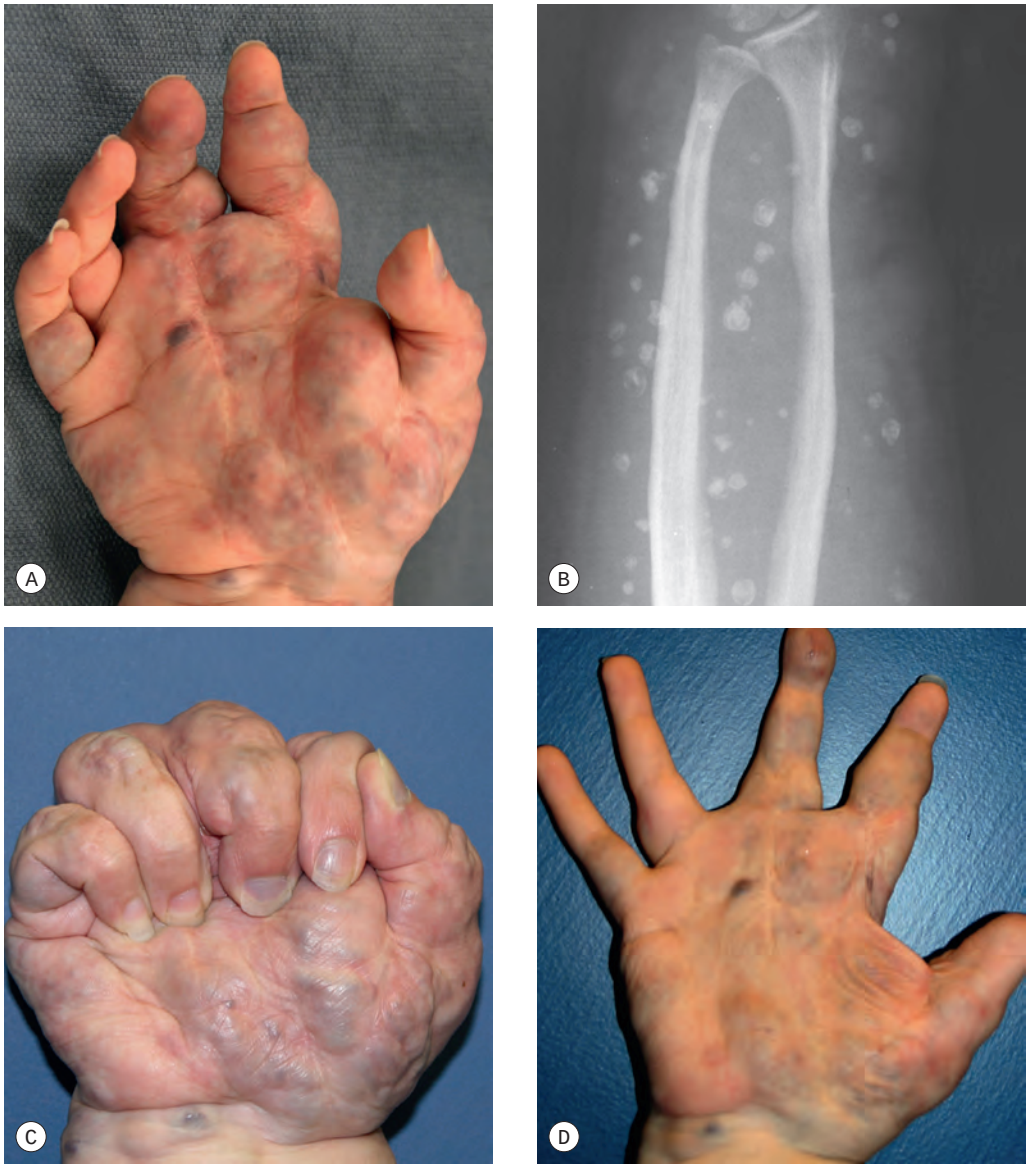

Fig. 31.10 Venous malformation (VM) hand. **(A)** In a dependent position, the hand with a diffuse VM becomes engorged; bulk and weight become a functional impediment. **(B)** Calcified phleboliths are often present. **(C)** Functional motion is impaired only by the malformation. **(D)** After elevation there is no pain, fullness, or congestion. This patient has an extensive VM involving the entire hemithorax with a large stagnant venous collecting system in the axilla. Consequently, she is on long-term anticoagulation.

with elevation, and have palpable regions of scar from previous inflammation around intralesional thrombi, which feel like small peas in a sac.

The configuration, size, and caliber of venous channels in VMs have no pattern, such as the characteristic microcystic and macrocystic cavities and channels of an LM. Large-caliber veins may be located on a digit, foot, and leg or within the axilla. Often these large, dilated, redundant draining veins of extremities place the patient at risk for clot formation and subsequent pulmonary embolism.

VMs do not progress from a slow-flow to fast-flow state; they grow (expand) commensurately with the child. Any enlargement following a partial resection represents redirection of flow into adjacent anomalous channels. There is definitely hormonal modulation with medium and large lesions. They often increase in size during the adolescent growth spurt, menses, while on anti-ovulant medication, and during pregnancy. In women who experience an exacerbation of their symptoms during pregnancy, there is no postpartum reduction to the previous size. Patients must be followed carefully through adolescence and subsequent pregnancies.[15,35]

Functional problems are related to the size, weight, and location of the VM. Pain and paresthesias are usually the result of local inflammation around intralesional thrombi or nerve compression, usually at the elbow, wrist, hand and/or tarsal tunnel of the foot. Areas of phlebothrombosis or local hemorrhage become swollen, firm and painful, especially when compressive garments are applied. Most symptoms are aggravated after exercise involving repetitive movements such as lifting, gripping, running, or kicking. Many VMs will be surprisingly large with minimal, if any, symptoms in young children.

Syndromes with VM

There is an emerging group of syndromes which contain VM and which have become clinically distinct (Table 31.7 ◍). Less than 20% of all VM patients will have a syndromic designation with a very specific pattern of malformation including

glomuvenous malformation (GVM)[66,67] and capillary malformation venous malformation (CMVM).[68] In the blue rubber bleb nevus syndrome (BRBNS),[69,70] small blue nodules are present in isolation or with extensive connections. A small number of upper limb patients present with combined lymphatic-venous malformations with or without capillary staining: LVM, CLVM (Klippel–Trénaunay) Understandably, this group of lesions can be confusing but the management is similar. Table 31.7 appears online only.

Complications of untreated VMs include pain, swelling, bulk, and contour deformity and psychosocial morbidity. Intralesional thromboses are the most frequent cause for pain. VM can cause leg-length discrepancy, hypoplasia due to disuse atrophy, pathologic fracture, hemarthrosis, and degenerative arthritis. VM of muscle may result in pain, weakness, fibrosis leading to joint contracture and subsequent disability.[65] Phlebothromboses within large, stagnant venous channels in the arm, axilla and ipsilateral chest wall have been the focus for pulmonary embolism. A coagulation profile should be obtained in all patients with an extensive VM, with or without capillary or lymphatic components, particularly if there is any history of bleeding, ecchymosis or hemarthrosis. High-risk patients should be placed on anticoagulation therapy (see below).

Diagnosis/patient presentation

At least 90% of VMs are diagnosed by history and physical examination. Dependent position of the anomaly will confirm the diagnosis: VM will enlarge due to reduced venous return in the extremity (Fig. 31.10C,D). Small, superficial, asymptomatic lesions require no further work-up. However, larger and/or deeper lesions should be evaluated by MRI to: (1) confirm diagnosis; (2) define the 3D extent of the lesion, and (3) plan long-term treatment. VM is hyperintense on T2-weighted sequences. In contrast to LM, VM will enhance with contrast, show phleboliths as signal voids, and may involve muscle. US may be used for some localized lesions; characteristic findings show slow-flow anechoic–hypoechoic channels separated by more solid regions of variable echogenicity. Phleboliths are hyperechoic with acoustic shadowing. Magnetic resonance venography (MRV) is helpful for large lesions of the arm, forearm, and chest wall. CT scans are used to assess skeletal VM.[57,71] Histological diagnosis of VM is rarely necessary, but may be indicated if there is a suspicion of malignancy or if the imaging is not confirmatory. Arteriography is not helpful (see Table 31.2 🌐).

Treatment/surgical technique

Compression garments are the first-line of treatment and are used to reduce blood stagnation within the lesion, thereby reducing the chance of expansion, localized intralesional coagulopathy (LIC), phlebolith formation, and pain. Those with pain and large lesions are given daily aspirin (81 mg) to prevent clotting. Large lesions are at risk for the vicious cycle of blood stagnation, stimulation of thrombin, and conversion of fibrinogen to fibrin. Subsequent fibrinolysis results in LIC. A chronic coagulopathy can cause either thrombosis (phlebolith formation) or bleeding. Low molecular-weight heparin (LMWH) is considered for those children and adults with significant LIC or those at risk for disseminated intravascular coagulation (DIC). Those with large VMs and low fibrinogen levels pre-sclerosis are given LMWH 14 days before and after the procedure. Anticoagulation is held for 24 h perioperatively (12 h before and after the intervention) to prevent bleeding complications. Patients who develop a serious thrombotic problem, such as a pulmonary embolus, require long-term anticoagulation or a vena caval filter.

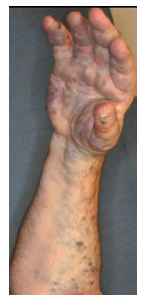
Sclerotherapy is the next treatment option for symptomatic lesions that cause pain, functional impairment, a mass effect, or major contour problems.[15,72] In the arm, elbow, and proximal forearm, sclerotherapy is safer and more effective than resection (Fig. 31.11 🌐). Symptomatic regions must be specifically targeted. Although sclerotherapy reduces the size of the malformation, it generates a tremendous amount of scar and does not remove the malformation. The VM usually re-expands, and multiple sessions are invariably needed, sometimes for a lifetime. Direct puncture sclerotherapy is used for VM. Most patients are managed under anesthesia using US guidance. The most common complications are skin ulceration (10–15%), local extravasation, compartment syndrome in the arm or forearm and secondary contracture (see Fig. 31.14A).(15) Sclerotherapy in the palm or near large nerves can result in painful neuropathy and should be avoided. Fig. 31.11 appears online only.

Post-treatment monitoring is required for large lesions with an extremity surgeon on-call for problems. Large VMs of the axilla and arm contain anomalous veins too large for sclerotherapy; these should be embolized. Sclerotherapy is most effective for small and large VM in the axilla, arm, elbow, and proximal forearm where muscle may be directly involved. Surgical resection is preferred in the distal forearm, wrist, thumb, and digits, where there is little muscle tissue (Figs. 31.12 🌐 & 31.13). The secondary scar generated by sclerotherapy in these regions is detrimental to nerve function, tendon and muscle gliding and joint motion. Large vascular channels respond better to sclerotherapy than small nests or clusters of VM commonly seen in GVMs or Maffucci patients. Surgical resection is preferred. We prefer to avoid sclerotherapy prior to resection, as it can cause scarring and complicate the dissection field. Fig. 31.12 appears online only.

Resection is reserved for VMs that are well localized in a single muscle group (such as the intrinsic muscles of the hand), lesions with thromboses, and those causing neurologic impairment or compressive problems (see Table 31.5). In the distal extremity, resection of the entire involved muscle group is preferred, especially for a small muscle–tendon unit. Examples include the intrinsic muscles for which other muscles can substitute or the extrinsic flexors for which tendon transfers are possible. Partial resection of these small muscle–tendon units cannot be recommended; this fails to improve function. Flexion contractures followed by prolonged rehabilitation often occurs after subtotal resection of muscles. The indications for surgical resection are primarily functional, but can also be aesthetic.

The principles of treatment are summarized in Table 31.4. The advantages of surgical resection in the upper extremity are: (1) a pneumatic tourniquet is used to provide a bloodless field; (2) all anatomic structures can be identified; (3) only the malformation is removed; (4) nerves, muscles, and tendons may be left injured; and (5) well-localized lesions can be completely removed. However, the recovery time is longer; the rehabilitation more difficult; and there is always a chance of local VM re-expansion in adjacent regions.

Table 31.7 **Variations of venous malformations (VM)**

	Common VM	BRBS	GVM	CMVM	Maffucci	Diffuse VM
Name, eponym	Venous malformation	Blue rubber bleb syndrome; bean	Glomuvenous malformation; glomangioma	Capillary malformation, venous malformation	Maffucci syndrome	Genuine phlebectasis of Bockenheimer; diffuse VM
Capillary stain	Absent	Absent	Absent	Present; involves mucous membranes; purple older	Absent	Absent
Skin appearance	Bluish discoloration, present at birth; wide distribution	Dark blue spots present at birth	Thickened and purple early; present at birth; cobblestone appearance	Skin, mucous membranes	Bluish to purple; thickened; nests and nodules	Diffuse; large, tortuous venous channels
Genetics	50% mutation in endothelial TIE2	Unknown	Mutation glomulin gene; chromosome 1 p21–22	Mutation TIE2, chromosome 9p21; possible 2nd hit mutation	Unknown	Unknown
Pattern	Sporadic; common; sexes equal	AD; sexes equal	AD; sexes equal;	AD; 1% all VMs; sexes equal	Sporadic; sexes equal; rare	Sporadic; sexes equal
Hemodynamics	Slow-flow	Slow-flow	Slow-flow	Slow-flow	Slow-flow	Slow-flow
Limb affected	All parts of body	All parts of body	All parts of body	Skin, mucosa, muscle	All limbs	All limbs
Skeletal involvement	Present, unusual	None	None	None	90% hands and feet; enchondromas	Present, diffuse, pathologic fractures
Visceral involvement	Yes	Yes: particularly bowel anemia common	None	None	None	None
Pathology	Deficient smooth muscle in vessel walls; dilated vessels; thrombus formation	Similar to VM, well delineated, thin-walled dilated vessels	Cuboidal glomus cells	Similar to common VM	Similar to VM; thick spindle cells	Similar to common VM
						


AD, Autosomal-dominant inheritance.

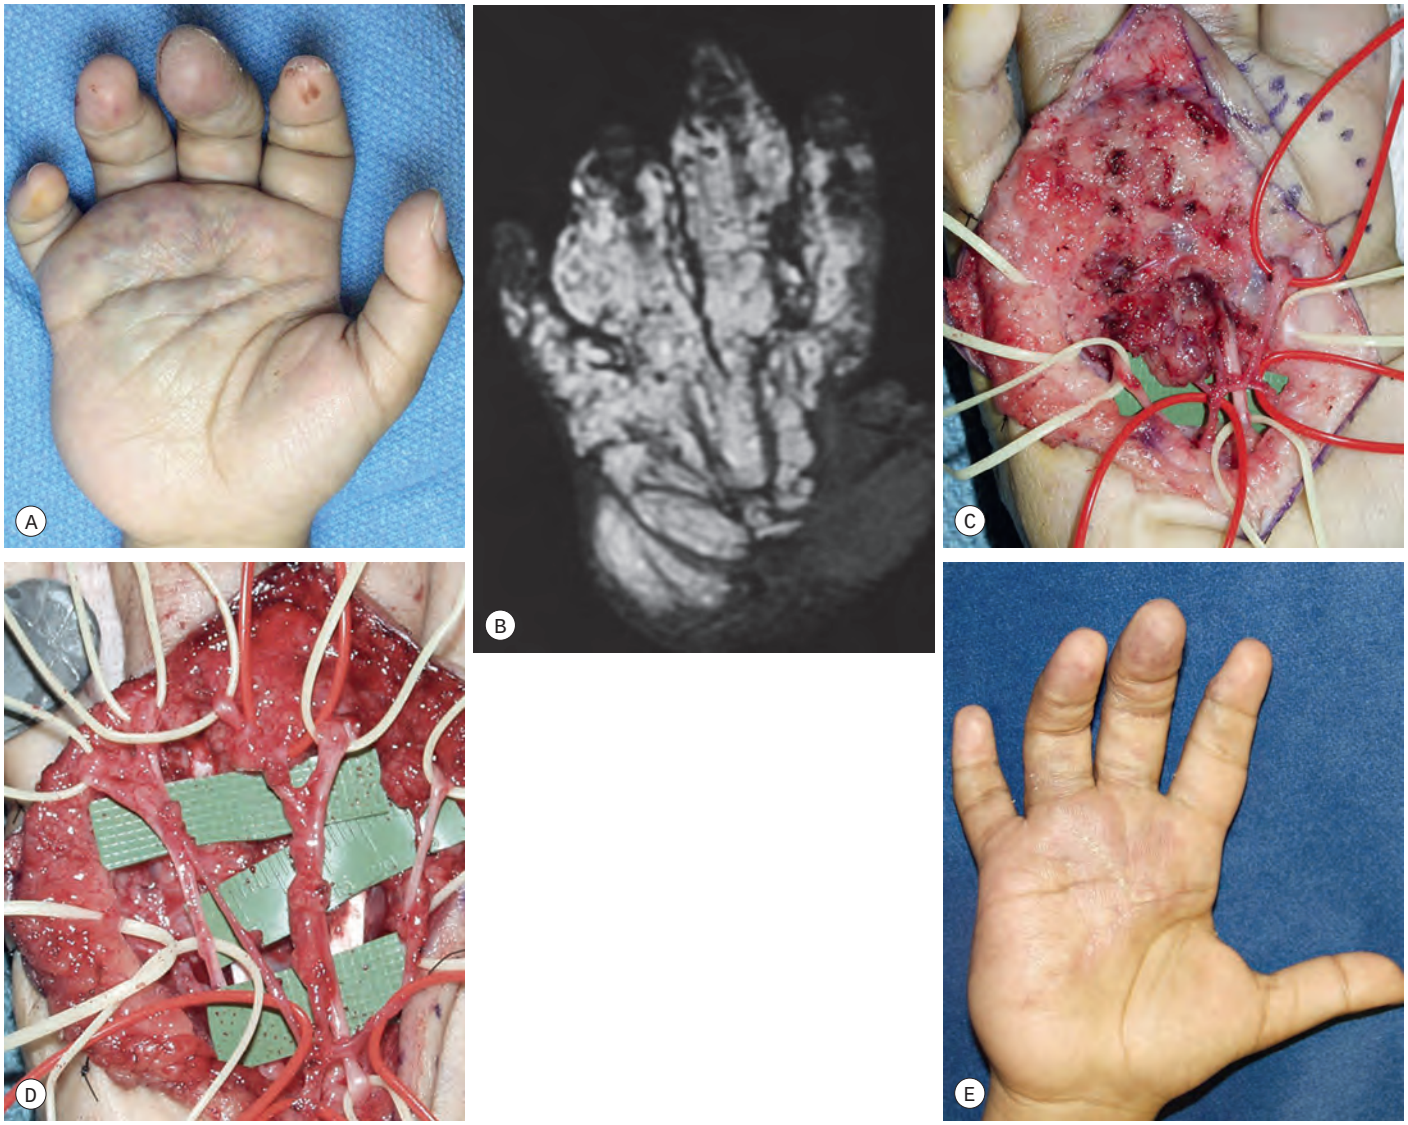


Fig. 31.13 Venous malformation (VM) palm. **(A)** This 6-year-old child with a diffuse VM of the palm could not wear garments due to painful intralesional thrombi. **(B)** The coronal T2-weighted images show multiple signal voids within a diffuse, through-and-through VM. The mid-palm was most symptomatic. **(C)** The dissection begins with identification of the palmar arch (red loops) and median and ulnar nerves (yellow loops). VM contains multiple thrombi admixed with dysplastic fat. **(D)** A complete proximal-to-distal resection was completed with preservation of all neurovascular structures, flexor tendons, and lumbrical muscles, including their motor branches. **(E)** Five years later, normal sensation and motion has been maintained. VM remains but is not symptomatic.

The proximal forearm presents one of the most difficult operative fields for the extremity surgeon due to the high density of important anatomic structures in a compact space. Subcutaneous VMs are not problematic in this area. Intramuscular lesions are difficult to resect because the potential for damage to adjacent muscle and injury to the many small motor branches of the median nerve, and particularly the posterior interosseous nerve on the dorsal forearm. Localized lesions deep within the flexor pronator region are difficult to approach without damage to the wrist flexors and deep digital and thumb flexors. Sclerotherapy is the first line of treatment (see Fig. 31.11). On the dorsal surface, it is much easier to identify and decompress the radial nerve through the Arcade of Frohse; however, the risk for injury to extensively involved extensor muscle bellies is high. VMs in this region are usually diffuse and extend well beyond the fascial planes into the muscles. Commonly, VMs and other vascular anomalies involve the dorsal interosseous system along the entire length of the interosseous membrane and may extend into the volar compartments. Surgical decompression of the cubital tunnel, radial tunnel as well as the volar side of the median nerve usually relieves neurogenic pain, which may also be secondary to bleeding, thrombophlebitis, or phleboliths within the VM. Neural wrapping with acellular dermal matrix, autogenous vein, other alloplastic materials or local uninvolved tissue is a helpful adjunct to any neuroplasty in this region.

The distal forearm, wrist, palm, thumb, and digits are more amenable to surgical extirpation because less muscle mass and more solid tendinous and neural structures occupy the region. Frequently, what appears to be a superficial lesion in the distal forearm and wrist extend deep to and through the interosseous membrane and involve the rete system. Resections in this region must be thorough, and usually includes removal of the interosseous membrane. Denervation of both

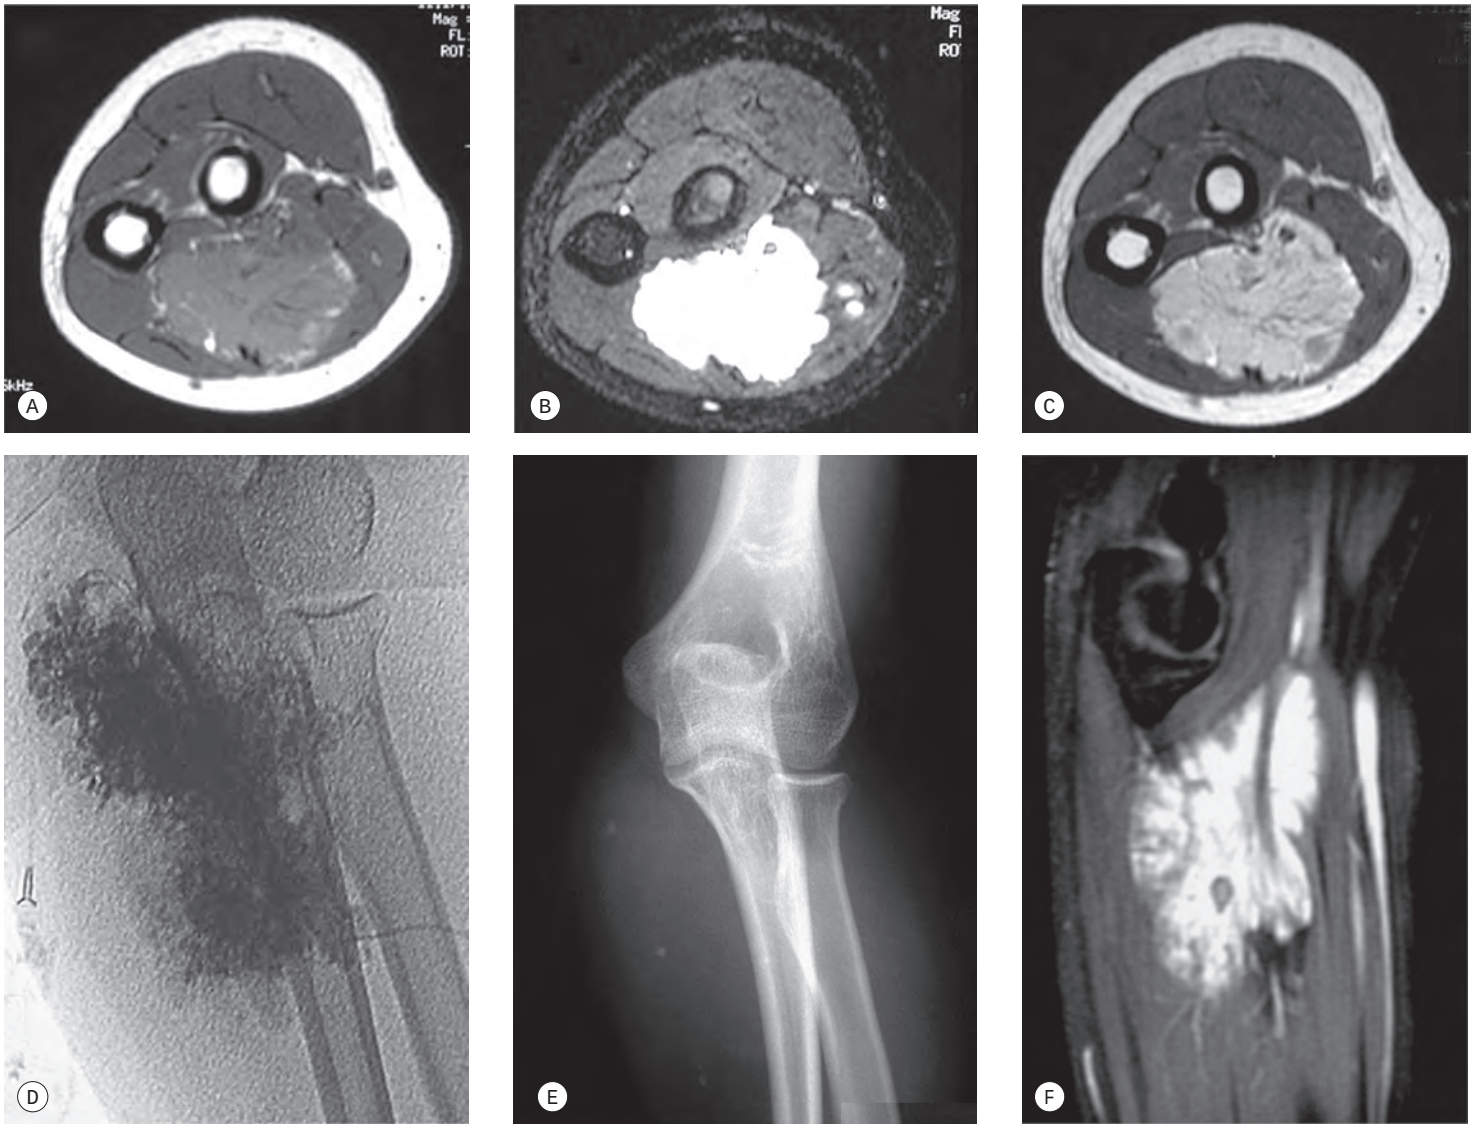

Fig. 31.11 Sclerotherapy. Radiographic studies of the vulnerable proximal third of the forearm show a venous malformation (VM), which is ideal for sclerotherapy: **(A)** Isointense to adjacent skeletal muscle on axial T1 sequence; **(B)** enhances on axial T1 plus gadolinium contrast; **(C)** shows signal voids on axial T2 representing phleboliths; **(D)** fills with direct puncture and injection of contrast; **(E)** shows small calcified phleboliths on radiographs; **(F)** has multilobulated structure with signal voids on sagittal T2 sequences.

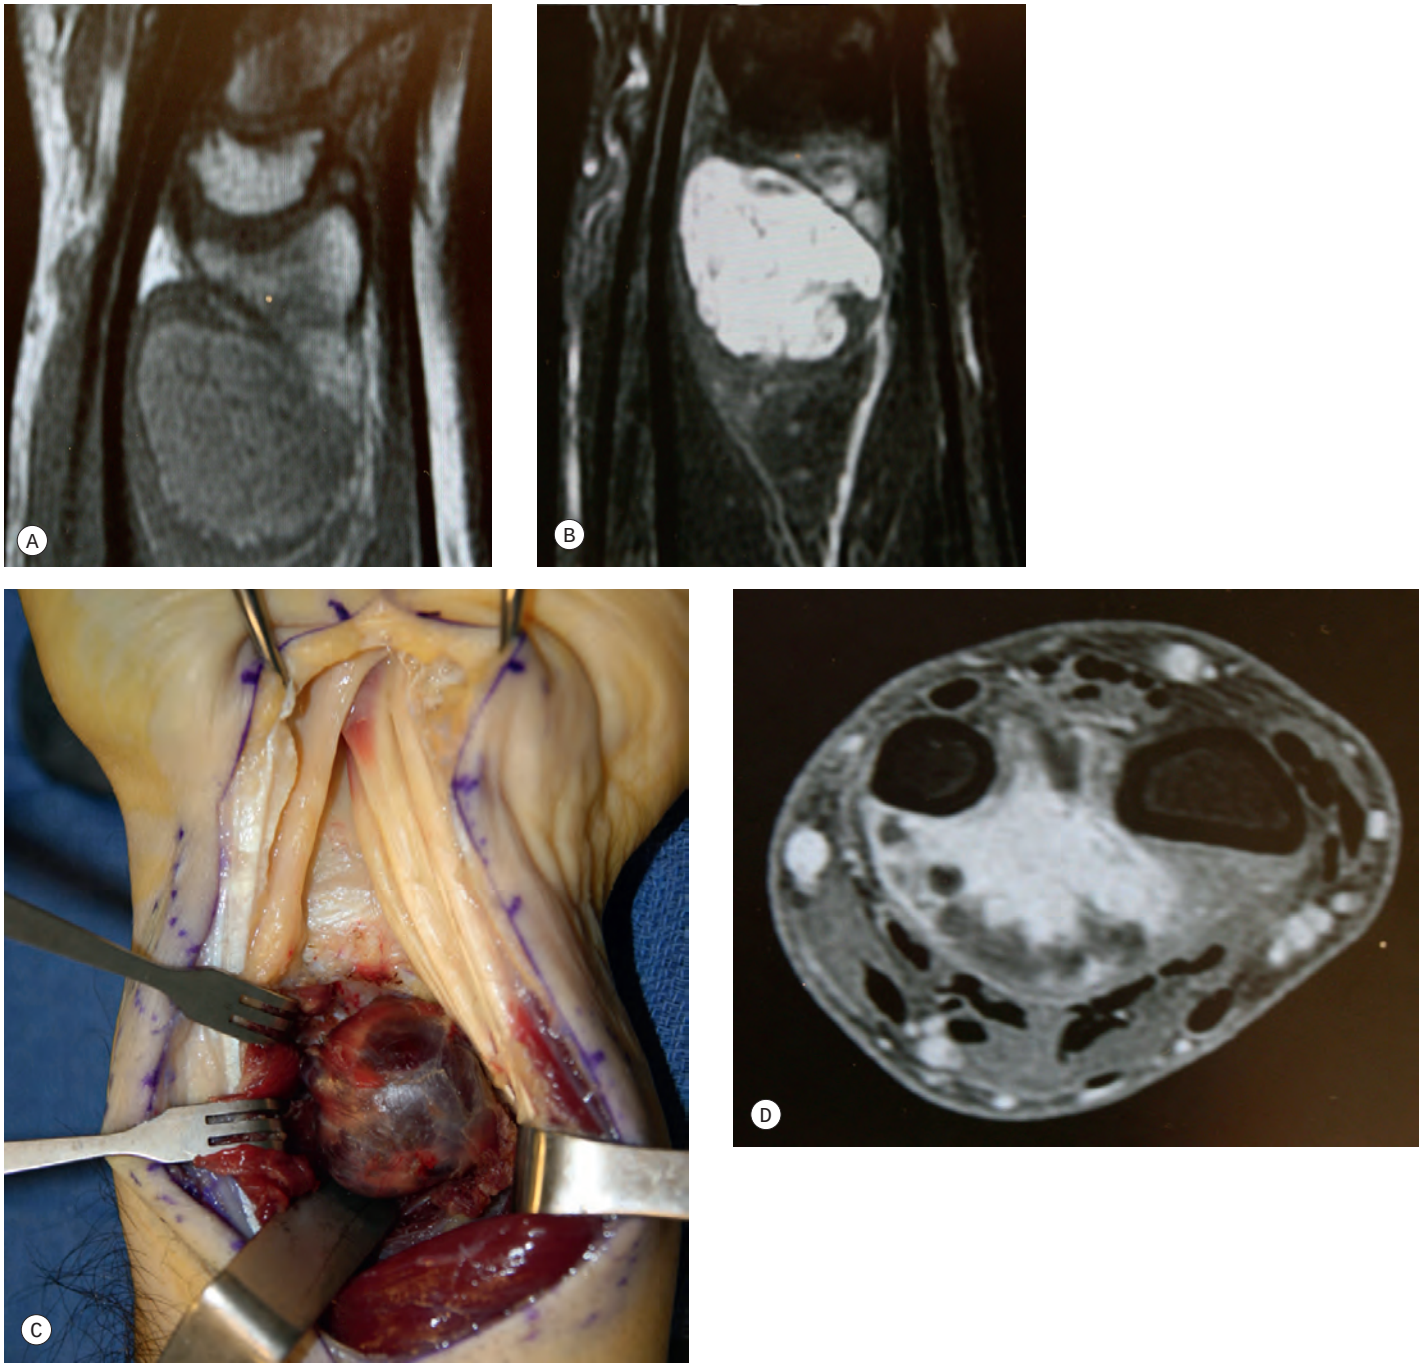

Fig. 31.12 Venous malformation (VM) distal forearm. **(A,B)** A middle-aged man presented with carpal tunnel symptoms. Coronal T1 (above) shows a lesion with signal voids and T2 sequences (below) demonstrate enhancement, both consistent with VM. **(C,D)** Enhanced T1-weighted sequences show extension across the interosseous membrane.

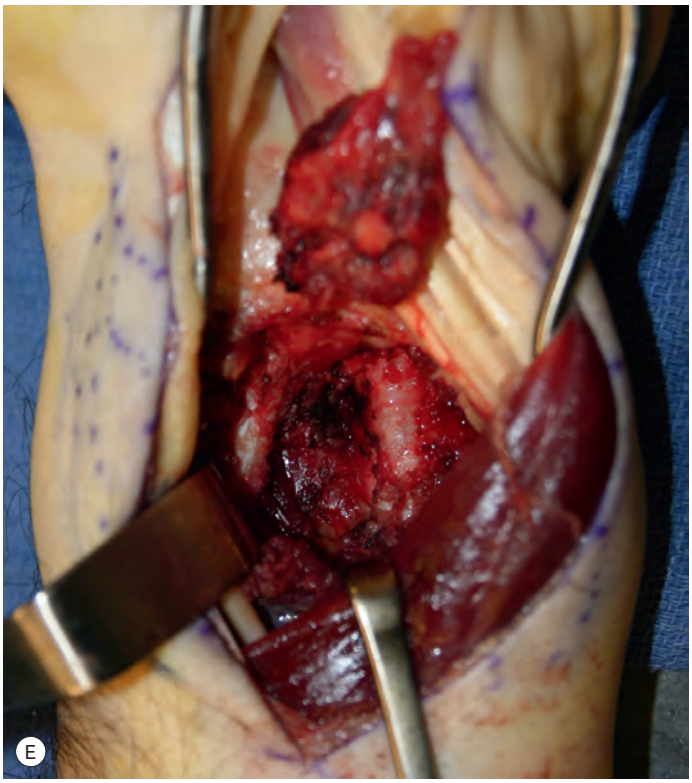

Fig. 31.12, cont'd **(E)** Excision included the pronator quadratus muscle. **(F)** Full function returned 6 weeks postoperatively.

Fig. 31.14 Complications of interventional radiology. Intrinsic compartment releases were necessary following sclerosis of this diffuse venous malformation of the entire palm of the hand. Ethanol was used to embolize this arteriovenous malformation with a nidus within the palm. The distal portions of the thumb, index, and long digits were lost.

and anterior and posterior interosseous nerves will alleviate postoperative wrist pain (see Fig. 31.12 ◍). The median and ulnar nerves are frequently involved in this region, but intraneural dissection is indicated only when there are symptoms. Secondary neuromas within the main nerves or their sensory branches at the wrist level can be severely disabling for both children and adult patients. A deep palmar VM commonly enlarges within the first webspace and extends along the adductor pollicis muscle beneath the first dorsal interosseous muscle. Both muscles are important in pinch and should be preserved if they are not extensively involved. Deep dissection beneath the palmar arch will often expose the deep motor branch of the ulnar nerve (see Fig. 31.13).

What appears to be localized VM in the palm and dorsum of the hand is always much more extensive than it appears clinically. The margins of many VMs may not be evident on MRI or MRV scans. Dissection in this region is difficult and general guidelines must be strictly observed (see Table 31.5). Sclerotherapy in this portion of the hand has many potential complications due to the high concentration of neurovascular structures, gliding tendons, and delicate intrinsic muscles (Fig. 31.14).

Outcomes, prognosis, and complications

Few outcome studies are available due to the extremely variable presentation of VMs within the upper extremity and the many syndromic designations and confusion in terminology. VMs can be resected with predictable results. Early complications often beget later problems and less than optimal outcomes. Problems occur in up to 20% of patients and are seen early (swelling, hematoma, delayed wound healing, skin necrosis) or late (neuroma, scar contracture, joint stiffness). Wrist and forearm flexion contractures following partial intermuscular resections are common for proximal forearm lesions. Symptomatic neuromas develop in 35% of those who have intraneural dissections.

Arteriovenous malformation

Arteriovenous malformation (AVM) results from an error in vascular development during embryogenesis in which an absent capillary bed causes shunting of blood directly from an artery into a venous system. This shunt occurs through a direct arteriovenous connection (fistula) or abnormal feeding vessels between an artery and a vein (nidus). This observation of Halsted in 1919 may explain why these AV connections are common in the central nervous system, where apoptosis is rare.[73,74] A number of genetic abnormalities have been described (Table 31.8). These lesions are present at birth only in one-third of patients; 15% involve the extremities. Almost 80% become clinically evident before the termination of adolescence and the natural history is one of slow progressive growth and expansion! These malformations worsen with time and are staged by the Schobinger system (Table 31.9). It is not unusual for a lesion to progress from quiescent through destructive phases. The timing of progression is not predictable when first seen. Table 31.8 appears online only.

Not all fast-flow lesions in the upper limb should be labeled as PWS. We have separated these lesions into four categories in which the arteriovenous flow is related to: (1) a direct AVM (Fig. 31.15); (2) flow through a nidus (see Figs. 31.14B & 31.19); (3) flow through a vascular tumor (see Fig. 31.17) and finally; (4) diffuse high-flow vessels perfusing all tissue planes (see Figs. 31.18 & 31.21). PWS is rare and should be restricted to the last condition.

Basic science/disease process

The cardinal features of AVM in a limb are warmth, pain, paresthesias, hyperhidrosis, and compression neuropathy. A CM may be the only initial sign of an AVM, which may not become evident until later in childhood. Vascular thrills and bruits are not always marked. In some patients, a pulsating mass and accompanying thrill may be psychologically disturbing. Many patients seem to tolerate symptoms for a lifetime (see Fig. 31.15). AVM may be present at the dermal level. Cutaneous mottling and atrophy, progressing to ulceration, are secondary to the "steal phenomenon", i.e., blood is shunted to the proximal portion of the limb, resulting in peripheral vascular insufficiency, usually first evident in the fingers, toes, hands, and feet (Fig. 31.16). Chronic infection, ulceration, recurrent bleeding, and intractable pain are the end-stage problems in these unfortunate patients. Paradoxical increased blood flow but decreased tissue perfusion hampers wound healing. These malformations are regional and are rarely found with associated fast-flow anomalies elsewhere in the body. Patients with an AVM involving the entire extremity and ipsilateral chest wall or those involving the entire lower extremity and pelvic region often demonstrate a positive Nicoladoni sign, a decrease in pulse rate with application of a pneumatic tourniquet to the affected extremity. A large AVM in an extremity can cause cardiopulmonary overload (Fig. 31.17 & see Fig. 31.21). Some children develop extraordinary postures to alleviate their pain (Fig. 31.18). AVMs do not cause disseminated intravascular coagulopathy. Intralesional bleeding can cause compartment compression. Bony hypertrophy and elongation are present in more than half of these affected limbs. Skeletal involvement carries an unfavorable prognosis but is not an absolute contraindication to surgical intervention. Fig. 31.18 appears online only.

Table 31.9 Schobinger clinical staging system		
Stage I	Quiescent	AVM mimics a capillary malformation or involuting hemangioma
Stage II	Expansion	Lesion larger, warmer, throbbing with thrill or bruits
Stage III	Destruction	Stage II plus ulcers, hemorrhage, persistent pain, tissue necrosis and bone destruction
Stage IV	Decompensation	Stage III plus increased cardiac output and cardiac failure

Diagnosis/patient presentation

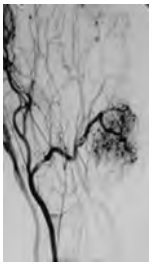
AVM can mimic other extremity malformations and there are many vascular conditions containing fast-flow malformations (see Table 31.8). Most lesions are diagnosed by history and physical examination, and fast-flow characteristics are confirmed by Doppler probe in the clinic. MRI may be obtained to: (1) confirm the diagnosis; (2) outline the true extent of the lesion; and (3) plan management. The T2-weighted sequences show tortuous, dilated, arteries and large draining veins, enhancement, and flow voids. The "nidus" is identified as a blush within the central portion of the lesion (Fig. 31.17A & see Fig. 31.19B). Magnetic resonance angiography (MRA) and CTA scans demonstrate the 3D characteristics and are preferred over angiogram by most interventional radiologists.[33] Extremity surgeons prefer angiography to show the caliber and flow dynamics of the shunts prior to any surgery.[2,15] Anatomic abnormalities are common in the upper limb and include: giant feeding vessels; persistent interosseous vessels; corkscrew configuration of arteries; large median artery; duplicated brachial systems; and large draining veins. Palmar arches are often obliterated with active shunting, and muscle groups may be completely replaced by active AVFs. CT scans are indicated for skeletal involvement. Although critical in the evaluation of other malformations, histopathological diagnosis of AVM is rarely necessary but can be important to rule out rare malignancies such as infantile fibrosarcoma.

Treatment/surgical technique

The puzzling question with fast-flow lesions is their unpredictable natural history and rate of progression. Simple

Table 31.8 **Combined and fast-flow malformations**

	Parkes Weber (PWS)	Ostler–Rendu–Weber	CM–AVM	PTEN–AVM	CLM	Klippel–Trénaunay
Eponym/ name	Parkes Weber; AVM with AVF	Hereditary hemorrhagic telangiectasia (HHT)	CM–AVM	PTEN-hamartoma syndrome (PTHS) Cowden, BRRS	CLM; CM–LM confused with CLOVES	KT; CLVM
Vascular malformation	Diffuse AVM with AVFs lymphedema	CM, visceral AVMs in liver and lungs	CM –small, pink	Multiple AVMs, VM	CM, LM	CM; VM (varicose veins); LM
Skin appearance	Pseudo CM on skin lymphedema	Telangiectasia lips, fingers mucosal-nasal epistaxis	Pinkish lesion with halo	CM; possible VM bluish discoloration	CM	Capillary stain, bluish pink, vesicles, maceration
Hemodynamics	Fast-flow	Fast-flow AVFs	Fast-flow in 30%	Fast-flow AVM in 50%	Slow-flow	Slow-flow
Cardiac compromise	Common	Rare, anemia	Possible	None	None	Possible
Arteriovenous fistuli	Multiple, often aneurismal		None	Multifocal	None	None
Lateral/deep venous anomalies	None	None	None	Clusters abnormal veins	Tortuous draining veins	Common; vein of Servelle lateral arm as in leg; varicose veins
Coagulopathy	None	None	None	Unusual	None	Present
Pattern	Lower → upper extremities		Lips, intraoral	Legs > arms/hand	Extremities equal	Lower > upper extremities
Genetics	Unknown	HHT1 mutation of endoglin HHT2 mutation ALK1	Mutation *RASA1*; positive family history	PTEN mutation	None	Unknown
Associated anomalies	Rare pelvic AVM; Cobb syndrome	AVM cerebral, spinal, liver and pulmonary	Cerebral AVM 7%	Macrocephaly; penile freckling (males); lipomas	None	Common: GI, GU, genital pelvic organs
Limb hypertrophy	Major, disproportionate osteolysis can occur	None	Absent	Absent	Uncommon; can occur	Minor to moderate
Symptoms	Warmth, pain, hypertrophy, sweating	Nasal epistaxis GI bleeding anemia	Warmth, pain, mass	Pain, mass effect; function	Cellulitis, size, bulk	Ulcers, cellulitis, weight and bulk
Venous stasis, skin ulcers	Ischemic changes; pseudo Kaposi changes	Telangiectasia ± bleeding	None	Absent	Vesicular maceration	Common
Clinical prognosis	Poor; progressive expansion	Good	Progressive with AVM	Progressive	Good	Stable; severe overgrowth common
						



AVF, Arteriovenous fistula; AVM, arteriovenous malformation; BRRS, Bannayan–Riley–Ruvalcaba syndrome; CLOVES, congenital lipomatous overgrowth with vascular malformations, epidermal nevi, and skeletal anomalies; CLVM, capillary–lymphatico-venous malformation; CM, capillary malformation; GI, gastrointestinal; GU, genitourinary; LM, lymphatic malformation.

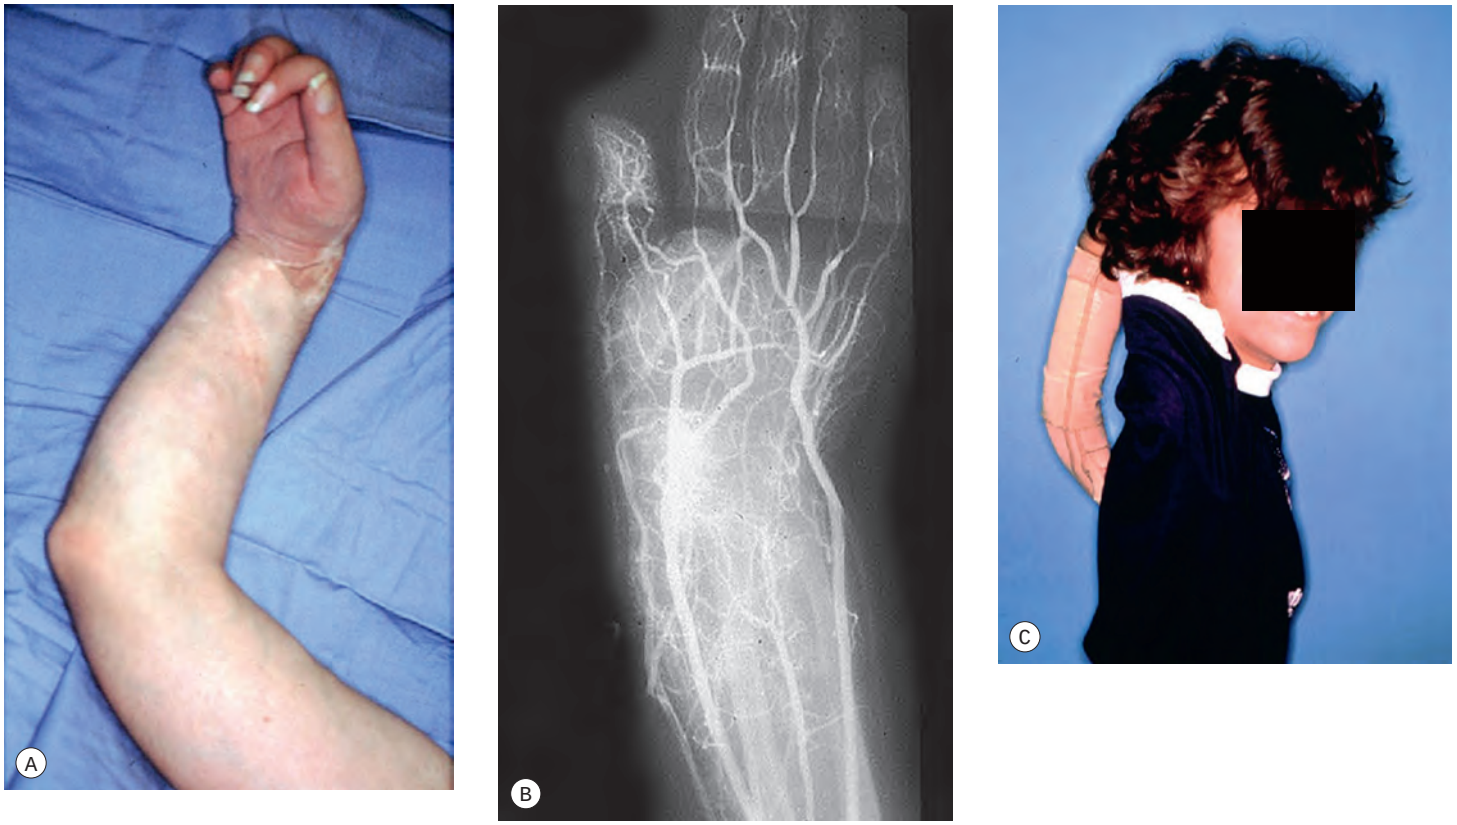


Fig. 31.18 Parkes Weber syndrome (PWS). **(A)** A 6-year-old child with a capillary malformations (CM) of the wrist and hand, and a pulsatile mass of her distal forearm. Diagnosis of PWS was made and she was treated with a compression garment. Flexion contractures gradually developed in the wrist and all digits. **(B)** Angiogram at age 7 showed diffuse hypervascularity and multiple microfistuli without large draining veins. **(C)** Pain gradually increased as she grew. She learned to control this pain by dislocating her glenohumeral joint, a maneuver that compressed the massively enlarged subclavian artery and vein. She often slept in this position.

Fig. 31.15 Natural history of fast-flow arteriovenous malformation (AVM). **(A)** A 67-year-old adult executive complained of gradual swelling and pulsation in the hand since teenage years. Attempted surgical removal of symptomatic regions had been aborted due to excessive bleeding. **(B)** Early angiographic sequences showed large, tortuous macro-fistulous shunts involving radial and ulnar arterial systems and both palmar arches; very little flow to the distal digits.

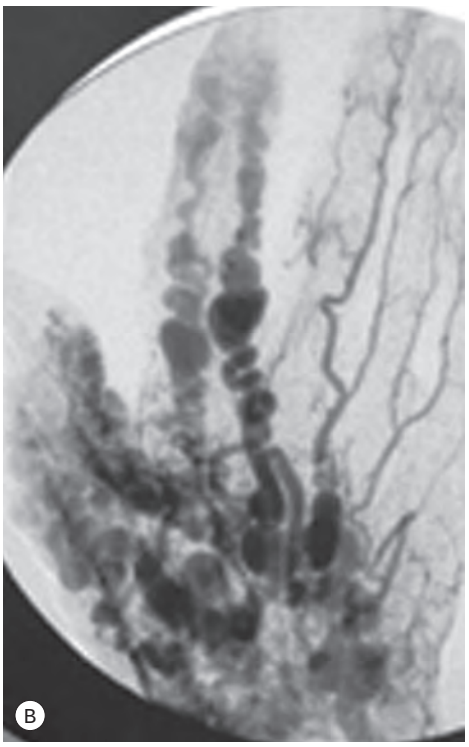

Fig. 31.16 Fast-flow arteriovenous malformation (AVM) with steal phenomenon. **(A)** Angiogram of a 21-year-old patient who presented with an asymptomatic bruit of the wrist shows an AVM involving the radial and interosseous systems. **(B)** Inverted arteriographic images taken 20 years later show large tortuous radial and interosseous vessels leading to large aneurysms with shunting in the distal metacarpal region. **(C)** Tip discoloration of the thumb and long digit caused by steal phenomenon. Distal ischemia of the thumb will ultimately progress to tissue necrosis.

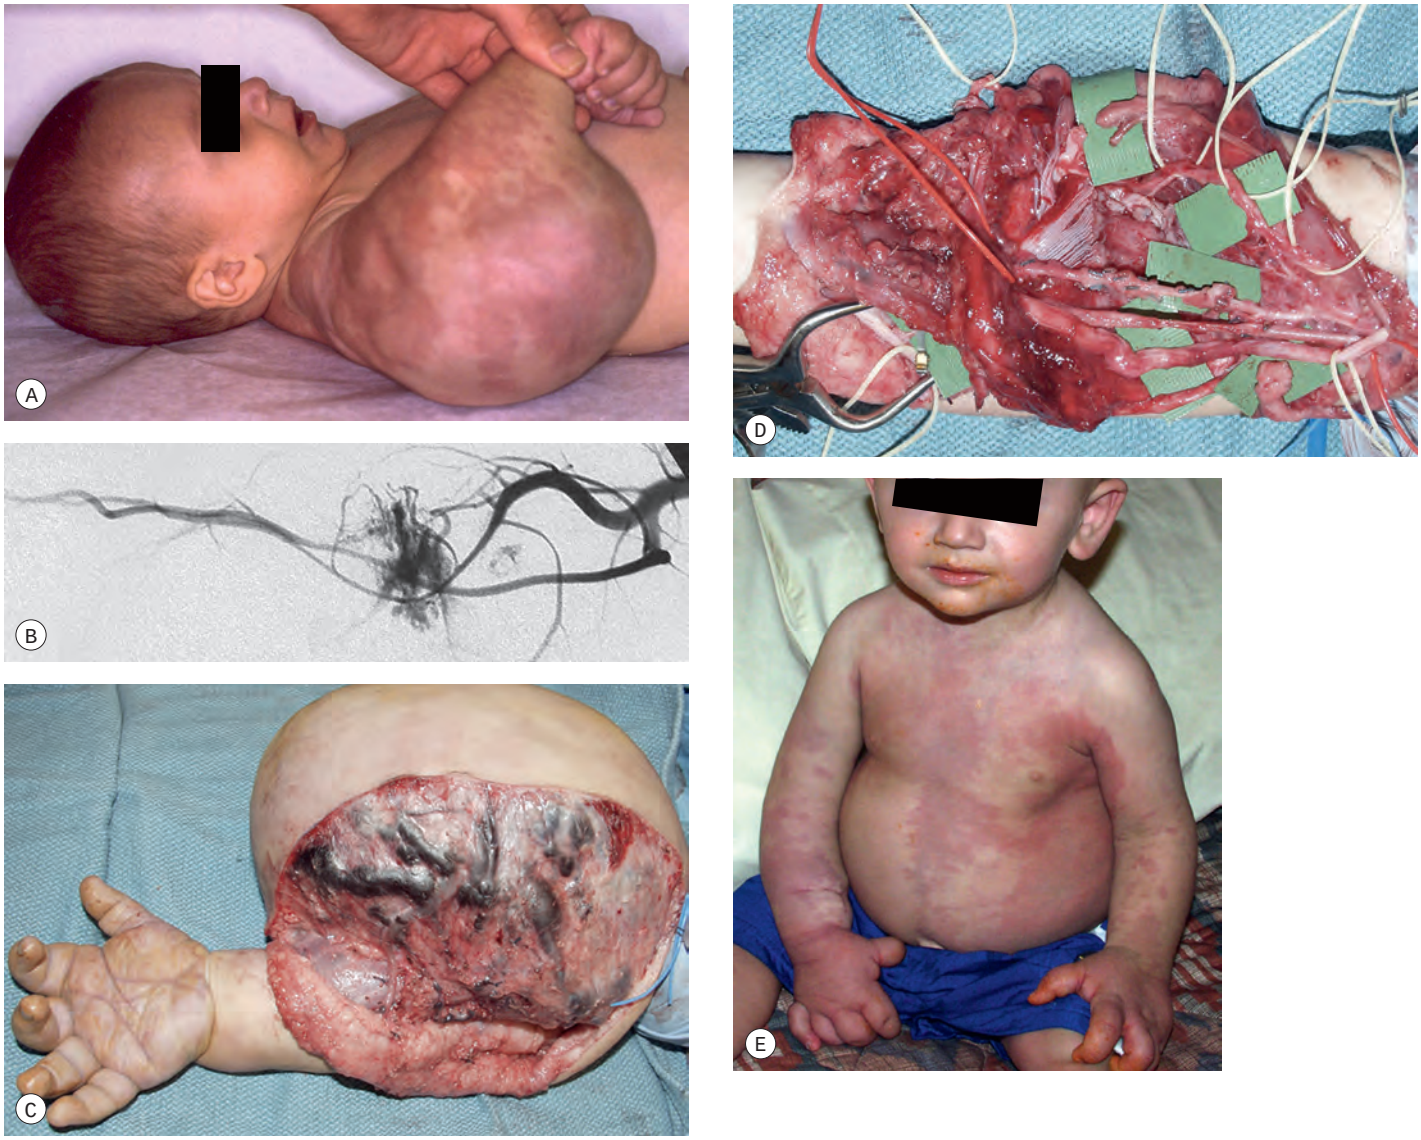

Fig. 31.17 CLOVES with arteriovenous malformation (AVM). **(A)** A 6-month-old baby was referred with large AVM of right arm and forearm, failure to thrive, and refractory cardiac failure. Arm amputation was recommended by many consultants but refused by the family. **(B)** Angiography showed nidus located at level of elbow and forearm. **(C)** Massively enlarged draining veins were encountered. Dissection proceeded toward the center of the mass. **(D)** Individual branches of axillary and brachial artery were mapped and surgically ligated. The dysplastic radial artery (red loop) was replaced with a graft; median, ulnar and radial nerves (yellow loops) were preserved despite massive stretching. **(E)** Incision healed well and patient maintained full elbow flexion/extension and sensation. There were also truncal capillary malformations, overgrowth of multiple limbs, and epidermal nevi. He was later diagnosed as CLOVES.

observation is the initial treatment in all but the most symptomatic AVMs. Compression garments may be of some help (see Fig. 31.18C ◍). The goal of treatment is to control the progression of the malformation and to alleviate symptoms: pain, ulceration, bleeding, distal discoloration, or functional problems. Management options include embolization, surgical resection or a combination (Fig. 31.19). Surgical resection offers the best chance for long-term control, but re-expansion rate following extirpation is high and the deformity created by the resection may be significant. Radical extirpation may often create a deformity worse than the malformation itself. Amputation is the definitive cure, which may be achieved with functional limitations (see Fig. 31.21). Therefore, embolization is the first line of intervention for type A and B lesions in the Schobinger I (quiescence) or II (expansion) stages. Well-localized lesions respond better than diffuse AVMs involving multiple tissue planes, but all lesions will re-expand to some degree, especially if the central nidus has not been obliterated.

It is important that the extremity surgeon understand the rationale of embolization, which is often used as the primary treatment for these lesions. Inert substances are injected into the nidus to obliterate the abnormal vascular channels, promote ischemia and ultimate scarring of the malformation. Substances used for this process may be liquid (ethanol, *n*-butyl cyanoacrylate (*n*-BCA), onyx or solid (polyvinyl alcohol particles, PVA), or coils of many varieties. It is critical that these materials are delivered directly to the nidus of the AVM. Obstruction of the inflow vessels is the major problem with selective embolization and will result in: (1) collateralization of vessels; (2) expansion of the malformation; and (3) aggravation of symptoms.[75] More recently, radiologists at our center

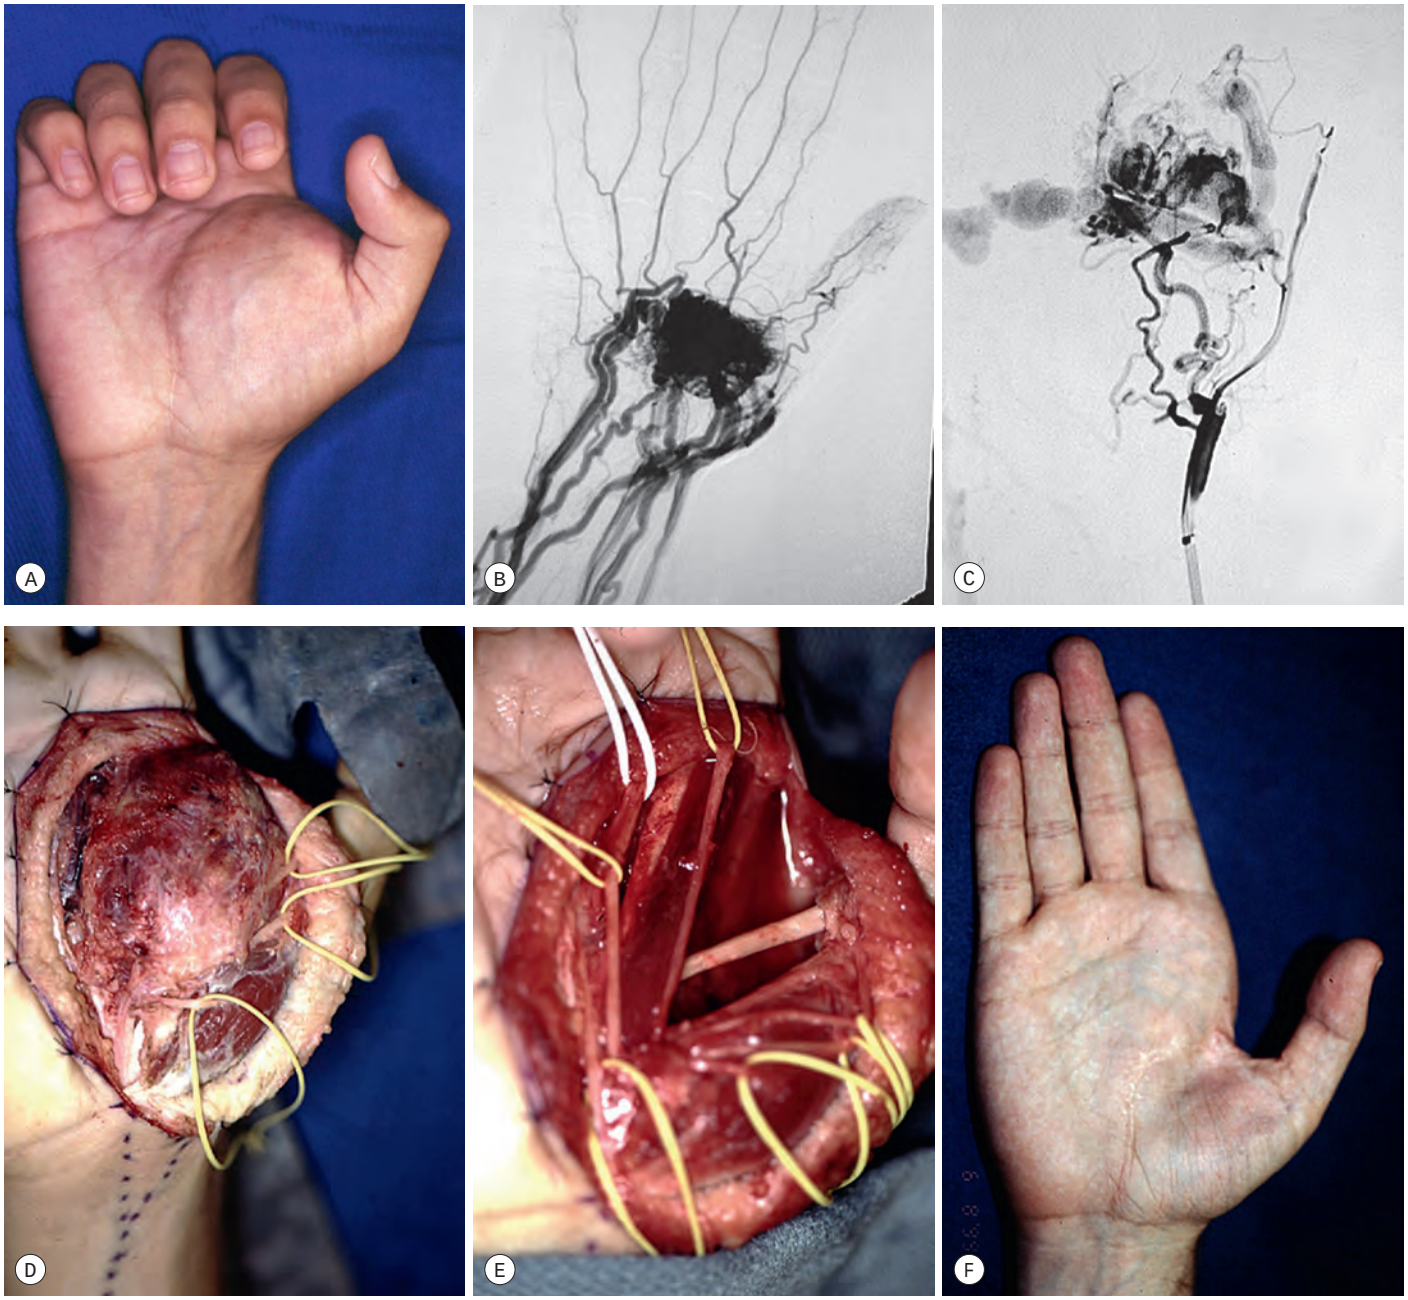

Fig. 31.19 Arteriovenous malformation (AVM) of hand. **(A)** Professional wrestler presented with painful mass in thenar eminence. Thrill first noted during adolescence. **(B)** Angiography demonstrated AVM nidus at superficial palmar arch, supplied by radial, interosseous and ulnar vessels. Distal digital and thumb arterial vaso-architecture was normal. Embolization performed with *N*-butylcyanoacrylate (NBCA). **(C)** Post-embolization study showed obliteration of most of AVM with residual large draining veins. **(D)** Two days after embolization, the mass was explored: yellow vessel loops mark recurrent motor branch and multiple sensory branches of the median nerve. **(E)** All nerves, flexor tendons, and uninvolved thenar muscles were preserved during resection. **(F)** Five years later, he continues to demonstrate good function. Palmar abduction is present (abductor pollicis muscle), but key pinch is weak due to subtotal loss of the adductor pollicis muscle.

have focused on obliteration of the outflow in high-flow lesions that have only a few large outflow venous channels. This approach has shown promising results but longer-term studies are needed to corroborate initial findings.

For temporary preoperative embolization, Gelfoam powder, PVA, and Embosphere are used instead of liquid agents. Over the past decade, our interventional radiologists have preferred onyx, an ethylene-vinyl alcohol copolymer. At the time of resection, the embolized tissue with its attendant inflammation will have a mass effect, which facilitates resection. Excision should be completed within 36–72 h post-embolization, before recanalization restores blood flow to the region of the lesion. The major complications to embolization are skin ulceration, local compartment syndrome, and rarely, distal ischemia (see Fig. 31.14B). Extremity surgeons must be available following these procedures in interventional radiology.

Resection is indicated whenever the AVM leads to chronic ulceration or bleeding, compartment compression, nerve compression, uncontrolled congestive heart failure (CHF),

gangrene, or unrelenting pain. The procedure must be tailored to the patient's needs. In all but the most localized lesions, resection for AVM in a limb is palliative. The surgeon who undertakes resection of an AVM in a limb must have specific objectives that can be accomplished during a safe tourniquet time. The general principles of treatment outlined earlier for slow-flow anomalies also apply to fast-flow anomalies (see Table 31.4). Problems arising during these procedures can get out of control; these are well known to all surgeons who have written about operating on these anomalies. Dramatic outcomes can be achieved with a well-planned and executed procedure (Fig. 31.20 ◍). There is no predictable procedure that when performed in childhood will prevent subsequent expansion of an AVM, short of a limb amputation. In few other areas of hand surgery is careful explanation of potential complications so important. Amputation of a very symptomatic, almost parasitic part is encouraged. Severe pain and bleeding are often the precipitating symptoms (Fig. 31.21 ◍). Figs. 31.20 and 31.21 appear online only.

The same anatomic concerns outlined with the slow-flow malformations apply to this group of very dynamic lesions. Nerves and tendons should be preserved. Heavily involved muscle groups should be resected. Revascularization of the hand, digit or thumb should be performed if both axial vessels have been excised. Similarly, marginal skin requires resection and appropriate resurfacing.

PTEN-associated vascular anomaly (PTEN-AVA)

Basic science/disease process

The PTEN (phosphatase and tensin homologue) gene encodes a tumor suppressor lipid phosphatase.[29] Children with these PTEN mutations have the PTEN hamartoma-tumor syndrome (PHTS). This is an autosomal-dominant condition, which in the literature has previously been called the Cowden syndrome or the Bannayan–Riley–Ruvalcaba syndrome (BRRS).[30,76] The PTEN mutation is associated with multiple benign and malignant tumors that require surveillance.

Males and females are equally affected. The lower extremities, especially the thighs and calf musculature, are involved much more frequently than the upper extremities, where the arm and forearm regions are more involved than the wrist and hands. Half (54%) of these patients have fast-flow malformations with arteriovenous shunting and are designated PTEN-AVA. These children have distinctive macrocephaly; males have penile freckling and these masses can be large and multiloculated. Large amounts of adipose tissue surround the shunts and the mass effect of the affected limb may result in functional compromise. The lesions directly involve the muscles, surround neurovascular tissues, and extend within intramuscular fascial planes. Bone is usually not involved. Lesions may grow to massive proportions.

Diagnosis/patient presentation

The diagnosis is made by physical examination and imaging (Fig. 31.22 ◍), and confirmed by histological and genetic analysis. Histology shows tortuous arteries with mural hyperplasia. Fig. 31.22 appears online only.

Treatment/surgical technique

Although sclerotherapy has been used to control large tortuous veins and isolated clusters, surgical resection is the definitive treatment of choice. Extirpation may be more difficult if prior sclerotherapy has been performed. Resections in the arm, forearm, and hand often involve microvascular dissections of involved neurovascular structures.

Parkes Weber syndrome (PWS)

PWS is an eponym denoting a fast-flow malformation in association with soft tissue and/or skeletal overgrowth and overlying CM.[32,33] The term is incorrectly used in its association with KTS and should not be used to describe all fast-flow lesions within the extremities.

Basic science/disease process

No genetic foci or mutations have been identified to date.

Diagnosis/patient presentation

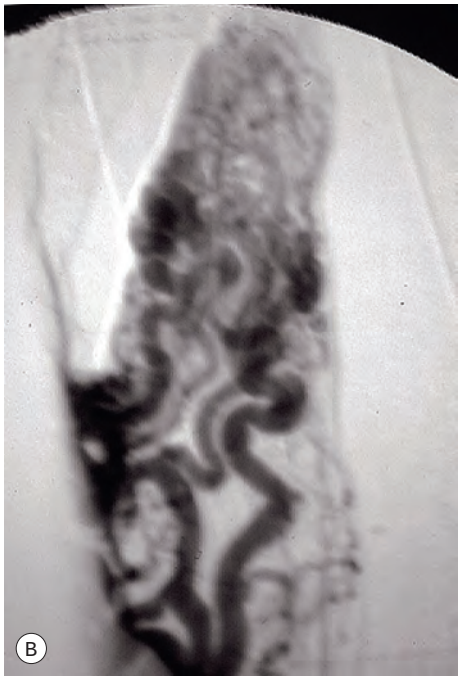
The diagnosis is made by physical examination and ultrasound. The lower extremity is involved much more frequently than the upper. Diffuse or localized CMs are often present; other skin changes include pseudo Kaposi lesions, lymphedema, and skin ulceration late in the progression of the malformation. Lymphedema is common. The angiograms in a classic PWS do not initially show specific AVFs with large draining veins. These early studies show diffuse high-flow vessels infiltrating the involved soft-tissue and skeletal structures without large draining veins so characteristic of shunts. The CM is often diffuse and irregular and covers the region of underlying hypervascularity (Fig. 31.21 ◍ & see Fig. 31.18 ◍). PWS should be distinguished from other fast-flow lesions: PTEN-AVA, other vascular tumors, AVM with AVFs, and CM–AVM. MRI, MRA, ultrasound, and biopsy are warranted with an increase in symptoms. The clinical prognosis is one of progressive expansion and destructions. Fig. 31.21 appears online only.

Treatment/surgical technique

Management is identical with the indications and principles previously presented for fast-flow lesions. Initial treatment is always conservative, but these children should be followed through adolescence and adulthood. Symptomatic regions respond to selective embolization. Cardiac compromise may be insidious; cardiologists must evaluate these children yearly. Regional resections are warranted for selective cases but must be carefully planned and executed with the realization that these lesions are often progressive. Amputation of nonfunctional digits, hands, and arms is usually delayed; pain is often the precipitating factor for an amputation. Experience has taught us that amputations of parasitic parts is often unnecessarily delayed either by the reluctant surgeons or anxious parents with unrealistic expectations.

Outcomes, prognosis, and complications

Children must be monitored both for cardiac symptoms and overgrowth issues. The progress may be slow and not predictable early in life. All patients have some degree of pain,



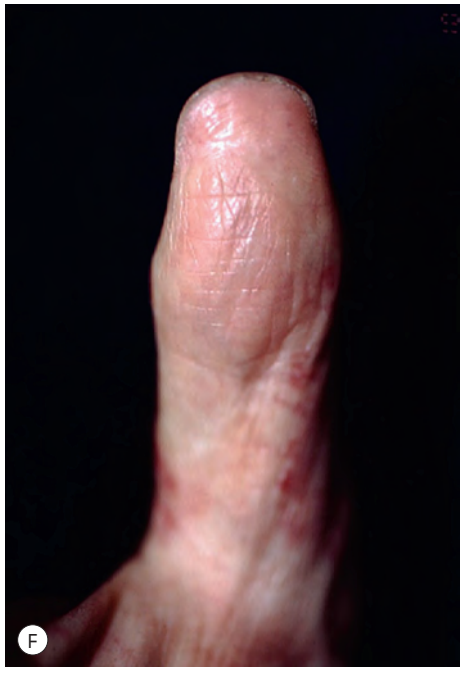


Fig. 31.20 Arteriovenous malformation (AVM) with arteriovenous fistuli of thumb. **(A)** A 60-year-old man presented with pulsatile bleeding from excoriated regions of his right thumb. He first noted swelling as a young child, and lived with periodic bleeding and ulceration his entire life. **(B)** Arteriography showed extensive macro-fistulous AVM involving radial side of his dominant hand. **(C)** Congenital absence of his left hand made him completely dependent on right upper limb. **(D)** Following resection of scarred and unstable pulp surface and debulking entire thumb, resurfacing accomplished with neurovascular island flap from ulnar side of long finger. **(E)** Flap extended to nail plate distally and included entire working pulp surface of thumb. **(F)** This grateful patient has a stable functional thumb, which he perceives is on ulnar side of the long finger.

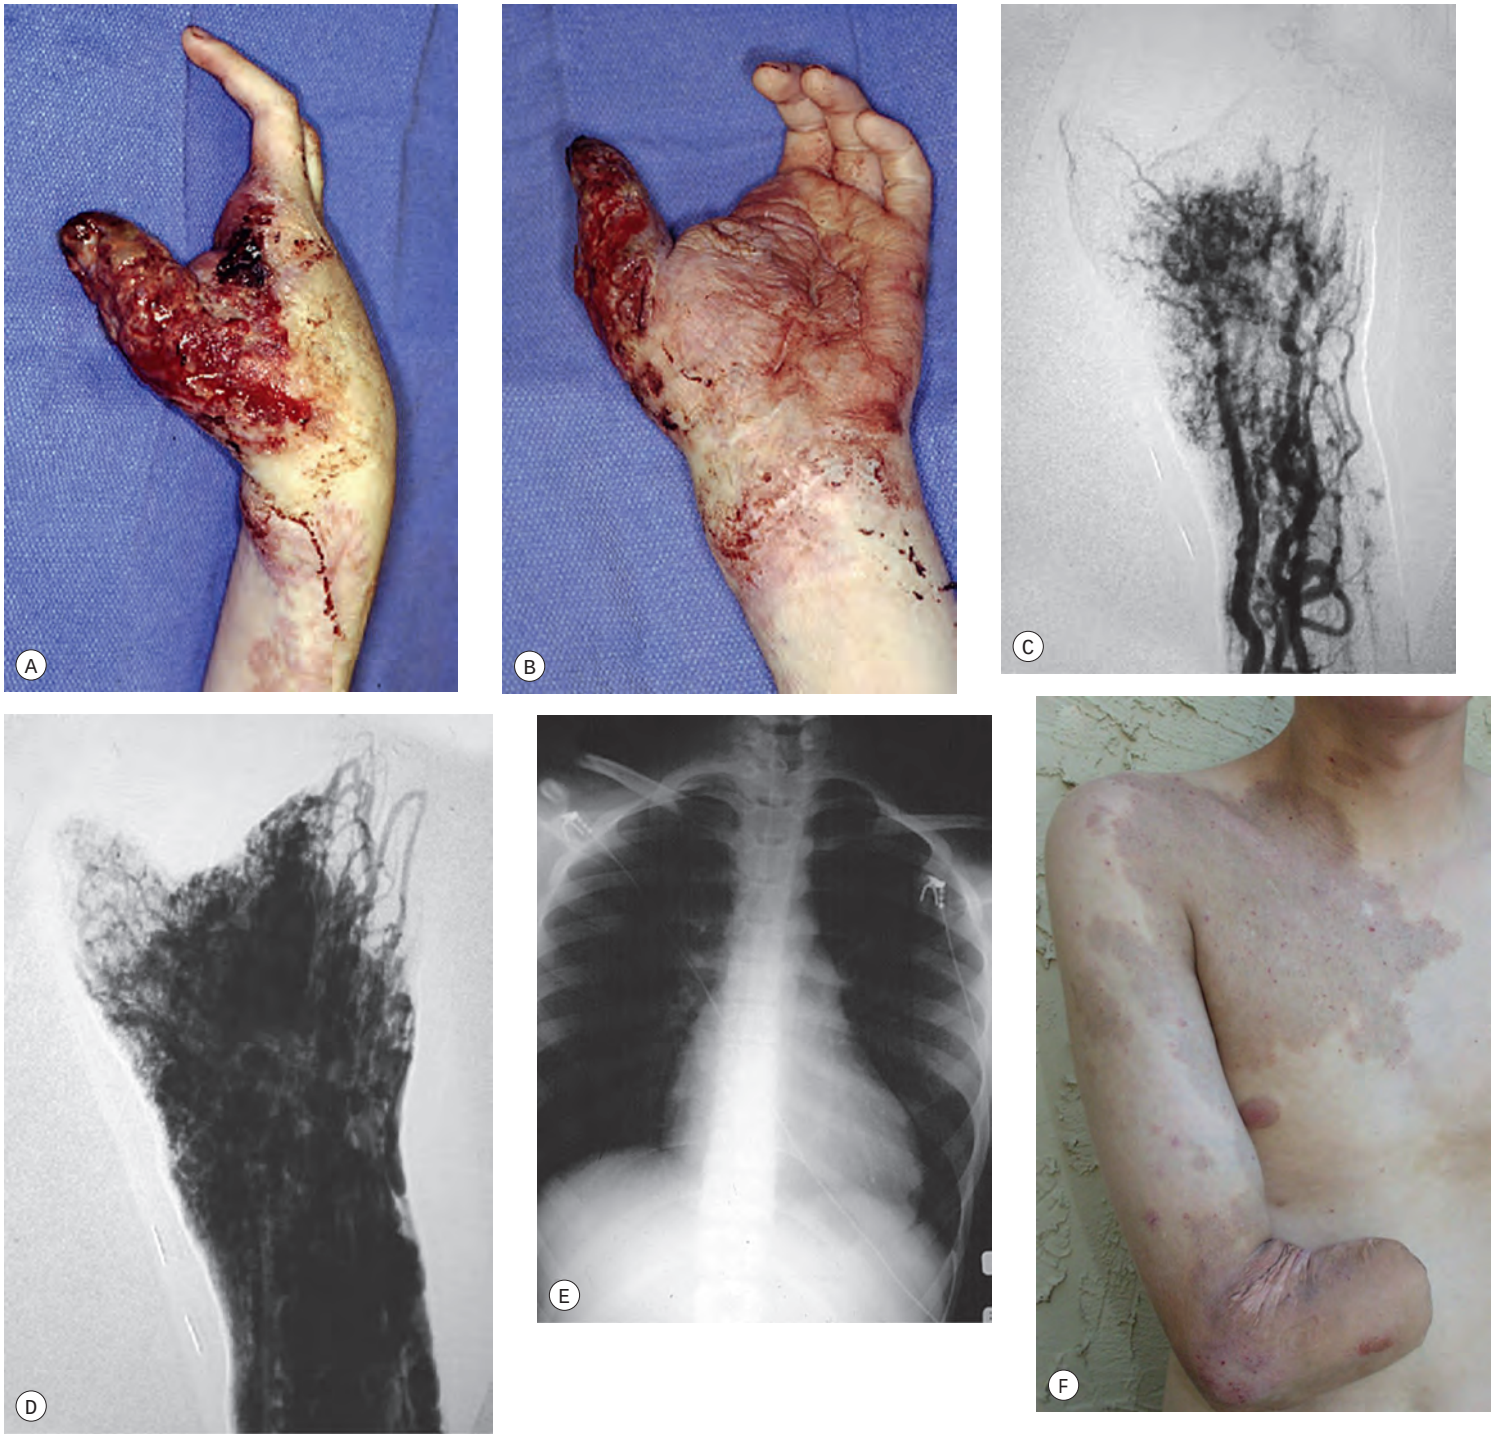

Fig. 31.21 Parkes Weber syndrome. **(A,B)** Teenager with type C arteriovenous malformation, and his parents wanted to save the hand. Index ray had been resected for uncontrollable pulsatile bleeding. The thumb was ulcerated; patient was suicidal because of unrelenting pain. **(C)** Angiography showed massively tortuous and enlarged axial vessels feeding microfistulous shunts within forearm and hand with involvement of all soft-tissue and skeletal structures. **(D)** Later sequence demonstrates extent of shunting and lack of distal digital perfusion. **(E)** Chest radiograph and electrocardiogram confirmed congestive heart failure (Schobinger Stage IV). **(F)** Below-elbow amputation followed by predictable recovery, normal adolescent growth spurt, and good function with his prosthesis.

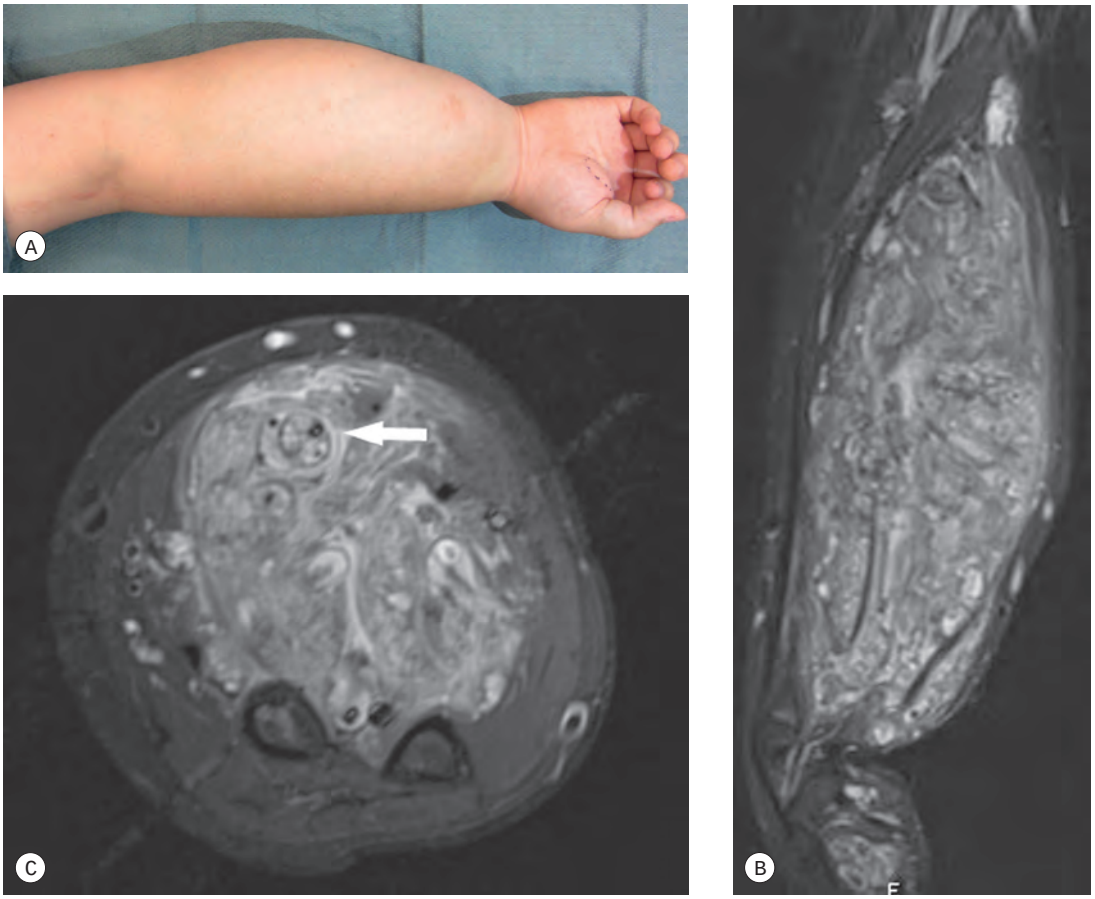

Fig. 31.22 High-flow PTEN lesion of the forearm. **(A)** This teenager has a large lesion of the forearm but has very little to no functional deficit. **(B)** Sagittal T2-weighted MRI images show the extensive nature of the lesion that involves the entire volar forearm down to the interosseous membrane. **(C)** PTEN lesions densely surround and involve large nerves. In this case, the median nerve is completely involved (white arrow), although the patient does not have any nerve symptoms at this point.

swelling, overgrowth, and nerve compression at some anatomic level. Selective embolization successfully controls symptoms in 70% of patients. We have never documented regression of this type of malformation.

Capillary malformation–arteriovenous malformation (CM–AVM)

Basic science/disease process

This is an autosomal-dominant condition caused by a loss-of-function mutation in the *RASA1* gene.[31,33] Patients usually present with a positive family history of similar lesions.

Diagnosis/patient presentation

The CM is evident by physical examination and is distinguished by a faint halo around the lesion. We have seen these in the upper extremity. Almost 10% of patients have an underlying fast-flow AVM involving the central nervous system, a very frequent location for AVMs. A full neurologic examination is indicated with a cranial MRI. Extracranial AVMs are rare in patients. Lesions are common in the lips or mouth.

Treatment/surgical technique

No treatment is necessary for the upper extremity CM. AVMs are followed symptomatically and treated as previously outlined.

Klippel–Trénaunay syndrome (KTS)

KTS is an eponym denoting a slow-flow capillary–lymphatico-venous malformation designated as CLVM and is readily distinguished from PWS by the slow-flow dynamics of the malformation.

Basic science/disease process

No positive genetic associations have been made.

Diagnosis/patient presentation

An accurate physical examination will determine the presence of both lymphatic and venous components, as the CM is obvious at birth. There is a wide range in clinical presentation.[77–79] There are no major hemodynamic alterations in the cardiovascular system. The lower extremities (95%) are involved much more frequently than the upper (5%) and the trunk and pelvis are rarely affected. The limb hypertrophy is not as profound as in patients with the Proteus syndrome, CLOVES syndrome, or in hemihypertrophy patients. However, upper limb involvement may be accompanied by massive soft-tissue enlargement of not only the upper limb but also the chest wall. In 10% of these limbs, hypoplasia may be present. Kyphoscoliosis and pulmonary compromise often develop as the child grows. Leg-length discrepancy is common. KTS patients are not at risk for Wilms tumors and do not need to be screened with abdominal ultrasound examination.[80] The VM pattern is similar to phlebectasias with large draining veins in the arm and axilla. There are usually diffuse clusters of large veins and sinuses involving muscle, fascial planes, and occasionally bone. All forms of LM may be present including skin vesicles, coalesced vesicles causing maceration and ulcers, macrocysts in the proximal portion of the upper limb, and microcysts in the more distal regions. All lesions are accompanied by large amounts of adipose tissue. Occasionally VM predominate; the upper limb equivalent of the lateral "vein of Servelle" is present and does communicate with the deep venous drainage system along the axial vessels to the limb. Because the genitourinary and gastrointestinal systems are commonly involved, these patients may be very symptomatic. Similar to the foot, massive enlargement of the wrist and hand with splaying of the digits with or without ulnar deviation may occur.

Treatment/surgical technique

Management is initially conservative and depends upon the predominance of the venous or lymphatic components. Management of the venous components is initially conservative. Epiphysiodesis to control bilateral growth symmetry is not as essential in the arm as it is in the lower extremity. Nerve compressions and lymphatic components respond very well to surgery. Surgical principles are the same. In the upper limb, resection is performed to improve function, relieve compression neuropathies, and restore motion and contour. Those with large lesions, chest wall involvement and those with large stagnant venous collecting systems in the arm and axilla are at risk for pulmonary embolus and are maintained on anticoagulants. Staged contour resections are difficult but well worth the effort.

Outcomes, prognosis, and complications

Clinical outcomes vary with the size and extent of the LVM and are similar to those for large isolated VMs and LMs. Outcome studies for upper limb KTS patients do not exist.

CLOVES syndrome

Congenital lipomatosis overgrowth, vascular malformations, epidermal nevi, and scoliosis syndrome (CLOVES) constitutes the components of a recently described overgrowth condition.[12,25,26,28] This disease entity has been linked to somatic activating mutations in the PIK3CA gene.[11,12,25]

Basic science/disease process

The upper extremity is usually involved. Previously, many of these children were diagnosed as Proteus patients but did not satisfy the criteria for inclusion. CLOVES patients do not have uncontrolled progressive skeletal overgrowth, and the soft-tissue enlargement consists primarily of dysplastic adipose tissue. Truncal CMs are present in all patients. Patients may also have fast-flow AVMs (see Fig. 31.17). Overgrowth in the limb is similar to that seen with LMs. It may or may not be oriented along a nerve territory (see Table 31.2 ◍).

Typical upper extremity findings include polydactyly, syndactyly, macrodactyly, and stiffness. Fatty overgrowth may extend proximally to the hand and forearm. Many patients have a large, spade-like hand (Fig. 31.23 ◍), an appearance that is accentuated when there is fatty overgrowth in the palm. In about half of these patients, the thumb is positioned in a hyperextended and hyper-abducted posture (see Fig. 31.22 ◍). Fig. 31.23 appears online only.

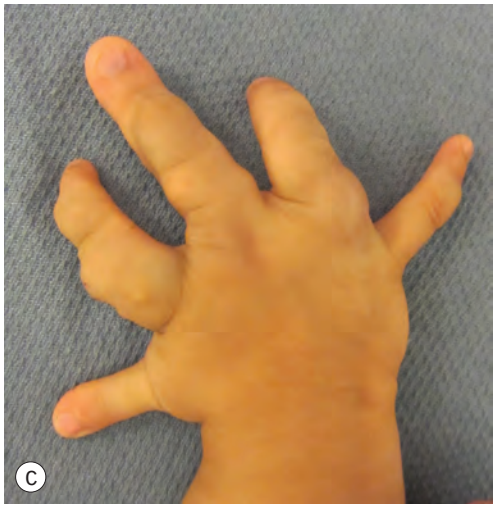

Fig. 31.23 Right and left hands in a patient with CLOVES syndrome. These pictures and radiographs demonstrate the prototypical CLOVES hands. Splaying of the digits with overgrowth and stiffness of one or more digits is common. In this patient, **(A and B)** the left thumb is hyperabducted to an extreme, lying directly opposite of the index finger. The lesions on the dorsum of the right hand **(C and D)** are subcutaneous lymphatic malformations.

Diagnosis/patient presentation

Diagnosis is based on clinical findings and starts with physical examination. Imaging can be tailored to specific areas as involvement with multiple different kinds of vascular anomalies is not uncommon. Differential diagnosis includes multiple overgrowth syndromes but differentiation based on clinical findings is usually possible. Guidelines for genetic PIK3CA testing have been recently proposed.[11]

Treatment/surgical technique

Resection of the lipomatous component, staged debulking and appropriate epiphysiodesis of the forearm and hand are predictable and useful for the individual patient. Skeletal angulation and rotation at all levels are corrected with osteotomies. For massively overgrown digits that are nonfunctional, the surgeon should consider amputation to allow better function for the rest of the hand.

Fibro-adipose vascular anomaly (FAVA)

FAVA is a recently described vascular malformation that appears in skeletal muscle in the extremities.[24] Long-term experience is lacking in this entity mainly because it was not recognized until recently.

Basic science/disease process

Most FAVA cases involve the leg. In the upper extremity, the forearm is most commonly involved. Small lesions involve portions of muscle whereas larger ones can involve an entire muscle or muscle group. The hallmark clinical finding in this lesion is pain that is worsened with activity. Contractures are common in larger lesions as more muscle is involved.

Diagnosis/patient presentation

Lesions appear similar to venous malformations on MRI but have larger fat and soft-tissue components. These lesions replace normal muscle fibers with fibrofatty overgrowth and phlebectasia (dilation of veins). Similar findings are noted on gross specimens. On histology, lesions show dense fibrous tissue, fat, and lymphoplasmacytic aggregates within atrophied skeletal muscle. There can be large, irregular, and sometimes excessively muscularized venous channels and smaller, clustered channels.

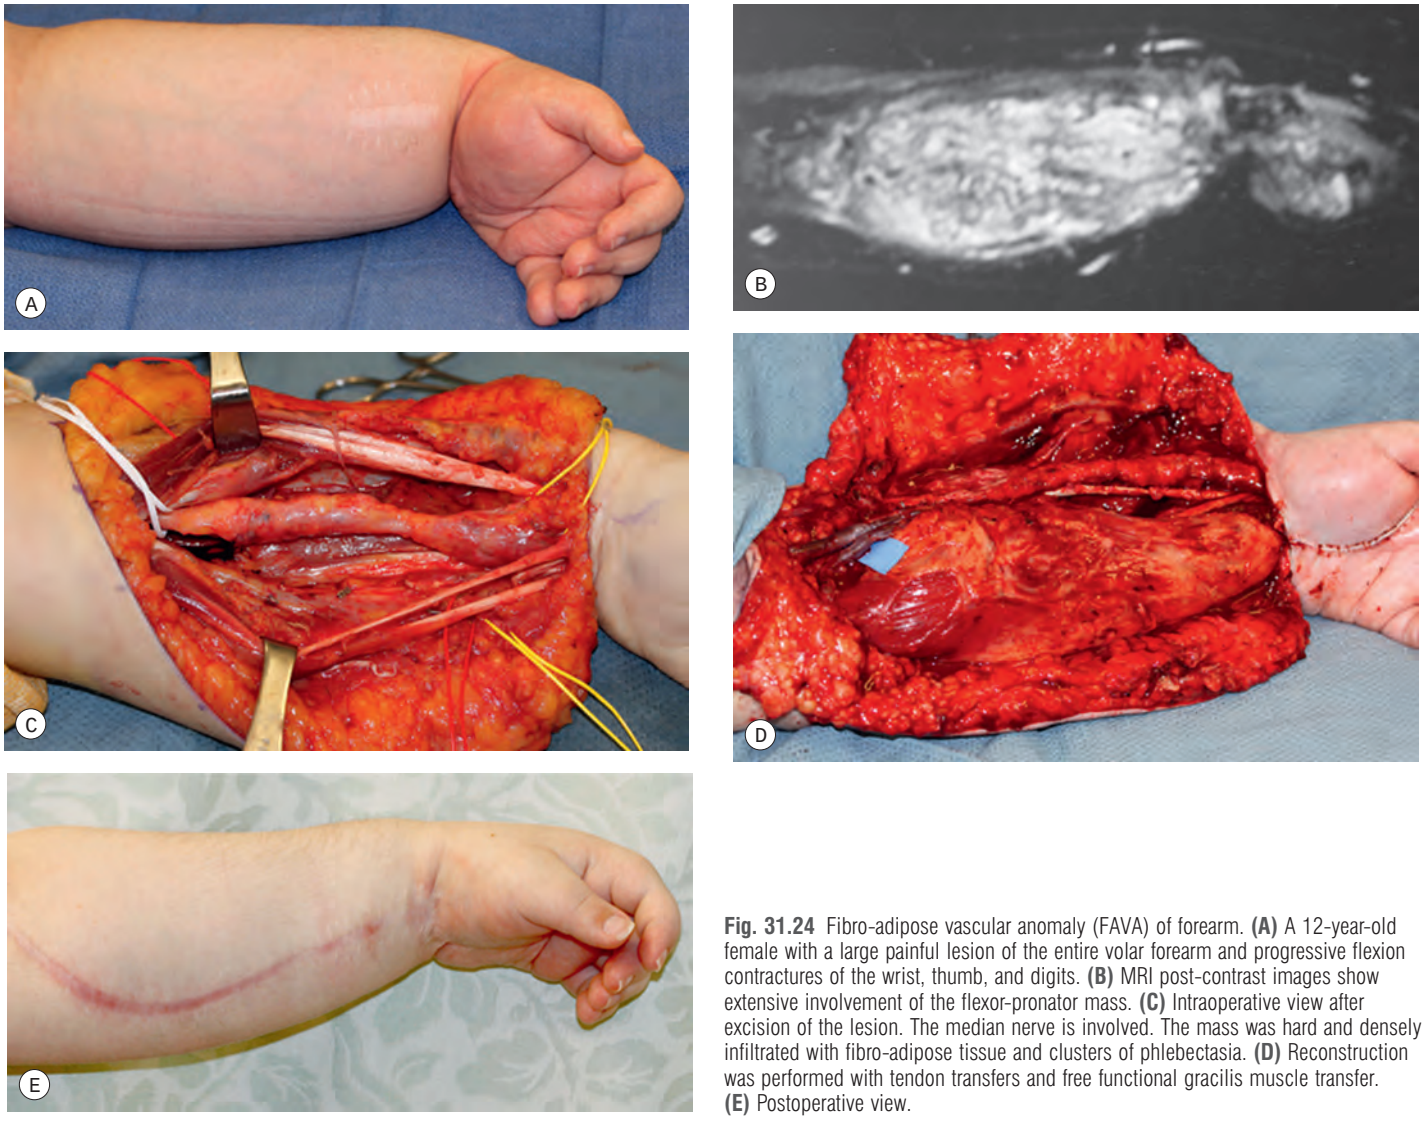

Fig. 31.24 Fibro-adipose vascular anomaly (FAVA) of forearm. **(A)** A 12-year-old female with a large painful lesion of the entire volar forearm and progressive flexion contractures of the wrist, thumb, and digits. **(B)** MRI post-contrast images show extensive involvement of the flexor-pronator mass. **(C)** Intraoperative view after excision of the lesion. The median nerve is involved. The mass was hard and densely infiltrated with fibro-adipose tissue and clusters of phlebectasia. **(D)** Reconstruction was performed with tendon transfers and free functional gracilis muscle transfer. **(E)** Postoperative view.

Treatment/surgical technique

Sclerotherapy, cryotherapy, and steroid injections have not been effective in treating this lesion. Pain may be relieved temporarily, but usually recurs. Surgical therapy is the only measure that provides long-lasting pain relief and improvement of contractures. Unfortunately, it usually involves resection of the involved muscle tissue – which can cause loss of function. In smaller lesions, functional compromise is less likely. In larger lesions of the forearm (e.g., those that involve most of the flexor/pronator mass) we have relied on local tendon and free muscle (gracilis) transfers to replace diseased muscle. The excision procedure is done in one procedure and the free tissue transfer several days later (Fig. 31.24).

Future directions

Since the last publication of this chapter, several exciting breakthroughs have been made in the molecular and clinical understanding of these lesions. These have been referenced liberally throughout the chapter and include discovery of somatic mutation in PIK3CA[12] and the mTOR[11,39] pathway as responsible for several overgrowth disorders, delineation of the fibro-adipose vascular anomaly that mainly affects the extremity (FAVA),[24] and further understanding in the molecular basis of other vascular anomalies.[81] There has been increasing use of mTOR inhibitors (rapamycin) to treat difficult, large malformations and early results have been promising with a tolerable adverse-effect profile. Nevertheless, there has been variability in response, and additional work is needed to better understand these lesions and reasons why some respond better than others. More basic science breakthroughs are inevitable and they promise better understanding and improved patient outcomes.

Peripheral nerve injuries of the upper extremity

Simon Farnebo, Johan Thorfinn, and Lars B. Dahlin

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Nerve regeneration after injury is orchestrated by delicate processes in neurons, non-neural cells, and other cells at various levels from the periphery to the central nervous system.
- The clinical effects of a nerve injury include not only impaired sensory and motor function, but also symptoms such as impaired dexterity, sensitivity to cold, and pain. Therefore, they have a severe impact on activities of daily living.
- Correct diagnosis and classification of the injury are crucial for appropriate treatment.
- The surgical approach and technique, as well as timing of surgery, are factors of importance for outcome.
- The type of injury, condition of the wound, and the vascularity of the wound bed are key factors influencing surgical decision-making.
- Various techniques for nerve repair are described, including epineurial, fascicular, and end-to-side repair, and techniques for nerve reconstruction.
- Factors of importance for outcome, such as age, delay before repair, and level of injury are discussed, as are means of evaluation after surgery.

Introduction

A nerve injury may have a profound impact on the patient's activities of daily living, with subsequent effects on professional life and leisure time.[1] Patients may have to change profession, or be left with a permanently impaired ability to work. Nerve injuries may, therefore, generate not only costs for society within the healthcare system for treatment and rehabilitation, but also outside the healthcare system resulting from lost production.[2] Nerve injuries most commonly affect the upper extremity. The incidence of injuries to the hand has been calculated as 7–37/1000 inhabitants/year in Europe.[3] Similar data are available for children (incidence 2.7/1000 children/year). Most hand injuries are minor, but injuries to the nerves (accounting for about 3% of hand injuries) usually impair hand function.[3,4] Few reports exist about the specific incidence of nerve injuries, but the incidence has been reported to be 13.9/100 000 person/year.[5] Most of the injuries to the hand (10%) and the wrist (63%) required less than a week in hospital. However, few inpatient and outpatient data have been reported. The incidence of a digital nerve injury is estimated to 6.2/100 000 inhabitants/year. The general pattern of distribution of both hand and nerve injuries between the sexes is that it is usually young (median age 29 years) men (up to 75%) who are injured. The incidence of a radial nerve injury associated with a fracture of the shaft of the humerus is around 0.12/10 000 inhabitants and year.[6] Based on these reports one may estimate that 70 000 and 29 000 patients in the European Community and in the US, respectively, injure a nerve trunk annually.

The costs of treatment and rehabilitation, including those for loss of production, after a nerve injury, may be substantial. The costs for injuries to a median and an ulnar nerve are roughly 70 000 USD and 45 000 USD, respectively [2]; 87% of these costs are the result of lost production. Costs are higher for patients with coexisting tendon injuries (≥4 tendons). In addition, costs within the healthcare sector are higher for patients who had to change jobs after the injury and in patients in whom both the median and the ulnar nerves were injured. Up to 69% of patients with an ulnar or median nerve injury are back in full-time work by 1 year after the nerve injury.[2,7,8] Age is one important factor for outcome after nerve repair,[2,9] which is probably based on better cerebral adaptation to the injury, particularly in young children. The clinical effects of a nerve injury include not only subjective impaired sensory and motor functions, but also subjective complaints, such as impaired dexterity, cold sensitivity, and pain[10]; thus, it can have a severe impact on activities of daily living. Altogether, nerve injuries can cause considerable problems for individual patients and costs for society. In the present chapter, the principles for repair and reconstruction of nerve injuries are outlined, with emphasis on the fact that such injuries should be treated promptly.

Basic science and natural history

Anatomy

Gross anatomy: the upper extremity

The brain and the spinal cord (central nervous system) are connected to targets by the peripheral nervous system, which consists of cranial nerves, spinal nerves with roots and rami, and peripheral nerve trunks with the peripheral components of the autonomic nervous system. The anterior and posterior nerve roots (that emerge from rootlets attached to the spinal cord) merge into the spinal nerve, where the anterior primary rami form the brachial plexus in the upper extremity (Fig. 32.1). The posterior primary ramus runs posteriorly, and supplies the muscle and skin of the posterior part of the neck and trunk; it does not enter the extremity. The anterior primary rami of the cervical nerve roots C5–8 and the ramus of T1 form the brachial plexus, from which the upper extremity receives its innervation through various branches.

C5–6 roots form the upper trunk of the brachial plexus, C7 forms the middle trunk, and C8–T1 form the inferior trunks. These trunks divide into anterior and posterior divisions in which the lateral and medial cords are formed from the anterior division, while the posterior divisions form the posterior cord, which mainly innervates the extensor muscles in the upper extremity. In contrast, the lateral and medial cords innervate the flexor muscles in the extremity. The musculocutaneous nerve originates from the lateral cord. The median nerve is formed by the joining of the lateral and medial cords, whereas the ulnar nerve branches from the medial cord together with the medial cutaneous nerves to the arm (brachial) and forearm (antebrachial). The radial and axillary nerves originate from the posterior cord. There is a segmental pattern of sensory and motor innervation (Fig. 32.2).

The anatomy of the plexus and the nerve trunks may vary considerably from person to person. Variations are seen in the forearm, where a "Martin Gruber" anastomosis may be found in as many as 15%, particularly between the anterior interosseous nerve and the ulnar nerve. A similar anastomosis may also be present more distally – Riche–Cannieu (branch between the motor branch of the ulnar nerve and the thenar branch of the median nerve in the thenar region in the hand: Fig. 32.3).

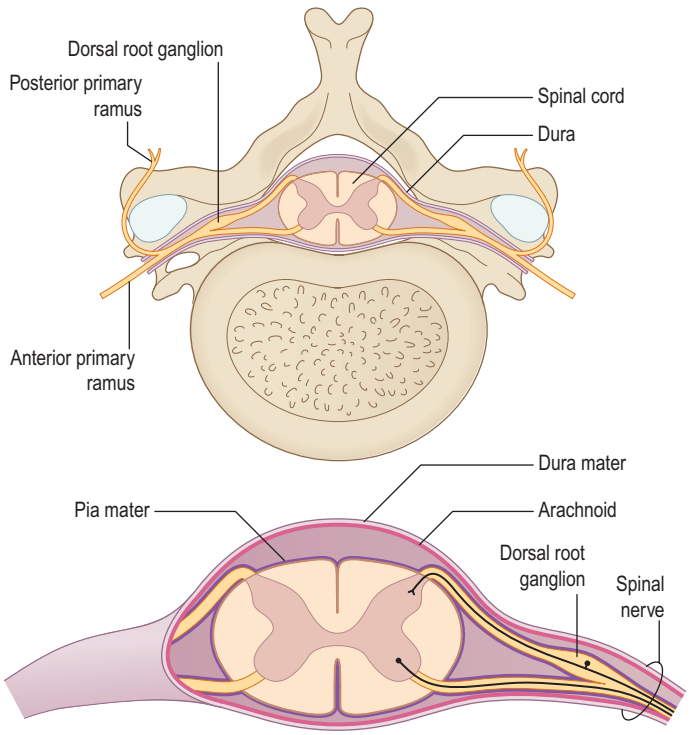

Fig. 32.1 The anterior and posterior nerve roots, which emerge from rootlets attached to the spinal cord.

The neuron and supporting cells

The cell bodies of the motor and sensory neurons are located in the spinal cord and in the dorsal root ganglia, respectively, with their axons extending out to their respective targets in the periphery. The sensory neuron is pseudo-unipolar, with one branch of the axon extending into the posterior part of the spinal cord. The transition from the central to the peripheral nervous system takes place in the rootlets (or less often, in roots of the nerves) of the transitional zone, which are almost cone-shaped.[11] In the central part, the neurons are surrounded by oligodendrocytes and astrocyte processes, whereas in the peripheral nervous system axons are closely associated with Schwann cells. In myelinated nerve fibers, each axon is embraced by a series of continuous Schwann cells that create the myelin sheath. The border between individual and enwrapping Schwann cells is called the node of Ranvier (Fig. 32.4). Each nerve fiber is enclosed in a basal lamina (or basement membrane). In contrast, several thinner axons run in troughs in one Schwann cell – non-myelinated nerve fibers. Each Schwann cell therefore embraces several axons. The diameter of nerve fibers varies, and extends from 0.4 to 1.25 µm (non-myelinated) and from 2 to 22 µm (myelinated).[12] The number of nerve fibers also varies with nerve trunks. In addition, the number of nerve fibers decreases with age: as many as 26% of the nerve fibers may disappear between the second and eighth decades.

The nerve trunk

A number of nerve fibers are enclosed in bundles around which there are flattened supporting cells and layers of collagen that form the perineurium. These bundles of fibers surrounded by the perineurium are called fascicles, which are embedded in loose connective tissue (called epineurium); this is composed of collagen fibers and fibroblasts (Figs. 32.4 & 32.5). The space inside the fascicles is called the endoneurial space, in which the pressure is slightly positive (endoneurial fluid pressure); it consists of collagen fibrils, and cells such as fibroblasts and occasional macrophages and mast cells. Lymphocytes (CD4+ and CD8+) and macrophages are not generally found in the endoneurium (except after injury), but may be present in the epineurium. The amount of connective tissue varies among nerve trunks, and also within the same nerve trunk. More abundant connective tissue is therefore located in the nerve trunk at sites where extra protection is needed (such as joints and superficial nerve trunks). The term "mesoneurium" refers to the additional loose areolar tissue that is

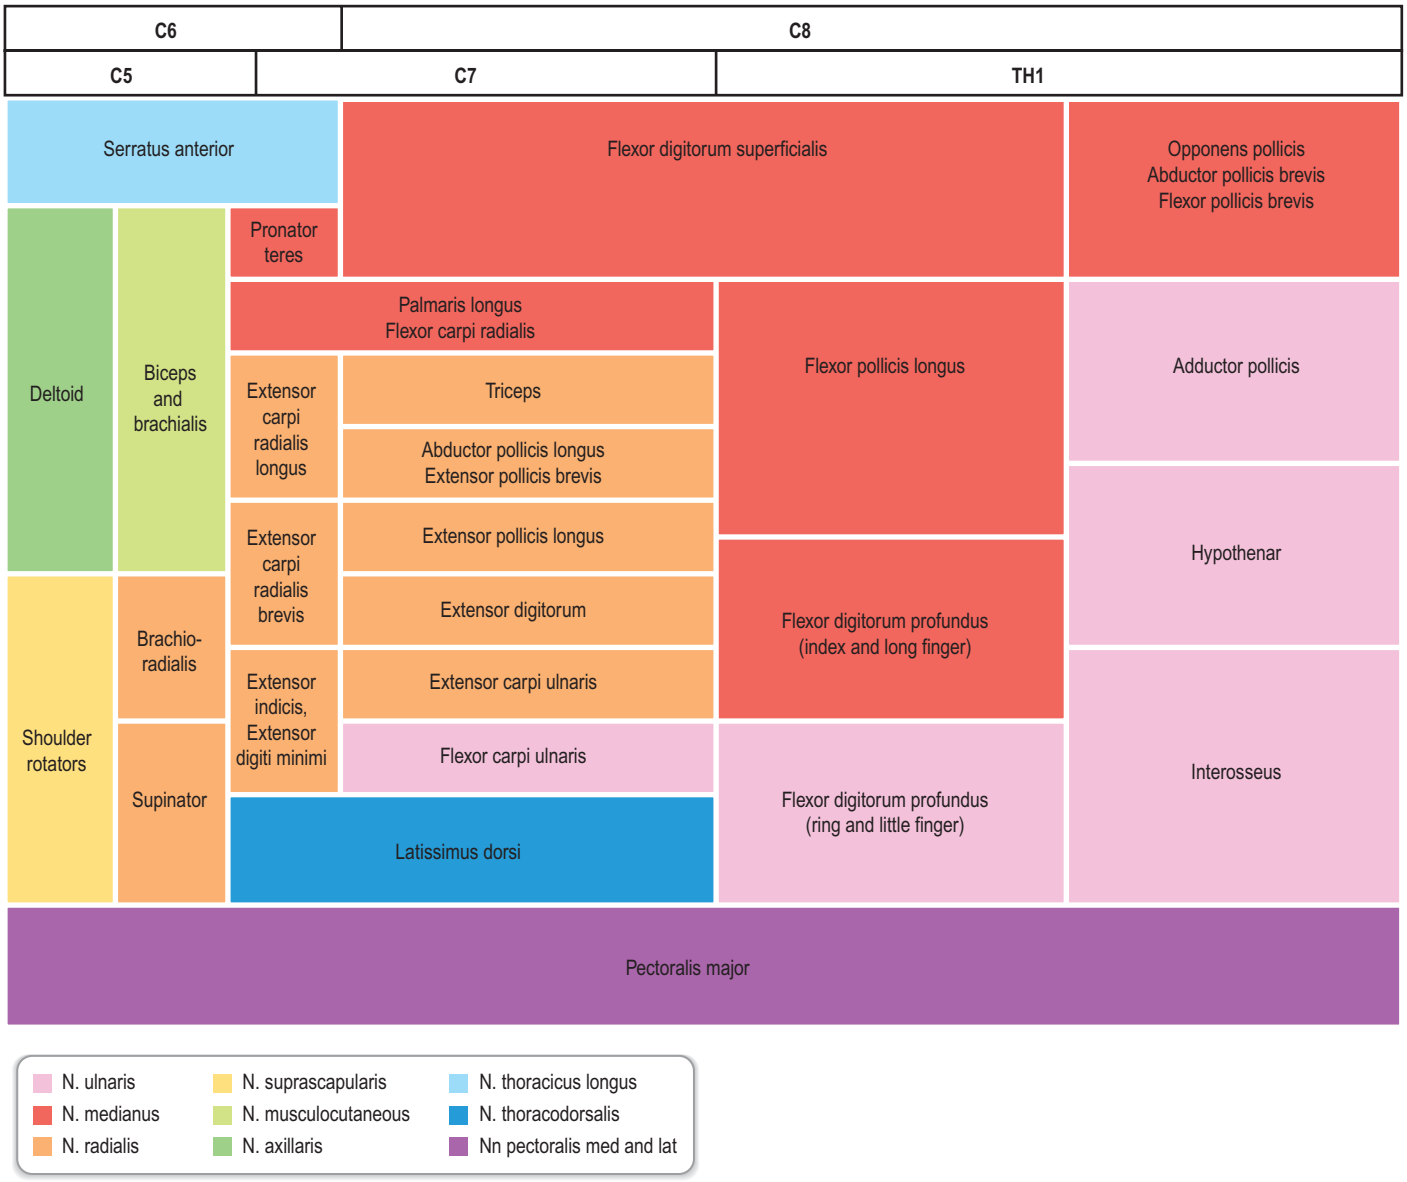

Fig. 32.2 The origin of the nerves of the brachial plexus (C5–Th1, top), and their target muscles.

located superficially to the epineurium. This tissue allows for the gliding of the nerve trunk (excursion) during movements of the extremity.

There is topographical segregation of fascicles and nerve fibers in the nerve trunks, particularly in their peripheral parts.[13,14] The latter anatomical feature permits dissection of a bundle of fascicles that can be used in nerve transfers.

Blood supply

Nerve trunks receive their blood supply from segmental blood vessels (Fig. 32.6), which branch into plexuses in the epineurium, perineurium, and in the endoneurial space. The blood vessels inside the fascicles consist mainly of capillaries, which are provided by circulation through blood vessels that pierce the perineurium obliquely. The epineurial blood vessels are more susceptible to trauma than the endoneurial vessels and so epineurial edema develops more easily than endoneurial edema. Because of the extensive reserve capacity of the intraneural blood supply, it is possible to mobilize a nerve over an extended length without disturbing the blood supply. In addition, the blood vessels adjacent to the nerve trunks have a coiled appearance that allows excursion of the nerve trunk. In addition to the vasa nervorum, there are also nervi nervorum, such as free nerve endings in the epineurium, perineurium, and endoneurium.

Physiology

To allow for propagation of the action potential, ions are exchanged between the axon and the extracellular space at the nodes of Ranvier (see Fig. 32.4). As this exchange occurs only at the nodes of Ranvier in myelinated nerve fibers, the conduction velocity jumps from node to node. In myelinated nerve fibers this saltatory conduction induces high conduction velocity. In contrast, the propagation of impulses is more continuous in non-myelinated nerve fibers. After a nerve has been injured, the process of Wallerian degeneration (see

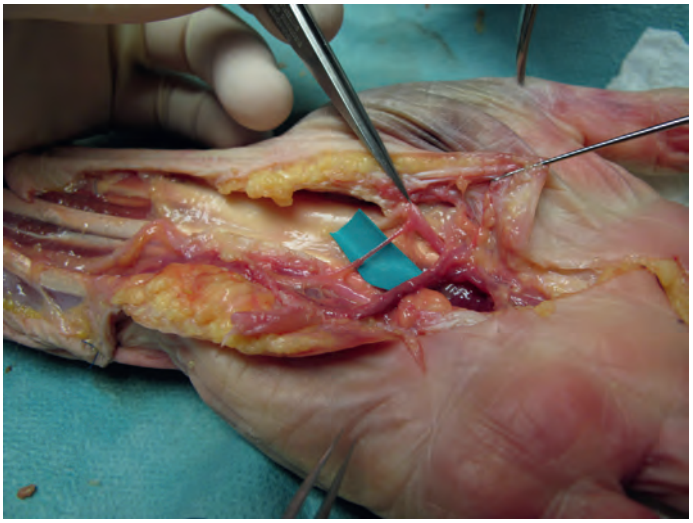

Fig. 32.3 An anatomical preparation of the Riche–Cannieu anastomosis in the palm. This highly variable, although common, anastomosis between the median nerve motor branch and the deep ulnar nerve provides a potential pathway for enormous variation in intrinsic muscle innervation.

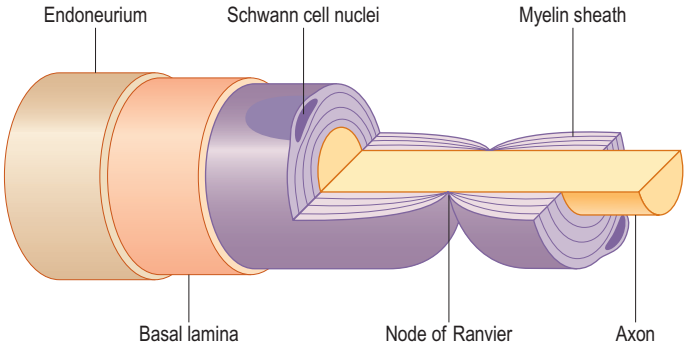

Fig. 32.4 Close-up of myelinated axon and the node of Ranvier.

below) takes some time in humans, which explains why it is possible to record propagation of an impulse in an injured nerve by electrical stimulation at neurography for many days after the injury. It is generally agreed, therefore, that neurography should be done no earlier than 3–4 weeks after the injury if signs of degeneration are to be found.

The cytoskeleton of the axon contains neurofilaments and centrally located microtubules. Essential molecules are transported along the microtubules both from the cell body down to the periphery (anterograde) and from the periphery up to the cell body (retrograde) with energy-dependent axonal transport. This transport has several functions, such as recycling of materials that are not used in the periphery, provision of membrane constituents, neurotransmitters, and necessary cytoskeletal components to the axon. Transfer of important molecules is essential for survival and signaling, both in the normal state and after nerve injury. After cellular injury, these signals are rapidly initiated from the environment by translation into intracellular messengers or commenced in the axon at the site of injury. These changes involve profound alterations in transcription, translation, and post-translational processes in the cells after the injury.

Degeneration and regeneration

After a nerve injury, deep and intense processes are initiated in the injured neurons and their axons and in the non-neuronal cells, particularly the Schwann cells. In the cells a number of temporary and spatially orchestrated mechanisms guide survival and regeneration. In addition, there are mechanisms that lead to apoptosis of the cells. The signal transduction processes are not clarified, and this is a target of intense research. After the peripheral nerve trunk has been injured by transection or avulsion, the proximal part of the axon is resealed to form a new surface on the tip of the axon – a process that is influenced by the presence of calcium. There is usually a slight retraction of the proximal axon, which is related to the number of injured Schwann cells. At the tip of the axon, signals are formed in the signal transduction processes and transferred to the nucleus of the neuron where the functions are changed from maintenance to survival and growth.

The distal nerve segment

Schwann cells are extremely important for the function of the peripheral nerve, both in the normal state and after injury. After injury, there is disintegration of the axons and the myelin sheath in the distal nerve segment, the latter released by Schwann cells. It is important to remove myelin and

the disintegrated axon to allow and prepare a conducive environment for the regenerating axons. Both macrophages and Schwann cells can therefore contribute to the cleaning up mechanisms, where their relevance varies over time.

The timing of nerve repair is of crucial importance for a successful outgrowth of axons after injury,[15,16] which can be related to a large number of factors that are up- and down-regulated by Schwann cells after nerve injury. After the Schwann cells have been activated, they proliferate along the inside of their basal lamina, and form the bands of Büngner.

Neurotrophic factors and their receptors are upregulated in Schwann cells after injury, and these may include neurotrophins (such as nerve growth factor and brain-derived neurotrophic factor), fibroblast growth factors (such as β-fibroblast growth factor), neuropoietic cytokines (such as ciliary neurotrophic factor and leukemia-inhibitory factor), and other groups of factors, such as insulin-like growth factor, transforming growth factor, and interleukins.

Apoptosis (programmed death) of various cells, such as macrophages and Schwann cells, an event that is initiated by release of pro-apoptotic molecules from the mitochondria (intrinsic pathway), can be activated through the death cell surface receptors (extrinsic pathway; like Fas and tumor necrosis factor receptor 1). The number of apoptotic Schwann cells in the distal nerve segment is increased if the transected nerve is repaired after a delay.[17]

All these changes in the injured neuron and its axon and in the Schwann cells have the common goal of regrowth of the axons into the distal nerve segments down to their targets. Regrowth is a delicate process in which numerous sprouts emerge from the distal part of each axon. On the tip of each sprout there is a growth cone, which is formed as a small hand on which the "finger-like" filopodia palpate the environment with the purpose of finding guidance structures (Fig. 32.7). Intricate mechanisms direct rate and direction of extension of the growth cones, where actin filaments are polymerized and organized.[18,19] Microtubules are polymerized in the growth cones. The growth is a dynamic process, where the filopodia/growth cone is repulsed or attracted depending on the local mechanisms and the structure of the environment.

The extracellular matrix is extremely important for the outgrowth and advancement of the growth cone. Proteins, such as laminin, fibronectin, galactins, tenascin, and collagens, stimulate outgrowth. Laminin exerts its stimulatory effect through cell surface glycoproteins called integrins, which interact with the intracellular actin in the growth cone and in the filopodia, thus navigating outgrowth of the axon. Precise knowledge about how axons grow and how growth is directed is still limited.

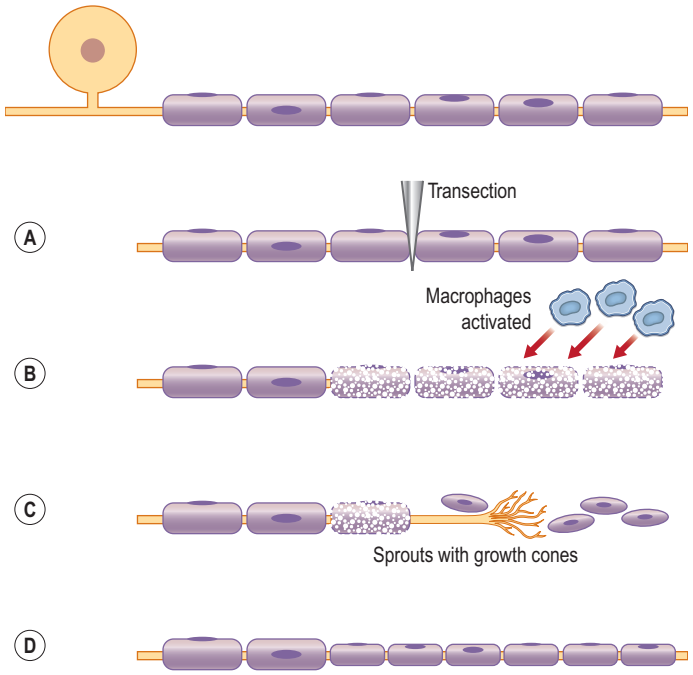

Fig. 32.7 As the nerve is severed **(A)**, activated macrophages and Schwann cells will immediately start the removal of myelin and remnants of the disintegrated axon, to allow for a conducive environment for the regenerating axons **(B)**. Within just a few hours numerous sprouts emerge from the distal part of each axon and form the sprout growth cone that will guide the regeneration process distally **(C)**, until nerve regeneration is complete **(D)**.

Diagnosis and presentation

Formal classification of injury

Nerve injuries can be divided into two main groups: those that will temporarily block nerve conduction without loss of axonal architecture, and those with severe damage that will result in axonal degeneration distal to the injury (Fig. 32.8). This may be one useful clinical way of approaching nerve injuries, but more formal classifications have been presented to describe the complexity of the lesions further, in particular the Seddon classification,[20] in which injuries were divided into three groups of increasing severity (neuropraxia, axonotmesis, and neurotmesis). This classification was modified by Sunderland[21] and by Mackinnon[22] to include six degrees of injury. In Table 32.1 we summarize the differences between the three classifications, and the specific neural changes are illustrated in Fig. 32.9.

Neuropraxia

First-degree injury

In neuropraxia there is a physiological block of conduction, but no disruption of the neural architecture at the site of injury, and there are no degenerative changes within the nerve. The pathogenesis is most often external compression, surgical traction, or local ischemia. Complete recovery is the general rule, and the healing time can vary from a few days to 3–4 months. Tinel's sign is not present over the site of injury.

Axonotmesis

Second-degree injury

In second-degree injuries, true degeneration of axons is initiated. Axonal damage leads to distal (Wallerian) degeneration, although the basal lamina of the Schwann cells remains intact. The axons regenerate through their own endoneurial tubes by axonal contact and guidance of the regenerating growth cones at a rate of 1–3 mm/day. No topographical mismatch will occur, and the integrity of sensory and motor nerve fibers remains intact. Tinel's sign is present, and the progress of recovery can by followed by the gradual recovery of motor

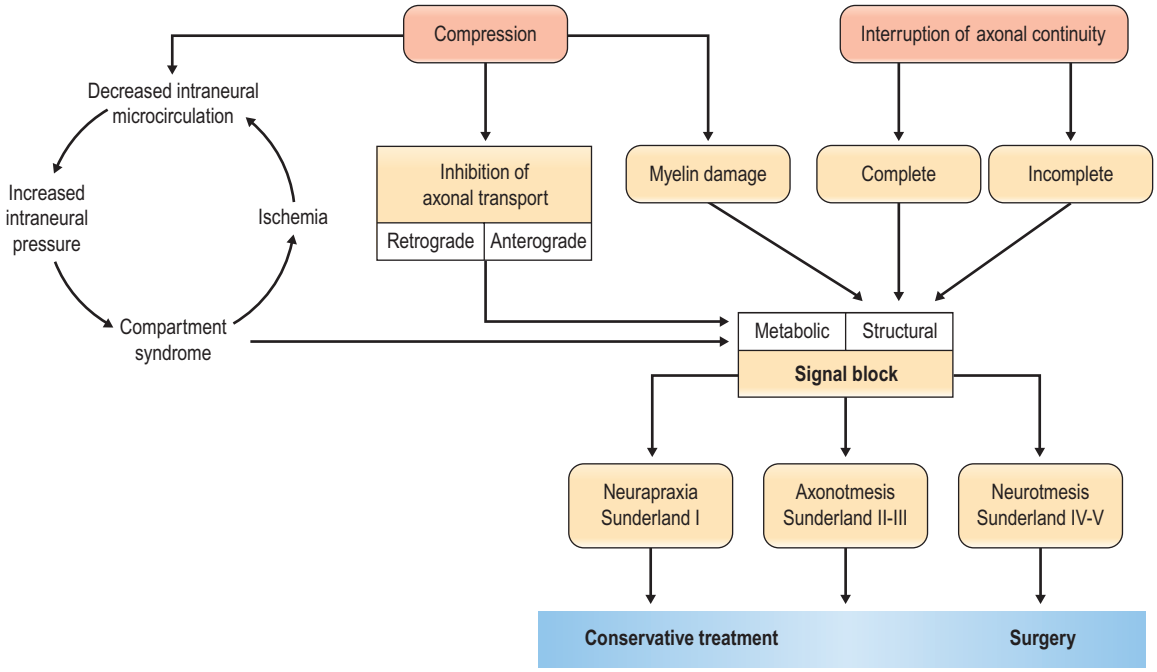

Fig. 32.8 Schematic flowchart of neuronal response to nerve compression and interruption of axonal continuity.

Table 32.1 **Comparison between the Seddon, Sunderland, and MacKinnon classifications of nerve injury**

Seddon	Sunderland	MacKinnon	Description
Neuropraxia	1		Local physiologic block with paralysis but no anatomic disturbance of the nerve. Full recovery is expected
Axonotmesis	2		Nerve injury with degeneration of the distal segment. Intact endoneurium and perineurium. Full recovery occurs at rate of 1.5 mm/day
	3		Endoneurial damage with subsequent scarring and incomplete regeneration. Variable recovery
Neurotmesis	4		Nerve damaged with complete internal structural disorganization. Nerve trunk remains intact. No functional recovery unless operative intervention
	5		Nerve trunk cut completely. Early operative intervention necessary for restoration of some function
		6	Mixed nerve injury

or sensory function distal to the injury. Full recovery is expected.

Third-degree injury

In a third-degree injury, the architecture within the perineurium is disrupted together with axonal damage. The fascicles remain intact, although progression of axonal regrowth will be with less precision as the axonal guidance is impaired and mismatch of fibers will occur. Axonal mismatch follows to a larger extent in proximally based injuries as the fascicular organization is usually of mixed motor and sensory patterns. The clinical outcome is hard to predict, mainly because of subsequent intrafascicular scarring and the failure of some

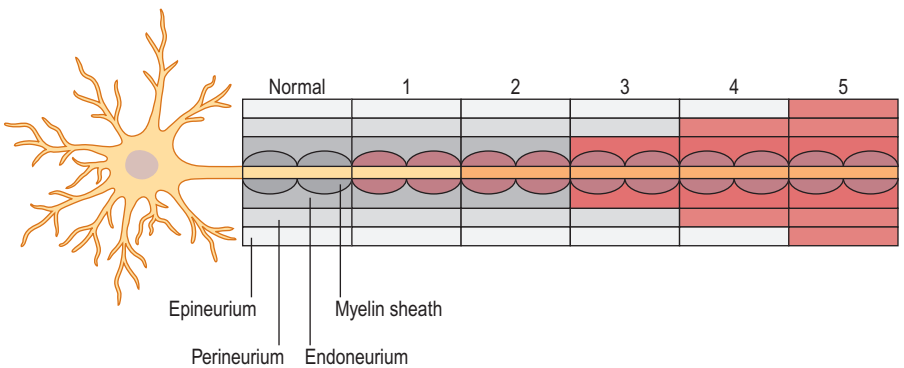

Fig. 32.9 Schematic of damaged structures within an axon according to the classification of Sunderland grades 1–5. Change in color (red) and pattern indicates damage to each structure. Yellow represents an axon and its neuron.

axons to regenerate. Tinel's sign is present and progresses distally with recovery. Microsurgical resection and grafting may not be beneficial in these cases.

Neurotmesis

Fourth-degree injury

In a fourth-degree lesion, the epineurium is intact, but all other parts of the nerve are damaged. The formation of an intraneural scar impairs both axonal regeneration and reinnervation, and typically forms a neuroma at the site of injury. A more profound retrograde neuronal effect than in a third-degree injury is expected, and this causes a higher incidence of neuronal death. Tinel's sign is usually present over the site of the injury, but there are no signs of recovery, or proximal-to-distal progression of regeneration. The injury requires complete excision of the neuroma and microsurgical nerve repair, usually with nerve grafting.

Fifth-degree injury

In a fifth-degree injury, the nerve is completely transected. Recovery of function is dependent on surgical repair, with or without nerve grafting. These injuries are most commonly associated with injuries that include the surrounding structures, such as tendons, muscles, bones, or blood vessels.

Sixth-degree injury

The sixth-degree injury was added by Mackinnon to take account of mixed injuries,[22] for example those that occur after closed traction damage to a nerve, or gunshot or stab wounds that cause partial injuries to a nerve. This type of injury is often referred to as a neuroma in continuity, in which all degrees of nerve injury, from normal to neurotmesis, may coexist within the scarred nerve. A neuroma in continuity typically results from failure of the regenerating nerve growth cone to proceed beyond the injury to reach its peripheral targets. It occurs within an intact nerve with continuity in response to internally damaged axons and fascicles, resulting in a distal portion of the nerve that no longer, more or less, functions properly. Surgical exposure is often necessary and intraoperative electrodiagnostic studies can help to distinguish fascicles with signs of recovery from those without (grades IV and V).

Clinical examination

A correct diagnosis is crucial. Confirmation of a nerve injury is usually not hard, even though every nerve injury is unique in its character and highly variable in its symptoms. Lack of active movement, such as against resistance, because of paralysis of the muscles supplied by the nerve, can be seen immediately after the injury if the nerve is completely transected. However, when motor defects are minor or overshadowed by more striking sensory deficits, the diagnosis can sometimes be overseen, particularly in an incoherent patient. The patient's history and understanding of the mechanism of the injury are therefore important for the evaluation of the injury and identification of those that will be improved by operation. It is important that every patient with a dysfunctional nerve and a wound overlying the course of a nerve is regarded as having a transected nerve until proved otherwise (Fig. 32.10).

Functional evaluation

Motor and sensory function should be carefully examined and documented in all patients with injured extremities. Motor evaluation should include pinch and grip strength, and assessment of weakness and atrophy of individual muscles. Sensory function should be evaluated with the patient unable to see what the examiner is doing. Acutely, it may be easy to assess the patient's ability to feel pain, such as that applied by forceps, in the innervation area of an individual nerve such as a digital nerve. Assessment of two-point discrimination and the patient's ability to separate sharp and blunt objects for testing of protective sensation can also be used. Loss of sympathetic function, with vasomotor and sudomotor paralysis, gives the loss of ability to produce sweat in the innervated segment of skin, which will look red, dry, and "polished." Tinel's sign is present, and continuous severe pain over the region of injury usually indicates a more severe injury.

Electromyography/neurography

In case of confusing diagnostic signs, electrophysiological studies can help to establish the diagnosis and to identify injured nerve branches, although the results must be interpreted with caution during the first 3–4 weeks. It may take up to 4 or even 6 weeks after the injury before signs of nerve degeneration and muscular denervation can be detected.[23] It is stressed that waiting for an electrophysiological examination should not delay exploration of an injured nerve if indication for surgery is strong.

Intraoperative conduction studies can be of help, particularly in the case of a previously closed injury that has failed to show satisfactory recovery at follow-up. Intraoperative examination enables a higher grade of specificity as the observed nerve or even individual nerve fascicles can be anatomically isolated, and action potentials across the scarred area can be evaluated.[24] If electrical recovery is recorded over the area of interest, the patient can be classified as Sunderland grade II or III, in which case spontaneous full recovery is expected. If no electrical recovery can be seen, the patient should be graded Sunderland grade IV or V and will most likely benefit from nerve resection and grafting. However, in the case of a neuroma in continuity (sixth-degree injury), the picture is more complex. Some fascicles will need resection and grafting, whereas others are actually grade II–III and will recover spontaneously. In these cases, postoperative outcome may be uncertain and the decision to operate is hard as intervention may result in a tedious and potentially damaging dissection with internal and external neurolysis and resection of damaged sections. However, it may sometimes be possible to distinguish injured fascicles that require nerve grafting from intact healthy fascicles intraoperatively. Intraoperative electrophysiology is therefore warranted and extremely helpful in decision-making during the procedure.

Wound inspection

Peripheral nerve transections rarely occur in isolation. Depending on the extent of the injury, surrounding structures

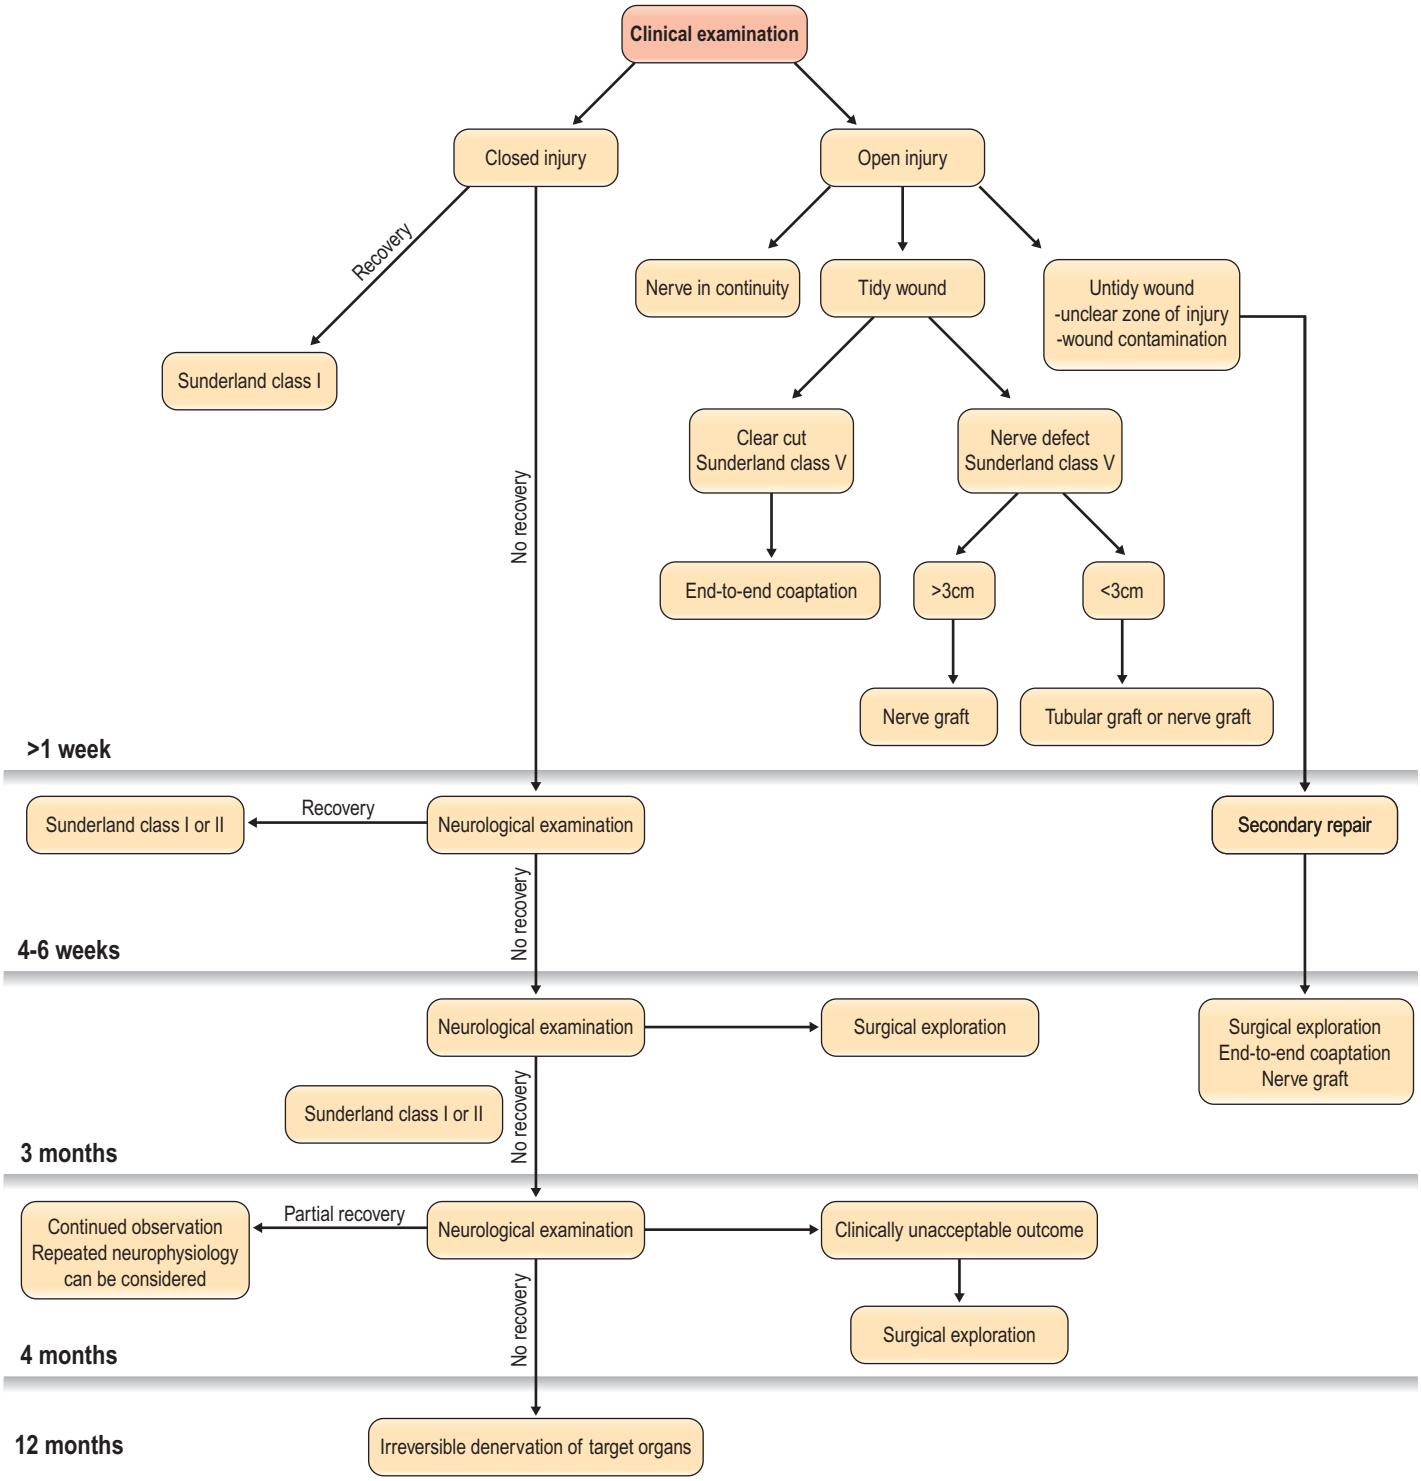

Fig. 32.10 Algorithm for open and closed nerve injuries. Flowchart showing timing of surgical exposure and nerve repair.

may be crushed, lacerated, avulsed, or otherwise damaged. Extensive tissue damage and an unclear zone of injury together with a contaminated wound are factors that influence management and may result in delayed neural repair. Extensive debridement and cleaning of the wound are essential for a satisfactory final outcome, and to decrease the risk of a complicating infection and subsequent scarring.

Sharply transected nerves are easier to manage than crushed or avulsed ones. In a sharp transection, the zone of injury is limited, and the nerve can usually be prepared and repaired at the primary operation. If, however, the nerve is seriously crushed or longitudinally avulsed, the zone of injury is harder to establish and delayed excision of the damaged nerve followed by repair may improve outcome.

Ideally the repaired nerve should be surrounded by a well-nourished soft-tissue bed, muscle, or fat. In severe cases, this implies that the damaged soft tissues surrounding the injured nerve need to be replaced by a soft-tissue transfer to reconstitute a gliding surface either before secondary reconstruction or in connection with the primary reconstruction.

Patient selection

All patients with a suspected nerve injury should be judged individually as a number of factors must be considered before the decision to explore is made (see Fig. 32.10). When one is considering sharp lacerations, traction injuries, blast injuries, or a combination, some key factors must be considered that will be of decisive importance in the timing of operation and the approach, including the type of injury and condition of the wound, and the vascularity of the wound bed.[25,26]

Type of nerve injury

In cases where there are clinical signs of nerve injury, but there is no wound, the treatment should be conservative for the first 4–6 weeks, when clinical signs of recovery of function can be investigated. If at this point there has still not been a complete spontaneous recovery, electrophysiological examination can be done. This may be repeated if there is only partial, but insufficient, recovery before any operation is considered. In case of a closed injury where no recovery has been seen at all after 3 months, clinical and electrophysiological examination should be considered.[27] If there are no signs of spontaneous recovery during this period, exploration of the injured nerve is indicated. However, if there is partial recovery during the first 3 months, regular re-evaluation may be indicated for up to another 3 months.[28] The important point is to see if any recovery at all is present.

Nerve injuries with open wounds should always be explored. If the nerve is in continuity, it should be treated as a closed injury, and the clinical and electrophysiological function should be evaluated for up to 3 months. In contrast, a clear-cut injury with the nerve ends closely approximated is suitable for immediate repair, whereas a crush injury usually is not. In the latter case, there might be difficulties in distinguishing between viable and non-viable tissue, which would call for careful debridement before any nerve repair is tried. In addition, when the patient presents with signs of an incomplete injury for which there is a chance that spontaneous recovery can yield a better outcome than immediate repair, reconstruction is preferred at a later stage only if the clinical results of conservative treatment are not satisfactory. Therefore, one of the most challenging aspects of a nerve injury will be the decision-making regarding timing of nerve exploration and reconstruction in complex cases such as open crush injuries or gunshot wounds. In these cases, the primary goal should always be to go for careful debridement and viable tissue coverage. Nerve reconstruction can thus only be considered when the surrounding tissue provides a viable environment for the nerve (see condition of the wound, below). In case of an open injury, where the patient presents with a sensory and/or motor function deficit, but with a macroscopically intact nerve upon surgical exposure, a close follow-up is essential for assessment of the nerve function. Such cases, which include open wound crush injuries and gunshot wounds, should, as the surrounding tissue envelope has healed, be treated the same way as closed traction injuries (Table 32.2). Neurological examination is performed regularly, sometimes together with recurrently performed neurophysiological testing, and surgery is usually performed if no signs of regeneration or reinnervation occur (e.g., for some injuries, exploration after 3 or 4 months). It is, however, important to stress that all open wounds, where the patient presents with a sensory or motor loss, should be explored in the acute setting, in order to obtain the best outcome.

Condition of the wound

The state of the wound is important. A clean wound calls for an early repair, whereas an untidy wound needs careful debridement to remove non-viable tissue before any nerve reconstruction is undertaken. In severe cases, there may be a need for multiple debridements. In these cases, the nerve repair is better planned as a secondary reconstruction that can be done when other structures have healed with better chances of satisfactory soft-tissue coverage of the reconstructed nerve. Such a reconstruction is preferable within 3 weeks. At the time of re-exploration, the zone of injury is likely to be better defined, and scar tissue can more easily be extracted.

Table 32.2 Differing treatments for different types of nerve injury

Type of nerve injury	Neurography/EMG	Exploration	Revision	Repair or reconstruction
Sharp transection	–	Immediate	Immediate	Immediate
Open wound – nerve crush injury	4–6 weeks[§]	Immediate	Immediate	Immediate* Delayed[†]
Closed traction injury	4–6 weeks	Delayed	–	3–4 months[‡]
Open wound – gunshot wound	4–6 weeks[§]	Immediate	Immediate	Immediate* Delayed[†]

*If there is macroscopic nerve discontinuity on exploration, repair or reconstruction should be performed after repeated revision to ensure that the wound is tidy.
[†]If there is nerve continuity on exploration, the nerve injury should be treated as a closed injury so that repair or reconstruction is performed only when there is no sign of nerve regeneration (Tinel's sign), e.g., for some injuries, exploration after 3–4 months.
[‡]Repair or reconstruction is performed after 3–4 months if there are no clinical signs of nerve regeneration or reinnervation.
[§]If the nerve is in continuity on exploration, neurography/EMG can be performed in the same manner as for closed injuries.
EMG, electromyogram.

Treatment and surgical techniques

Immediate compared with delayed nerve repair

General principles

Any nerve injury may be repaired immediately, or after a certain delay. If the conditions are favorable, immediate primary suture is the method of choice, resulting in the most favorable outcome,[29] as based on the neurobiological temporally diverse events outlined above. One of the most important prerequisites for primary repair is that it must be completed with little or no tension,[30–32] otherwise a nerve graft should be considered.[33] Several authors have argued that more than 80% of all nerve lesions can be sutured immediately with a primary end-to-end coaptation.[34,35] In these studies, it had to be possible to coapt the nerve endings with a single 9-0 nylon suture, without either separating the endings from each other or tearing the epineurium, to qualify for a primary end-to-end suture.

Primary immediate repair is technically easier than delayed repair, as approximation by rotation of the distal and proximal ends is more obvious when the epineurial vessels are present and clearly visible.[36] The elastic recoil of nerve endings that inevitably occurs as the nerve is injured is also easier to overcome in the acute phase. As time passes, the nerve endings will become embedded in fibrous scar tissue and end-to-end coaptation will be more difficult without tension or more extensive mobilization.

Clinical tips

- Ensure optimal condition of the wound bed.
- Careful debridement of injured and lacerated tissue is imperative.
- If the zone of injury of the nerve is unclear, go for secondary nerve reconstruction.

Timing

Immediate repair is preferable within the first 48 h, but some authors have suggested that it may also be done successfully during the first 1–3 weeks [37]; however, recent experimental neurobiological data have clearly pointed out the advantage of early nerve repair. This implies that patients who present with uncomplicated open nerve injuries that happened more than 48 h previously benefit from nerve repair that is delayed in the sense that it is done after the wound has healed completely. Practically, the implication is that the nerve should be repaired as soon as possible, preferably within 2–3 weeks of the injury. The rationale for this approach is to reduce the risk of iatrogenic infection secondary to operation on a contaminated wound. A longer delay will also cause difficulties in doing primary repair due to scar formation and retraction of nerve endings, but most importantly, injured parts of the nerve ends should be resected to obtain viable nerve ends for optimal coaptation.

A delayed nerve repair, i.e., more than 3 weeks after the injury, usually requires a nerve graft. Nerve graft procedures can be done several months later, but the regenerative response of neurons and particularly of Schwann cells decreases over time (see sections on physiology, above, and autografts, below).[38]

Clinical tips

- Open wounds should always be explored as soon as possible if a nerve injury is suspected.
- Delay in nerve repair or reconstruction causes impaired functional outcome.
- If the nerve is in continuity, it should be treated as a closed injury.

Surgical approach

The incisions follow the general principles of plastic surgery in that the main objective is to prevent contractures and scars in areas of maximum sensory perception (Fig. 32.11). Wide exposure is often recommended to obtain a detailed anatomical overview, and it offers a safer dissection as the area of injury can be approached from healthy tissue outside the zone of injury. This often means that the traumatic wound needs to be extending proximally and distally, which is particularly important in secondary reconstructions.

Clinical tips

- Wide exposure and careful dissection to obtain well-vascularized tissue flap are vital for nerve coverage.
- Approach the nerve injury from viable tissue – thus, "from the known to the unknown."
- Use of a tourniquet is always advised.

Principles of nerve repair

General principles

Proper and thorough microsurgical technical skills are crucial in nerve repair. An atraumatic approach with minimal tissue damage, using microsurgical instruments under either loupe magnification or a microscope, is essential (Video 32.1 ▶).

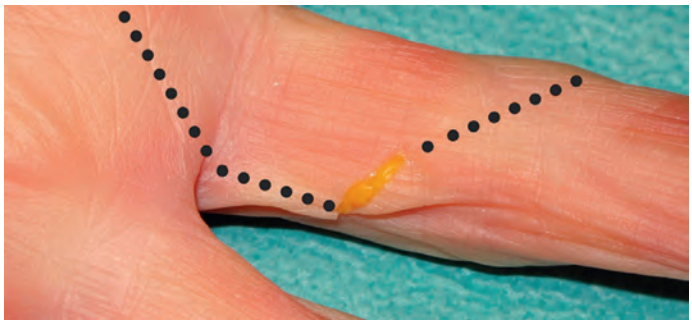

Fig. 32.11 Small stab wound on the radial side of the index finger. Loss of sensation distal to the wound calls for exploration. A modified Bruner incision is used.

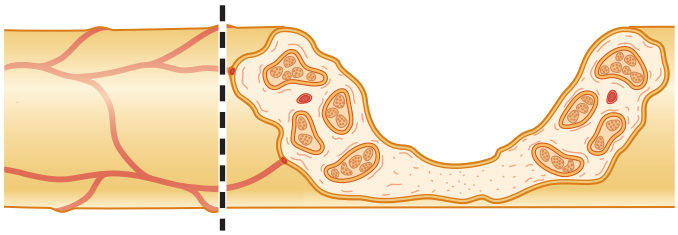

Fig. 32.12 A lacerated nerve and the cut-off line for debridement. The dashed line illustrates suggested resection line to reach healthy nerve tissue.

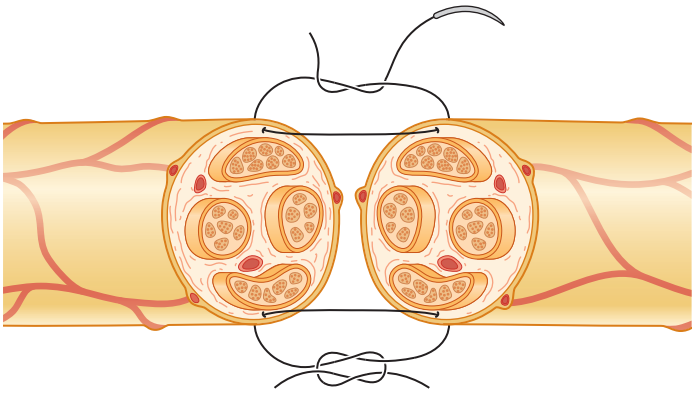

Fig. 32.13 Standard epineurial repair with nylon sutures. To get proper fascicular alignment, nerve endings are aligned based on the pattern of the blood vessels within the epineurium.

First, the injured nerve ends must be identified. Non-viable tissue must be resected, preferably with a surgical blade or using microsurgical scissors, to allow visualization of healthy fascicles that help the adaptation in primary nerve repair (Figs. 32.12–32.14 and Video 32.2 ▶). When repairing a nerve it is preferable to align the nerve according to its fascicular pattern, which may help topographical arrangement and improve outcome. If later reconstruction is planned (secondary reconstruction), the nerve ends may be tagged with a non-resorbable suture, and sutured to other structures in the wound. This is primarily to prevent the retraction of the nerve that inevitably happens after transection, but also to facilitate identification at a secondary procedure. If the nerve is allowed to retract, it will become tethered in fibrous scar tissue and lose its elasticity and normal excursion. The normal longitudinal excursion of the nerve needs to be taken into consideration, as the immediate demand for suitable length will depend on it. The normal excursion of the median and ulnar nerves is thought to be around 1.5 cm at the wrist when taking the wrist from full extension to full flexion.[39,40] This length should preferably be added to the nerve deficit when estimating the total defect and assessing whether a nerve graft is needed or not. In a primary repair, the longitudinal extension is retained and the nerve can therefore be approximated with minimal tension.

Second, the ultimate aim is a tension-free repair to enable the nerve to heal in optimal conditions. Usually, some dissection of the nerve trunk is necessary to achieve this. Even a small elongation through longitudinal traction will have a potentially devastating effect on the vascular supply to the nerve endings, with subsequent effects on the viability of the Schwann cells,[29] as stretching of a nerve trunk has been shown to impair intraneural microcirculation.[41] Nerve blood flow decreases approximately 50%, with substantial recovery in 30 min after 8% elongation, whereas 15% elongation produces approximately an 80% reduction in blood flow with minimal recovery.[30] Some dissection of the nerve trunks proximal and distal to the injury is therefore often needed to alleviate tension, and this can be done without interfering with the segmentally approaching blood vessels. Other means of alleviating tension, such as transposing the ulnar nerve anteriorly

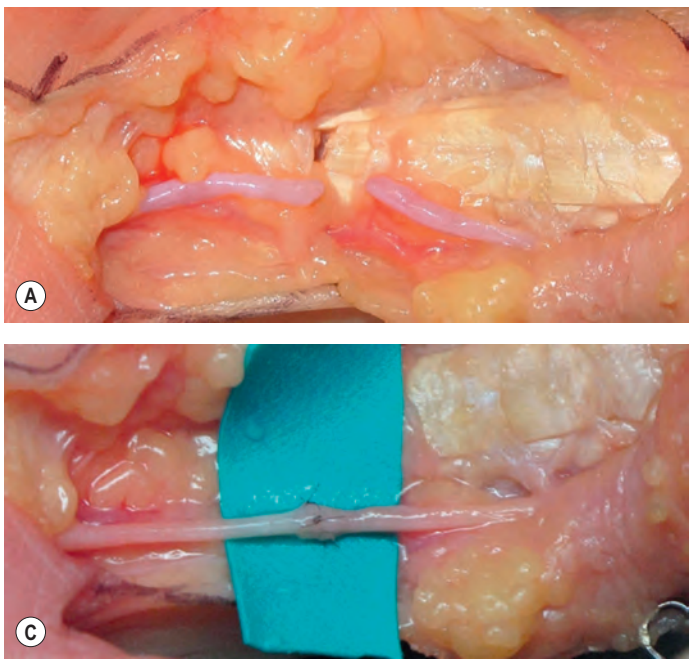

Fig. 32.14 Peripheral nerve repair of a digital nerve using standard epineurial end-to-end coaptation. **(A)** Nerve injury with minimal gap. **(B)** Epineurial suture. **(C)** Complete coaptation with minimal tension.

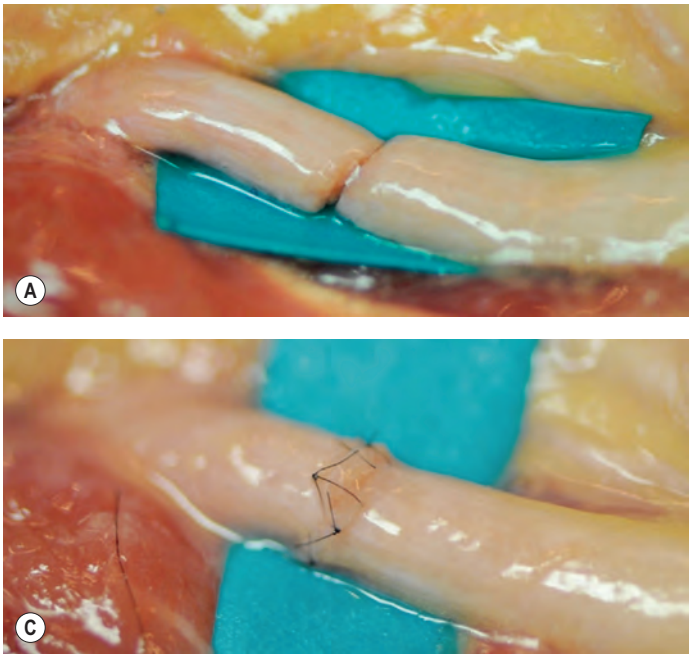

Fig. 32.15 Patient with a median nerve injury that is repaired with standard epineurial end-to-end coaptation at minimal tension. **(A)** Nerve injury with minimal gap. **(B)** Mushrooming seen when healthy nerve tissue is reached after resection. **(C)** Complete coaptation with minimal tension.

and therefore increasing excursion over the elbow, can be considered to enable a tension-free direct suture. It is, however, important to bear in mind that mobilization by dissection can theoretically impair the blood supply to the nerve endings. This issue has been an issue of debate,[42–44] although clinical experience from ulnar nerve transposition points to the fact that intraneural microcirculation can resist considerable mobilization, and that gentle handling of the nerve can be acceptable.[43,44]

As complete lesions almost always result in some retraction of the nerve endings, there is in most instances a gap between the ends that makes a completely tension-free suture rare. The nerve endings generally need trimming, which means that some nerve tissue has to be resected to reach viable parts. Under the microscope this is seen as "mushrooming" of the fascicles together with slight retraction of the epineurium from the neural stumps (Fig. 32.15B). It is hard to give a general rule for how much tension is acceptable in each individual case, but if flexion of a joint is necessary to shorten the distance between the nerve ends, the resulting tension will usually be too great, and further dissection or nerve grafting should be considered (Figs. 32.16A & 32.17A).

Third, the nerve endings should be rotated to their correct positions by matching fascicles, branches, or the longitudinal

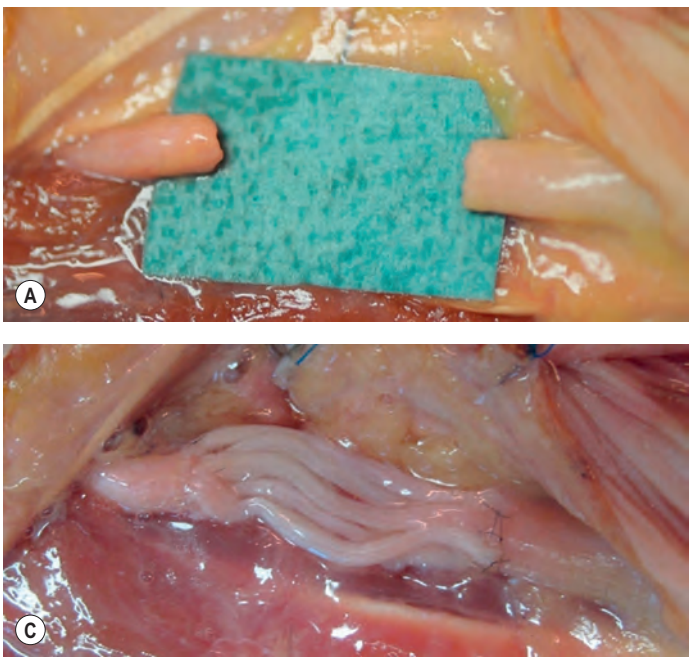

Fig. 32.16 Patient with a lacerated median nerve that, after resection of the destroyed part, remains with a nerve deficit **(A)** that is bridged with multiple cables of sural nerve grafts **(B,C)**. Note that the individual cables are about 15% longer than the gap.

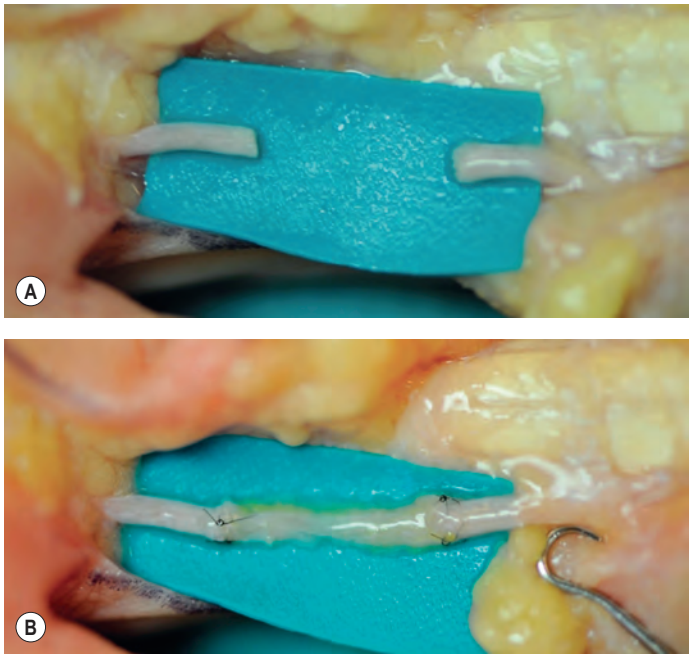

Fig. 32.17 **(A)** Digital nerve laceration. **(B)** The nerve gap was bridged with a single autograft from the lateral cutaneous antebrachial nerve.

epineurial vessels of the two nerve endings, which decreases the risk of mismatch between bundles of axons (Figs. 32.15A & 32.18). Correct coaptation facilitates a good postoperative outcome.

Nerve endings are commonly coapted with interrupted 9-0 or 10-0 nylon sutures. It is generally thought that a minimal amount of suture material is preferable, and the number of sutures should be no greater than the minimum number required to ensure coaptation of the nerve stumps. It is important that the nerve ends are not closed too tightly so that the fascicles become malaligned and crumple in the process.[45] Outward-pointing fascicles are sometimes found, and should be cut with microscissors. They are then able to retract to within the coaptation and will subsequently probably be able to regenerate sufficiently.

Other means, apart from nylon sutures, of maintaining the primary repair can be considered, particularly if the repair is to be made by a relatively inexperienced surgeon. The use of fibrin glue as an alternative, or as an adjunct, to epineurial sutures has been evaluated in rats after transection of the sciatic nerve.[46,47] The results showed that fibrin glue is as good as suturing in experienced hands, and superior to sutures when the surgeon is inexperienced.[43,46]

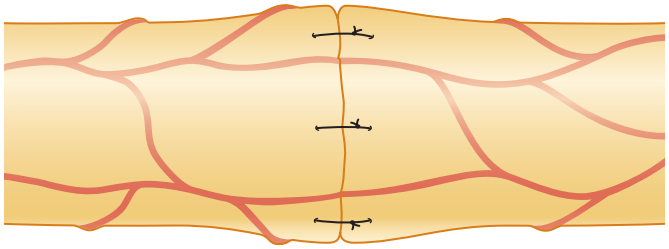

Fig. 32.18 End-to-end coaptation. Note that the epineurial vessels match.

Clinical tips

- Proper magnification, appropriate equipment, and microsurgical skills are crucial.
- Resect non-viable tissue carefully, possibly stepwise, to visualize healthy nerve endings – look for mushrooming.
- Important for tension-free coaptation – if flexion of joints is needed, consider nerve reconstruction.
- Aim at fascicular match – look for intraneural vessels to help with alignment in repair and reconstruction.

Epineurial compared with fascicular repair

The nerve trunks may be adapted either at the level of the epineurium (see Fig. 32.12) or the fascicles (Fig. 32.19). Which method is preferable has been a matter of debate, probably because the scientific evidence is not entirely clear as the data are based on experimental studies in rats and primates with their inherent methodological problems.[48,49]

The theoretical advantage of the fascicular repair over the epineurial repair is that it facilitates regeneration with a better chance of keeping the axonal specificity to sensor or motor end organs. However, fascicular repair requires a more profound dissection to identify the individual fascicles at the two ends, which in turn may increase the risk of compromising the vascular supply. An epineurial repair with careful rotation of the nerve trunks is therefore thought to be as effective, particularly more distally. The dissection is technically more difficult as the individual fascicles are hard to identify clearly distally. A group fascicular adaptation is preferable, for example with lesions of the ulnar nerve at the wrist. Great care should be taken to make sure that sensory and motor fascicles are located both proximally and distally through dissection, and coapted separately (Fig. 32.20).

Clinical tips

- Epineurial repair is preferable as long as it is technically possible.
- Apply a limited number of sutures, maybe with fibrin glue as an adjunct to sutures.
- Group fascicular repair is a good option when sensory and motor fascicles are distinct, such as with the ulnar nerve at the wrist level.

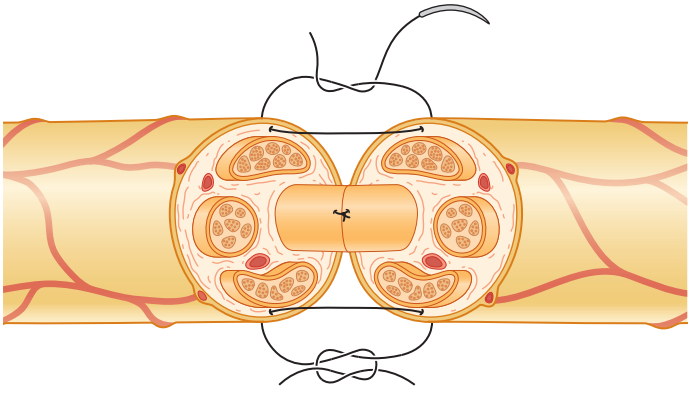

Fig. 32.19 Group fascicular repair with nylon sutures. Corresponding groups of fascicles are sutured through the interfascicular epineurium.

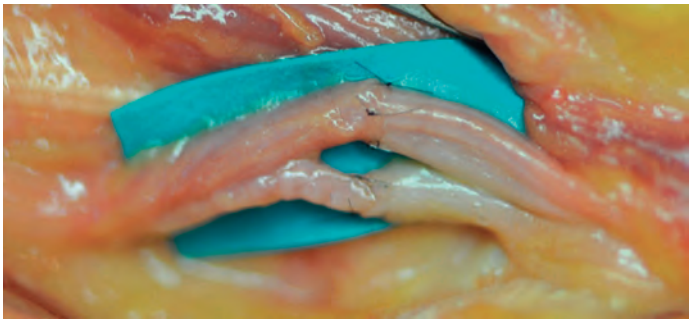

Fig. 32.20 Ulnar nerve injury at the wrist level. Note how the motor and sensory fascicles are anatomically separated. A group fascicular coaptation is performed.

End-to-side nerve repair

When conventional surgical methods are unavailable, particularly if the proximal stump is absent, or after injuries to nerve proximally in the extremity (such as in high ulnar nerve injuries), the distal end of an injured nerve can be attached to an "uninjured" donor nerve.[50,51] Collateral or terminal sprouting of donor nerve axons occurs, and donor site morbidity associated with the harvest of a nerve graft is avoided. In addition, the distance traveled by regenerating axons to reach their targets is shortened. Theoretically this implies that a single neuron possesses the ability to innervate two targets, but one of the branches is probably pruned away.[51] Several studies have indicated that the outgrowth of axons from the donor nerve requires an axonal injury to induce sprouting.[52] At present, experimental and clinical experience with end-to-side coaptation has, at best, achieved mixed results, depending on the type of reinnervated nerve and donor nerve.[53] More extensive clinical and laboratory experiments are presently produced, which is required before end-to-side suturing generally can be included with the more established techniques of nerve repair.[54,55] However, for reinnervation of muscles from motor donor nerves, the end-to-side techniques have been reported to be useful.[56]

Wound closure and immobilization

The wound should be closed with interrupted sutures and a local anesthetic may be given before dressing. It is preferably given through a blunt cannula inserted between the stitches. Sharp needles should be avoided to reduce the risk of neurovascular damage proximal to the injury if the site of repair/reconstruction is located superficially.

A plaster should be applied, primarily to restrict excessive movement, avoiding tension in the repair, and still allow some range of movement for controlled early mobilization. The plaster should position the extremity in such a way that it both releases tension and prevents excessive movement. For digital nerve injuries, the wrist is immobilized at 30° of flexion and the metacarpophalangeal joints at 70°. The splint is usually extended just past the proximal interphalangeal joints to prevent hyperextension. Immobilization with plaster of Paris, with controlled restricted range of movement, is usually maintained for 3 weeks before full range of movement is allowed in digital nerve repairs. In repairs of larger nerve trunks a prolonged protection of the suture line may be recommended up to 6 weeks postoperatively, to avoid extensive extension of the wrist or elbow.

Nerve reconstruction

Clinical tips

- Always consider a nerve reconstruction to alleviate tension at the coaptation site when trauma or debridement has left a nerve deficit or when joint movements are expected.
- Autologous nerve grafts are still considered the gold standard compared to artificial conduits.

Autografts

Nerve reconstruction involves the use of a nerve graft to overcome a lack of continuity after an injury (see Figs. 32.16 & 32.17). The use of autologous grafts is still the method of choice despite the fact that other strategies, such as nerve and muscle allografts or synthetic materials, have been proposed, but they demand a more complex approach than a primary nerve repair to be successful.

The rationale for using a nerve autograft in reconstruction is to alleviate all tension at the site of suture. If tension is completely avoided, axonal sprouting to cross the two sites of repair will be easier than over a primary repair site under unfavorable conditions.[57] The axonal outgrowth through the nerve graft depends on the diameter of the graft and the vascularity of the tissue bed. The selection of donor nerve will therefore be much influenced by size, as survival is dependent on diffusion from the surrounding tissues. Neovascularization will occur through capillary ingrowth from the periphery and nerve ends.[57,58] Smaller nerves (for example, the sural, and the medial and lateral antebrachial cutaneous nerves) will therefore revascularize easily, and thicker nerves will carry the risk of central necrosis and scarring as a result of poor diffusion. Only one cable is needed when smaller nerves, such as digital nerves, are bridged (see Fig. 32.17), whereas multiple cables may be needed to bridge the gap in larger damaged nerve trunks (see Figs. 32.16 & 32.21).

Approach and preparation

The initial steps in preparing the nerve tissue are no different from those for primary nerve repair. However, when the ends are being resected to create a clean-cut surface, it is important to expose the nerve carefully, including the whole zone of injury. This enables proper evaluation of the viability and vascularization of the nerve and surrounding tissues. In crush or high-velocity injuries, this principle is central. As with all tissue injuries in which the zone of injury is not clear, late effects on viability call for second looks and re-evaluations. When the nerve is explored after the surrounding tissue has healed, it is important to remove any scar tissue carefully, or preferably to approach the nerve lesion through a separate incision. This includes raising a flap that at closure of the wound will enable good tissue coverage.

Nerve ends

A good way to find out whether the nerve endings are viable is to look for "mushrooming" (see Fig. 32.15B), which is a sign of transected viable axons that will be able to sprout after

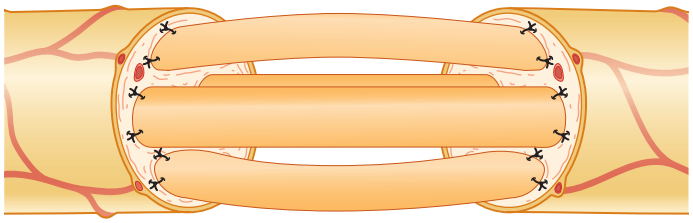

Fig. 32.21 Schematic presentation of autograft repair. Each segment is coapted to the corresponding group of fascicles of the nerve endings. Note how the individual grafts are applied quite loosely.

reconstruction from the resection site, indicating that the nerve is a suitable recipient for a nerve graft.

The gap

To harvest a proper graft it is essential to calculate the maximum gap that is going to be bridged, and this has to be done in relation to any movement of a joint that might occur later on.

Length of graft

Because the graft may shrink slightly, it should be about 15% longer than the maximum gap.[59] Nerve excursion must be considered, and length is best assessed with all adjacent joints fully extended (or in certain cases, such as radial nerve injury at upper arm, in a flexed position).

Harvest of the graft

The size of the nerve trunk to be bridged is the main factor to be considered when deciding which donor nerve will be most suitable to use as a graft. Donor site morbidity and functional deficit also have to be considered when choosing the proper donor nerve (Table 32.3).[60] Patients should be well informed about these aspects before the harvest. The most common grafts are the sural nerve, the medial antebrachial cutaneous nerve, the lateral antebrachial cutaneous nerve, or the terminal branch of the posterior interosseous nerve.

Gentle handling is of great importance and must follow the same principles as handling of all nerves. As the graft is harvested, great care must be taken that it is kept moist in a gauze soaked in saline. The grafts are sharply cut to proper length and a few millimeters of extra epineurium is removed from the ends of the graft.

Table 32.3 Common nerves used as autografts

Donor nerve	Length (cm)	Sensory defect
Sural nerve	30–40 cm	Dorsal aspect of lower leg and lateral foot
Medial antebrachial cutaneous nerve	10–12 cm* 8–10 cm†	Medial forearm
Lateral antebrachial cutaneous nerve	10–12 cm	Lateral forearm
Superficial sensory branch of the radial nerve	25 cm	Radial dorsal hand

*Above elbow.
†Below elbow.

Coaptation and maintenance

The nerve graft is preferably reversed at the time of placement to decrease the risk of diversion of regenerating axons through these cut-off branches. Depending on the size of the nerve trunk, the whole nerve or individual fascicles can be sutured using 9-0 or 10-0 nylon, if possible with fibrin glue as an adjunct. A sufficient number of fascicles are used to bridge the defect, preferably with one cable for each severed group of fascicles (see Figs. 32.16C & 32.21). The coaptation should not be too tight, as this can easily lead to crumpled nerve endings. Fibrin glue may be interposed to reinforce and lessen the risk of separation between the graft and nerve endings. Fibrin glue may also give an instant better match between the graft and the nerve end. The number of sutures should be kept to one or two. If multiple cables are used, the individual grafts are positioned so that they do not adhere too closely to each other. This is to allow diffusion of oxygen and other nutrients, and allow for rapid revascularization from the recipient bed. It must be stressed therefore that the viability of the tissue bed is of crucial importance for optimal survival of Schwann cells and successful axonal regeneration.

Donor nerves

Sural nerve

The sural nerve is often thought to be the main donor nerve for free grafting, because it can easily be harvested in lengths between 30 and 40 cm[61]; it originates from the tibial nerve dorsal to the knee joint (Fig. 32.22), and it has communicating branches from the peroneal nerve at levels distal to this. These communicating branches need to be identified and transected before the nerve is pulled out.

The sural nerve is identified through a short longitudinal incision halfway between the lateral malleolus and the Achilles tendon. If the nerve is gently pulled distally, the proximal course of the nerve can be palpated and extracted through 3–5 small transverse incisions that usually pose a minor aesthetic problem for the patient (Fig. 32.23). Alternatively a long dorsal incision can be used, which enables an easier dissection of the nerve and its small branches. It is preferable to cut the nerve beneath the fascia to reduce the risk of a troublesome neuroma. Nerve strippers can be used and endoscopic harvest has been suggested to reduce aesthetic morbidity at the donor site.[62] The area of diminished or absent sensation after the graft has been harvested is shown in Fig. 32.24, but is usually considered to be of minor importance to the patient.[60]

Medial and lateral antebrachial cutaneous nerves

The medial cutaneous nerve can be harvested from the distal border of the axillary groove to below the elbow (10–12 cm). In the forearm it is located medially (8–10 cm), close to the brachial vein, where it divides into three branches (Fig. 32.25). These branches correspond well in size to digital nerves. The consequences are usually of minor importance to the patient (Fig. 32.26).

The lateral cutaneous nerve (10–12 cm) is the terminal branch of the musculocutaneous nerve. It is identified at the

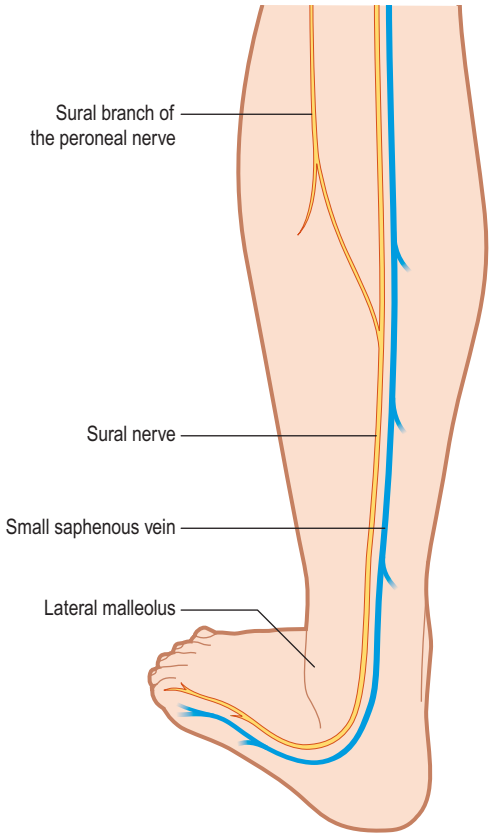

Fig. 32.22 Course of the sural nerve in the lower leg, shown in orange.

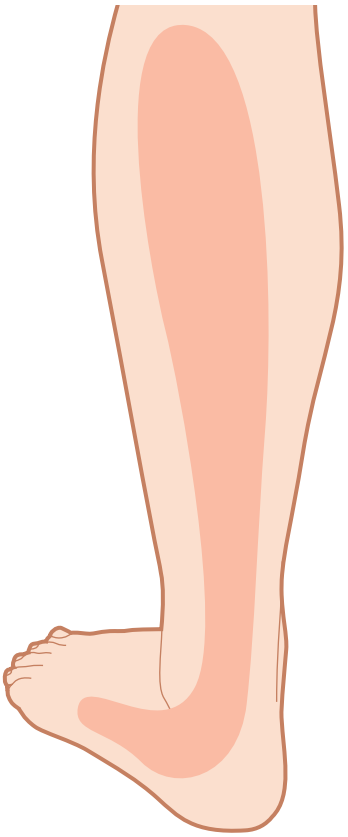

Fig. 32.24 Area of diminished or absent sensation after harvest of the sural nerve.

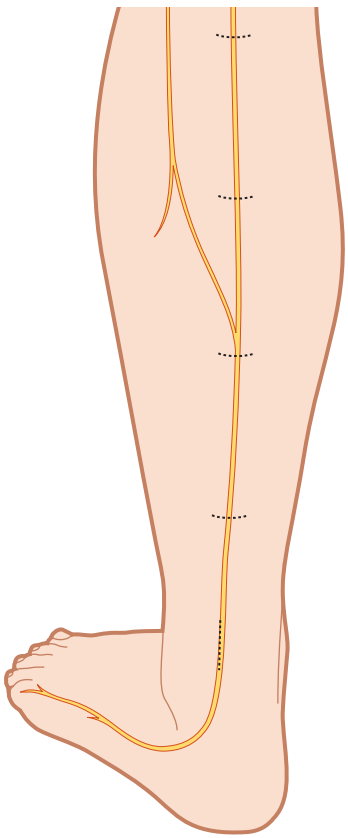

Fig. 32.23 Incisions to enable harvest of the sural nerve, shown by dotted lines.

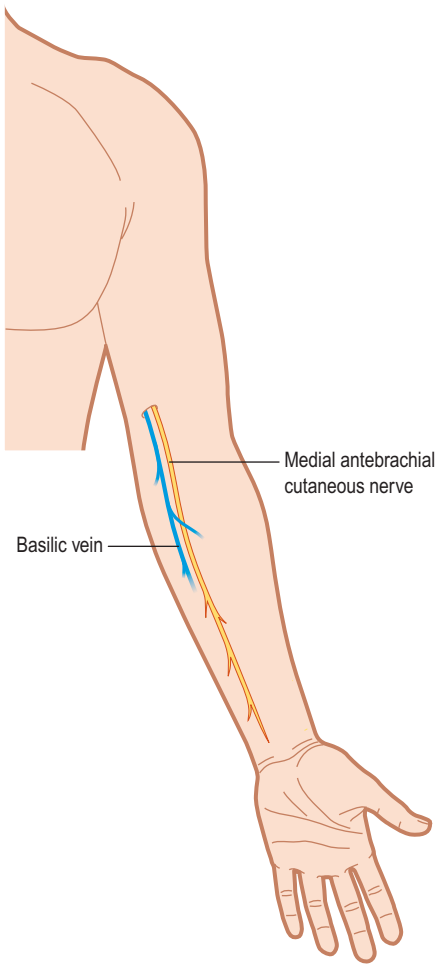

Fig. 32.25 Medial antebrachial cutaneous nerve shown in orange, and basilic vein.

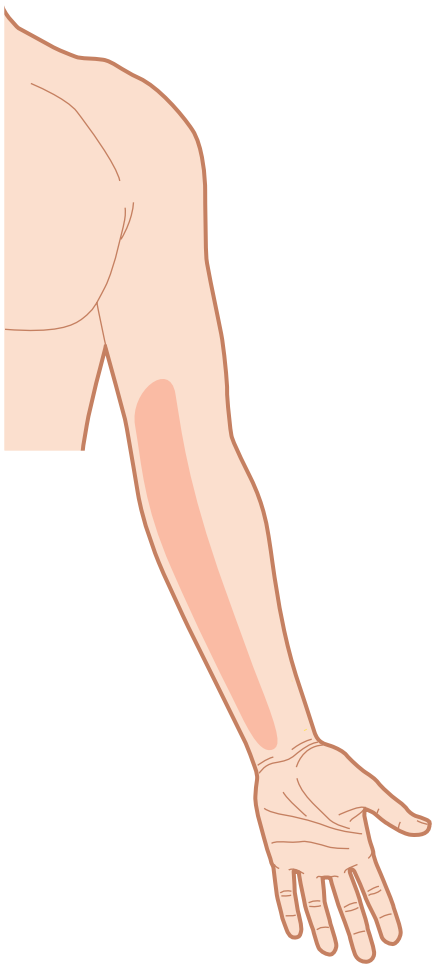

Fig. 32.26 Area of diminished or absent sensation after harvest of the medial antebrachial cutaneous nerve.

lateral border of the biceps tendon where it parallels the cephalic vein (Fig. 32.27).

A few short incisions are generally sufficient to harvest these nerves adequately. The consequences are usually regarded as more troublesome for the patient after lateral antebrachial cutaneous nerve harvest than after harvest of the medial antebrachial cutaneous nerve (Figs. 32.28 & 32.29).

The terminal branch of the posterior interosseous nerve

The terminal branch of the posterior interosseous nerve is simple to harvest dorsally just proximal to the wrist, lying on the interosseous membrane.[63] Generally, one can harvest a 4–5-cm long segment (1–3 fascicles), which may fit into a small digital nerve defect. Harvest causes no complications or loss of function, which is beneficial, especially in reconstructions of digital nerve defects. This was recently exemplified in a retrospective study, where posterior interosseous nerve grafts were shown superior to the medial cutaneous nerve of the forearm, especially in terms of donor site morbidity.[64]

Superficial sensory branch of the radial nerve

The superficial sensory branch is formed as the radial nerve is divided into a deep (the posterior interosseous nerve) and a superficial branch at the elbow level. The superficial branch runs beneath the brachioradialis muscle to surface distally about 8 cm from the tip of the radial styloid between the tendon of brachioradialis and the tendon of extensor carpi radialis (Fig. 32.30). It provides a 25 cm-long nerve graft, but is rarely used because it tends to cause painful neuromas. It is primarily used when large quantities of nerve grafts are needed in brachial plexus injuries. In the presence of a median or ulnar nerve injury, it is considered a relative contraindication to use it as a donor for nerve grafts (Fig. 32.31).

Other

The saphenous nerve (40 cm) has been used primarily in plexus injuries and as a vascularized nerve graft. The lateral femoral cutaneous nerve (20 cm) can be used as a last choice, but has the disadvantages of comparatively large sensory loss, and painful neuromas.

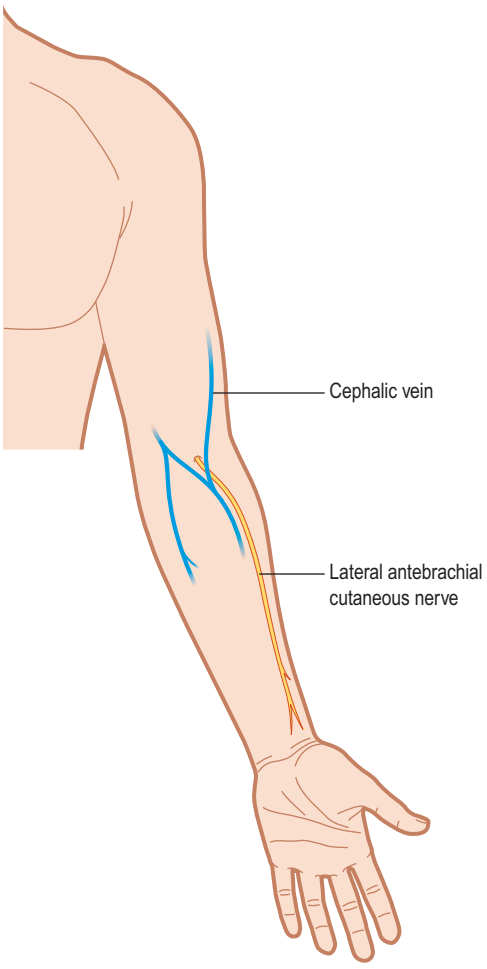

Fig. 32.27 Lateral antebrachial cutaneous nerve shown in orange and cephalic vein.

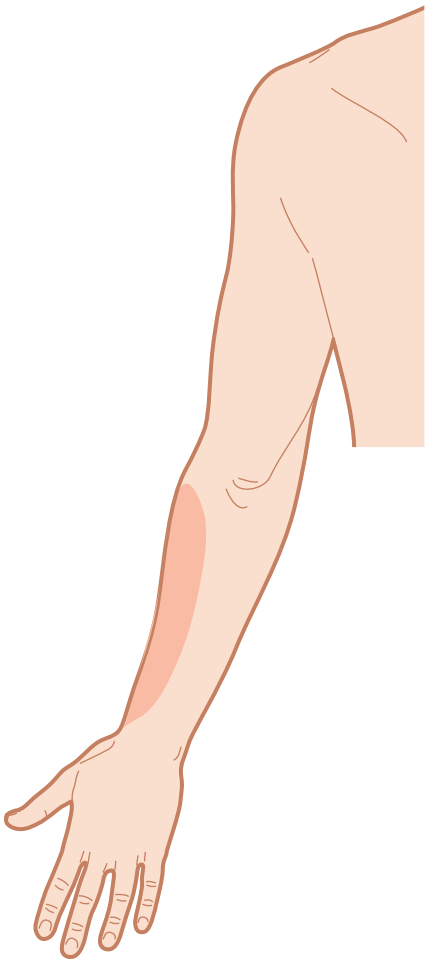

Fig. 32.28 Area of diminished or absent sensation after harvest of the dorsal aspect of the lateral antebrachial cutaneous nerve.

Tubular repair and artificial conduits

Autologous nerve grafts are still considered to be the gold standard for bridging defects in nerves. The superiority in outcome is thought to be mainly the result of their ability to provide a biocompatible scaffold that contains both Schwann cells and their basal lamina. These factors promote regeneration through natural production of growth factors and adhesion molecules, which will help stimulate neurite elongation and direction on site.[65] However, there are disadvantages with autografts, some of which have been mentioned above. Harvesting requires an extra surgical incision to obtain an otherwise healthy sensory nerve. There are limited sources of graft material, and the injured nerve and donor nerve may be mismatched at grafting.[66]

Our present inability to gain full functional recovery with autografts has been the main driving force behind the development of alternative means to bridge nerve defects. Tissue engineering has in recent years offered the opportunity to develop biodegradable guiding materials with tailored properties that imitate normal biological features. Structural stability is enabled, and both growth factors and supportive cells, such as Schwann cells or stem cells, can be added to give physical guidance to the regenerating axons. However, the latter procedure is far from clinical practice, but may be a possibility in the future. Formation of a longitudinally oriented fibrin matrix and accumulation of various tropic and trophic factors will ensue within the conduit, and this will further improve the physical conditions for nerve regeneration. Obviously, donor morbidity after graft harvest will be eliminated.

Biological conduits

The first attempt to bridge a nerve defect with a tube was published by Glück, who used a piece of decalcified bone to bridge a nerve gap.[67] Since then, several biological scaffolds have been used, including veins,[68,69] arteries,[70] muscles,[70] tendons,[71] and combinations such as vein–muscle grafts,[72,73] and acellular nerve allografts,[74–76] with variable outcomes. The main theoretical advantage of using biological constructs with a core matrix is the availability of a longitudinally oriented basal lamina and extracellular matrix components that direct and improve the regeneration of axons. In contrast, bridging methods using only tubular material, such as vein grafts or non-degradable or degradable nerve conduits (several are commercially available) lack this function and may be less attractive, at least theoretically. The use of composite

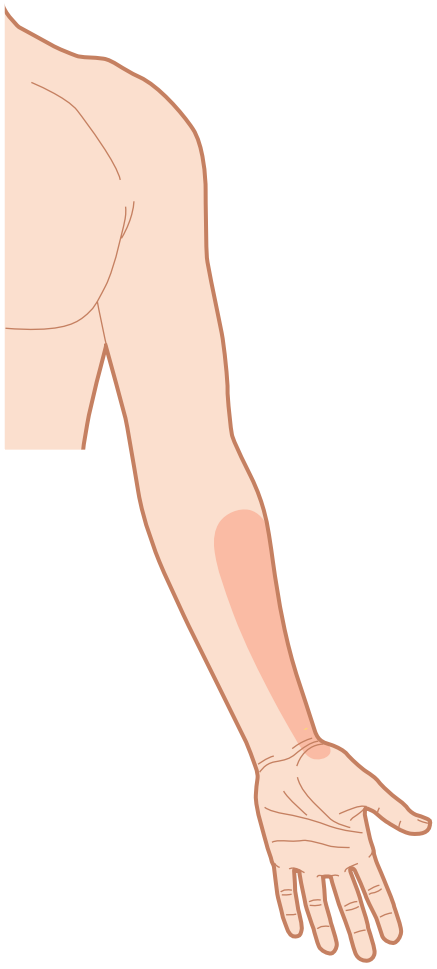

Fig. 32.29 Areas of diminished or absent sensation after harvest of volar aspect of the lateral antebrachial cutaneous nerve.

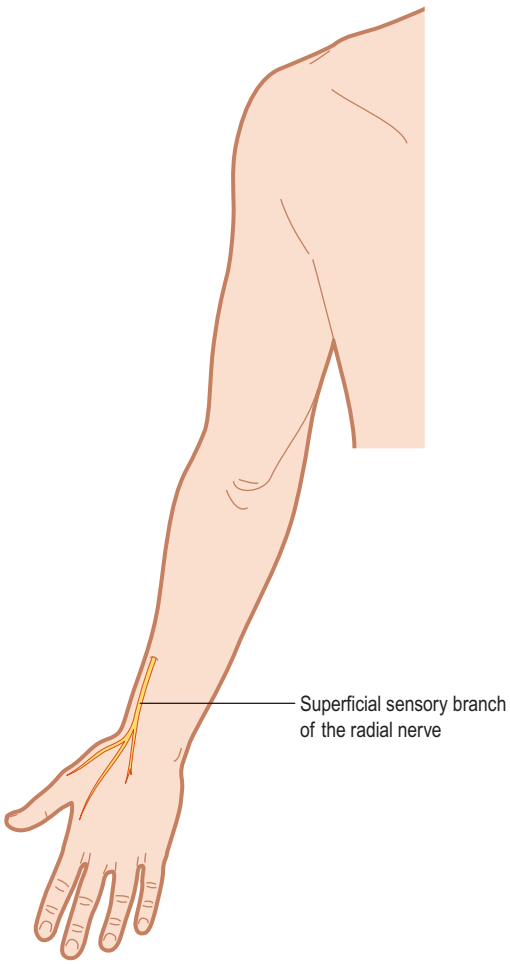

Fig. 32.30 Superficial sensory branch of the radial nerve.

biological conduits, such as combinations of veins and muscles, has therefore been explored. The main rationale for using this combination, apart from it being of autologous origin, has been that a collapse of the vein is prevented by filling the lumen, and that the vessel wall prevents the risk of axons sprouting outside the muscle. Nerve regeneration is propagated along the longitudinally oriented muscle fibers and no foreign material is used in the bridging process. In a recent retrospective study of nerve reconstructions of up to 6 cm-long digital nerve defects, comparing autografts, muscle-in-vein grafts, and direct nerve repair,[77] it was found that muscle-in-vein grafts yielded similar outcome as the nerve autografts, which have been slightly, but not significantly, worse than the ones after direct nerve suture. One advantage of muscle-in-vein grafts is the lack of donor site sensory morbidity.

Processed nerve allografts

Processed nerve allografts provide decellularized and predegenerated human nerve tissue as an alternative to conventional nerve autografts or tube conduits for nerve reconstruction. These grafts have shown promising results both in animal studies and early clinical studies, where they have been proven to be safe and effective in sensory nerves up to 30 mm; however, the maximal length of the nerve defect is not yet established.[78–81]

The three-dimensional structure of these acellular scaffolds contains many of the beneficial characteristics of nerve autografts. This includes not only the physical structure of the epineurium, and fascicles with endoneurial tubes, but also protein structures and guidance molecules specific for nerve tissue. It is hypothesized that the grafts thereby function as a guide for tissue regeneration, by stimulating a rapid revascularization and repopulation with host Schwann cells.

Today, commercially available processed nerve allografts are all manufactured from donated human peripheral nerve tissue. A detergent protocol is used to remove all cells and cause a pre-Wallerian degeneration of the nerve tissue in order to cleave growth inhibitors. The tissue is then sterilized prior to use as an off-the-shelf product.

In a large multicenter observational study, the RANGER Study registry, 71 nerve gaps in sensory, mixed, and motor nerves were reconstructed in 56 subjects. Overall, a meaningful level of recovery, defined as motor nerve function of M3 to M5 and sensory function of S3 to S4, was achieved in 86% of the patients with repairs with graft lengths up to 50 mm. Meaningful levels of recovery were also found in 89% of

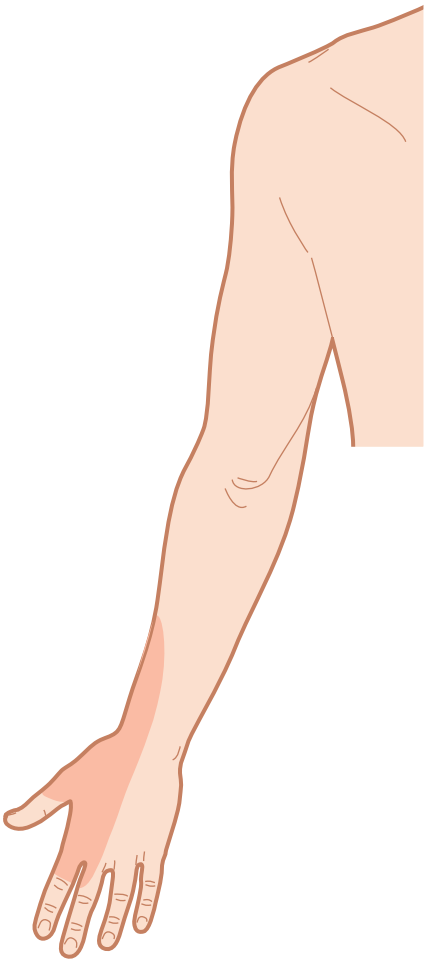

Fig. 32.31 Area of diminished or absent sensation after harvest of the superficial sensory branch of the radial nerve.

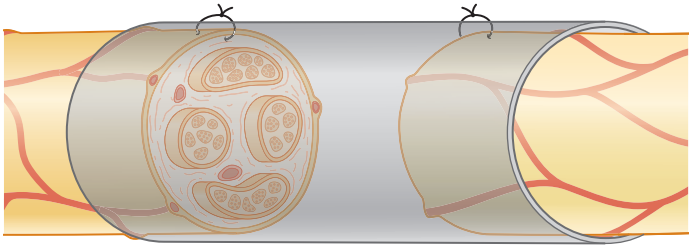

Fig. 32.32 A nerve defect bridged by a nerve conduit.

digital nerve repairs, 75% of median nerve repairs, and 67% of ulnar nerve repairs.[79,82] In a follow-up study of short-gap (i.e., 5–15 mm) sensory recovery, using the same material, it was shown that the outcome for nerve allografts were equivalent to previous data on autograft and exceeded those of conduits.[83]

Non-degradable conduits

The first artificial conduits used in preclinical and human trials were composed of non-resorbable polymers based on silicone and polytetrafluoroethylene[84,85] (Fig. 32.32). Silicone was chosen because of its inert material properties and because it is tolerated well by the recipient.[86] It has been used successfully in hand surgery for arthroplasty and two-stage tendon-grafting procedures for the last two decades. As silicone tubes are non-degradable and impermeable to large molecules, they also provide the necessary biological isolation from scar-forming elements of the wound and allow for accumulation of growth factors. A longitudinally oriented fibrin matrix containing macrophages is formed and there is migration of Schwann cells, ingrowth of axons, and neovascularization of the newly formed nerve trunk. Silicone tubes were used in a clinical prospective randomized study that compared tube repair and microsurgical nerve repair in median and ulnar nerve injuries.[87] Results showed no significant differences in outcome between the two methods, except for a decrease in cold intolerance in the conduit group at the 5-year follow-up.[88] The authors concluded that tubular repair may be preferable in the future when appropriate bioresorbable materials are available. However, utilization of a silicone tube is not an alternative when there is a nerve defect.

Biodegradable conduits

Increasing interest has turned towards the use of biodegradable materials as conduits. Ideally, the material from which the tube is made should be highly biocompatible and allow degradation to non-toxic end products. They should be mechanically stable, yet still flexible and porous to ensure supply of nutrients and provide a microenvironment that allows for the production of functional tissue.[65,89–91]

Polymer-based materials, such as collagen, polyglycolic acid polymer, and polylactide-caprolactone polymer, and other available materials such as chitosan conduits,[91] offer a high degree of flexibility in chemical and physical properties and are available commercially. Future inclusion of fillers, such as Schwann cells, or incorporation of biologically active substances in the polymers that are released as the tube is degraded are areas of massive research. Yet, at present, clinical experience in terms of randomized trials is lacking,[92] although increasing numbers of studies have reported promising results regarding recovery of both sensory[93–95] and motor function.[96,97]

In a level II study, Boeckstyns *et al*. randomized ulnar or median nerve injuries to repair with a collagen nerve conduit or with conventional microsurgical techniques. The use of collagen conduits was found to have a recovery of sensory and motor functions that were equivalent to that after direct suture when the nerve gap was 6 mm or less, as evaluated at 24 months after repair. At 12 months, however, there was a significantly better motor recovery in the direct suture group. Also, ulnar nerve lacerations were found to have a poorer prognosis compared to median nerve lacerations.[98]

Another recent prospective long-term follow-up on digital nerve reconstructions with collagen nerve conduits found that sensibility continued to improve in most cases after 12 months. Also, it was shown that the improvement of sensibility was associated with a significantly shorter nerve gap length with significantly better results if the gap length was <10 mm.[99]

Fillers

The main purpose of inserting filler structures in the conduits, whether in the form of guidance channels, hydrogels, or others, is to apply hapotactic cues (contact-mediated) to support axonal regeneration or chemotactic cues (diffusible) to guide the regenerating axons.[100] The most commonly used haptotactic cues are extracellular matrix proteins such as collagen, laminin, and fibronectin. Neurotrophic factors, such as nerve growth factor, glial-derived neurotrophic factor, and neurotrophin NT-3, are additives that act as chemotactic cues that will promote neuronal regrowth and sprouting.[65] Addition of cellular components, such as Schwann cells[101] and stem cells,[102] can further be used to improve the regeneration by creating a more optimal microenvironment. In the future, it is possible that "off-the-shelf" conduits may be filled with autologous supporting cells that are harvested and immediately prepared from the patient's injured nerve segments.[103]

Other techniques

Preclinical studies have indicated that shorter digital nerve defects can be bridged by applying longitudinal resorbable sutures that will act as a guide for the fibrin matrix that is formed to fill the defect. Schwann cells and axons will follow this matrix and thereby overcome the defect. The newly formed nerve trunk, which can be made in a branched pattern, is subsequently surrounded by a new perineurium-like structure and provides functional recovery.[104]

Nerve transfers

In recent years there has been an increasing interest in the use of nerve transfers in nerve reconstruction.[105] This technique has primarily been used in brachial plexus injuries, and is based on the assumption that less important nerves can be sacrificed, transected, and rerouted to be attached to a functionally more important nerve segment.[106,107] It can also be used after other proximal nerve injuries, and the procedure transfers a proximal nerve injury to a distal one. This is a tempting and valuable method that can be used when patients present late with nerve injuries, even in young patients.[108] The topic is further discussed in Chapter 33.

Clinical tips

- Current literature supports the use of conduits or acellular nerve allografts for reconstructions of nerve defects when the defects are limited, for example in digital nerves and larger nerves (median and ulnar nerves). In larger defects, conduits and allografts should be used with caution, and until proven effective for longer distances, we suggest nerve grafting for long defects.
- For sensory digital nerve defects, especially if the proximal stump is absent, cross-over end-to-side neurorrhaphy is a reconstructive option.

Postoperative care

General aspects

The role of early active mobilization after microsurgical nerve repair has been debated. It has been hypothesized that it may cause a change in tension at the site of nerve repair, which in turn will result in impaired functional outcome.[109,110] Experimental studies have indicated that intraneural scarring at the repair site can impede revascularization and reduce axonal regeneration across the suture line as a result of tension.[32,111] However, immobilization may result in an increase in scar tissue that surrounds the reconstructed nerve. Tethering of the nerve by scar tissue may lead to additional pain on movement.[112] Maintenance of full range of movement of the neuromuscular unit and preservation of movement of small joints are of importance in the postoperative phase. Intermittent, controlled mobilization in a protected splint is therefore thought to be beneficial for the patient. Most importantly, the nerve grafts should be applied at minimal tension with joints in an extended position and in a manner that allows subsequent full range of motion without causing tension over the repair sites. Surgeons should supervise physiotherapy and occupational therapy, check advancement of Tinel's sign and return of muscle function, which is recovered during rehabilitation.

Postoperative movement training

Dorsal splinting may be maintained for 3 weeks in a manner that allows intermittent early gentle mobilization within a protected range without putting the microsurgical repair at risk or tension. Although some authors have advocated that the nerve should be allowed to rest for 8 days before active and passive mobilization,[33] an earlier start to training may be appropriate within the limits of bandages and restrictive splinting. It is thought that early active movements may reduce the risk of the nerve being tethered in scar tissue,[59,112] which is a possible effect if rigid immobilization is adopted. Elevation of the hand is recommended for the first week postoperatively. Sutures and plaster are usually removed at 3 weeks and active exercises of the fingers can then be initiated. Prolonged protection of the suture line may be recommended up to 6 weeks postoperatively, to avoid extensive extension in the wrist. These general principles apply for digital nerves as well as major nerve trunks and nerve grafts.

Sensory re-education

Cortical reorganization

After an acute nerve transection, the brain must compensate for the loss of sensory input.[113] First, a gross decrease in the number of fibers is seen, as well as a topographical mismatch. A "silent area" is created in the nerve's representational area in the brain. However, adjacent cortical areas expand instantly and occupy this former nerve territory.[114–117] These changes are mediated by the unmasking of normally inhibited synaptic connections in the vicinity of this "silent area", and a reorganization of the somatosensory cortex occurs through processes of brain plasticity. This period is referred to as *phase 1* during rehabilitation – before any reinnervation has occurred in the hand. During this phase some training may be initiated.

Because of the mismatch and misdirection of the regenerating axons that happens at the repair site, areas of skin in the hand and muscles will not be reinnervated by their original axons to a large extent.[118] The original well-organized hand representation in the sensory and motor cortex alters into a distorted and mosaic-like pattern with disappearance of, and overlapping of, fingers.[114] As a result of misdirection and remapping of the representation of the cortical hand, "the hand speaks a new language to the brain" (*phase 2* during rehabilitation). A sensory relearning program that helps the brain to decipher the signals may assist it in interpreting the new language, which works well and improves outcome.[119] Recent data have indicated that it is beneficial for this process to begin when the reorganization in the sensory cortex has already started (phase 1)[116] and that this should not be postponed until touch can be perceived in the hand, as was earlier believed. Effectiveness in the relearning process is probably greatly influenced by the individual motivation of each patient. Coping strategies that are individualized for each patient should be considered, as adaptation to the condition is an evolving process by which the patient's own resources can be used to overcome problems in daily activities.

Sensory re-education in phase 1

During the early postoperative period (phase 1), various "babysitting" methods can be used until the hand becomes reinnervated by the outgrowing axons. Functional similarities exist between perception and imagery (the premotor cortex can be activated by just imagining a movement – so-called "motor imagery"). The corresponding phenomenon for sensory function is "sensor imagery". Imagining the hand being touched activates the same cortical areas as if the hand is really being touched.

Activation of "mirror motor neurons" in the premotor cortex by mere observation of hand motor actions by others plays a fundamental part in action, imitation, and action understanding.[120] Reading or listening to action words related to hand movements activates hand representational areas in the motor cortex and observation of touching a hand activates the corresponding representational areas in the sensory cortex. The patient's observation of the denervated hand being touched is already initiated during the first days postoperatively, which may activate the cortical hand area as a result of visuotactile interaction.[121]

In early sensory training, the multimodality of the brain is activated; the cortical audiotactile interaction is used to activate cortical sensory areas by listening to the sound of touch. A sensor glove, provided with minimicrophones at its fingertips, can be applied to the denervated hand.[122] Active touch of items is associated with a specific "friction sound", depending on the texture touched, which is transmitted to earphones. The patient can "listen to what the hand feels." If the sensor glove is used in the early phase after nerve repair, tactile discrimination may be improved considerably. To conclude, early re-learning, i.e., starting within the first week after a median or an ulnar nerve injury and conventional nerve repair, by using this described guided plasticity seems to have a potential to improve outcome during the first 6 months.[121]

Improving effects of sensory re-education – phase 2

A relearning process is required to adapt to the new and distorted afferent sensory input caused by axonal misdirection when familiar objects are touched. For this purpose, sensory re-education is routinely used in phase 2, when the hand has started to reinnervate, to regain tactile gnosis. Ways of touching, and the capacity to localize touch, are trained, followed by touching and exploration of items, presenting shape and textures of varying and increasing difficulty with eyes open and closed. Vision assists training and improves the deficient sense.

Repeated sessions of cutaneous anesthesia of the forearm increase the effects of sensory re-education and result in expansion of representation of the cortical hand[122] (Fig. 32.33). The hand is given more "brain space", which enables the improved processing of sensory impulses. Repeated application of a cutaneous anesthetic cream (lidocaine/prilocaine: EMLA), combined with intensive sensory re-education, increases the effects of sensory re-education with a considerable improvement in tactile gnosis (functional sensibility) in patients with repaired median nerves.[123,124]

Outcome

Assessment of outcome

Final evaluation of sensory and motor function should not be made until after rehabilitation has finished. Depending on the type of injury, the rehabilitation period may last for 12–24 months postoperatively to allow for reinnervation and sensory re-education,[125] although some authors claim that a follow-up time of at least 3 years is necessary to evaluate the final outcome.[126]

General aspects

Even though extensive amounts of data have been published on the results of nerve repair, there is no consensus on how to evaluate the outcome in a standardized manner. Different protocols for assessing the outcome have been proposed,[125,127–129] but none has been adapted uniformly. The evaluation instrument most widely accepted is the Highet Scale from 1954, adopted by the British Medical Research Council (MRC) (Table 32.4).

The outcome after nerve repair depends on to what extent the regeneration of the axons is successful, and how many of the axons reach their end target. Several factors that influence the results after nerve repair have been documented.

MRC scale

Several modifications of the British Medical Research Council's scale for nerve recovery have been described,[130] and the modification by Dellon *et al.* is probably the most used.[131] The sensory function is evaluated according to how the patient describes levels of recovery (see Table 32.1). Critics claim that

Table 32.4 The Highet Scale from 1954, adopted by the British Medical Research Council

Motor grade	Level of recovery
M0	No recovery
M1	Perceptible contraction in proximal muscles
M2	Perceptible contraction in proximal and distal muscles
M3	Contraction possible against gravity
M4	Contraction possible against resistance
M5	Full recovery in all muscles
Sensory grade	**Level of recovery**
S0	No recovery
S1	Recovery of deep cutaneous sensibility
S1+	Recovery of superficial pain and sensibility
S2	Recovery of superficial pain and some touch
S2+	S2 recovery with hypersensitivity
S3	Recovery of pain and touch without hypersensitivity
S3+	S3 recovery with localization and some two-point discrimination
S4	Complete recovery with normal two-point discrimination

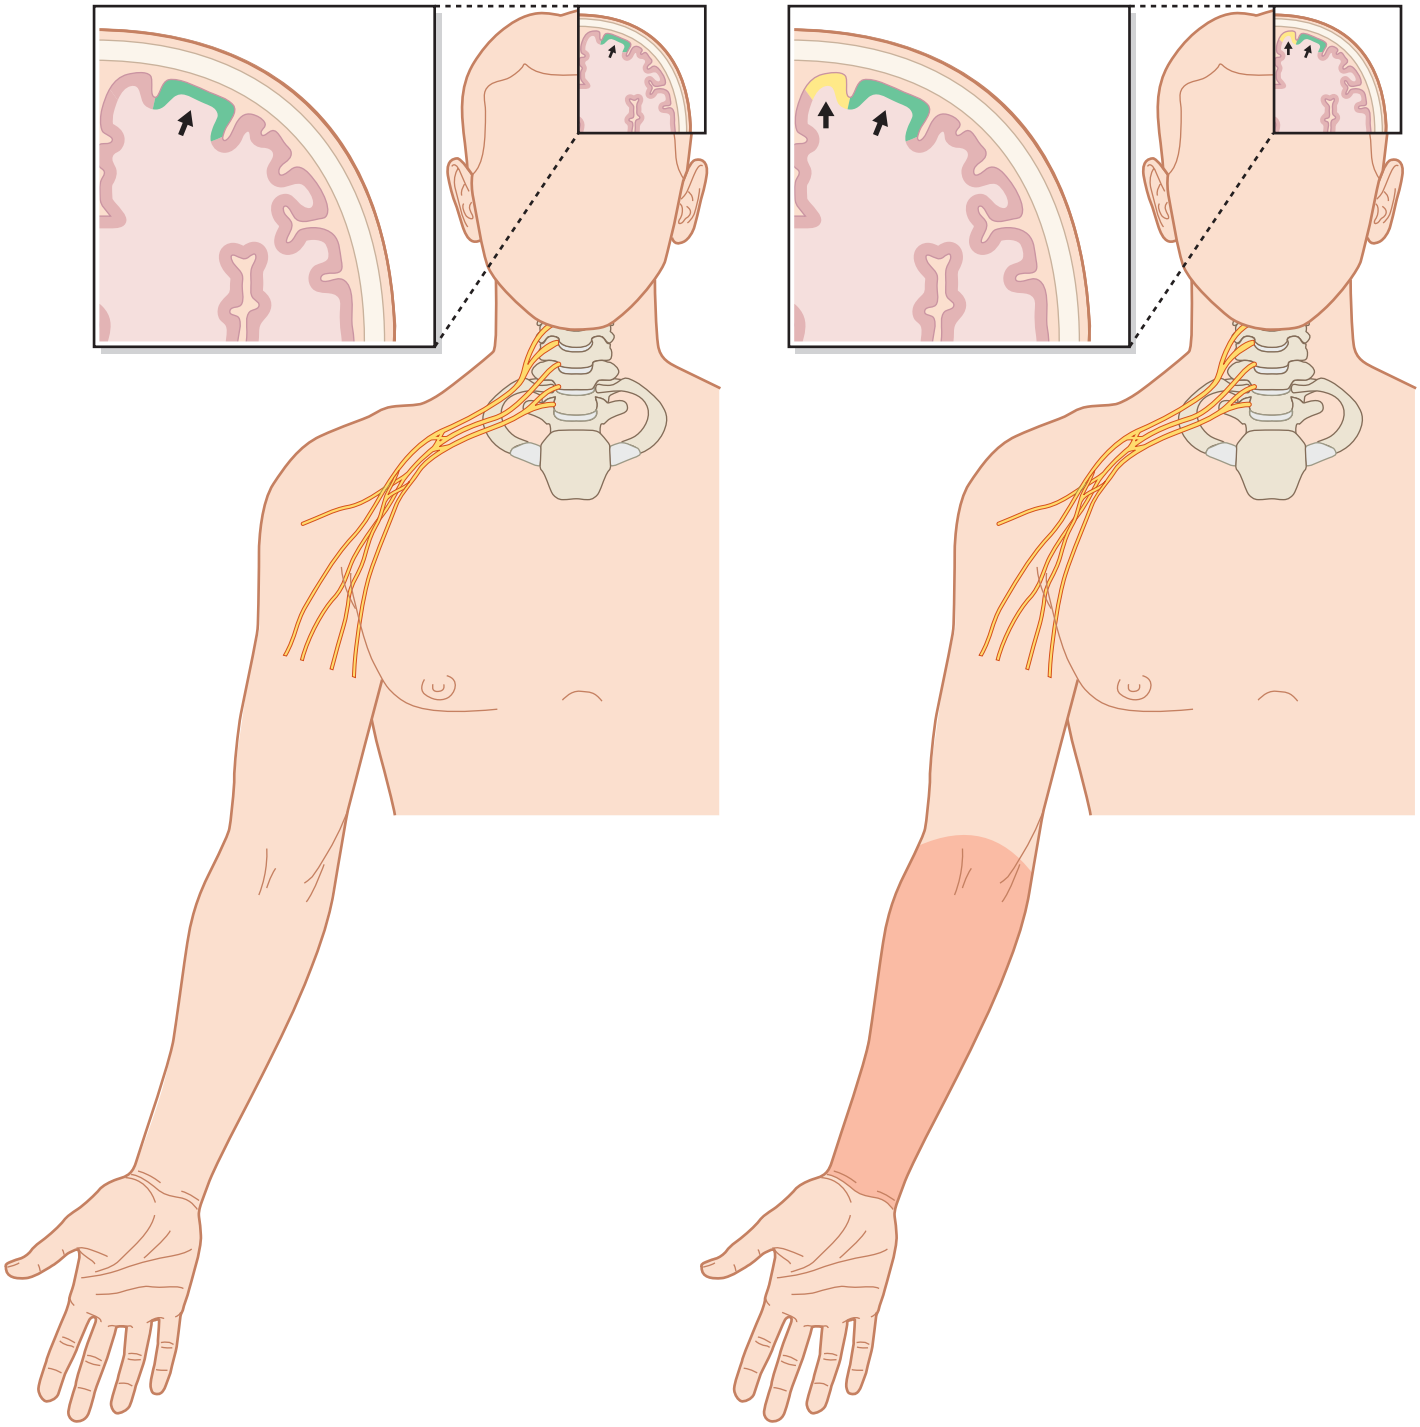

Fig. 32.33 Brain plasticity. Repeated sessions of cutaneous anesthesia of the forearm increase the effects of sensory re-education and result in expansion of representation of the cortical hand. The hand is given more "brain space", which enables the improved processing of sensory impulses.

the MRC scale is based on subjective findings without any attempt to standardize defined methods of evaluation, which complicates our ability to compare different sets of patients as well as results from different observers.

The Rosen score

To enable improved interpretation of patients' functional outcome after nerve repair (median and ulnar nerves), Rosen and Lundborg presented a protocol that illustrated patients' functional limitation in activities of daily living.[128] This protocol is based on previous studies that investigated what methods are most effectively used to study the temporal aspects of the outcome after nerve repair.[125] Three domains of function were described: (1) sensory; (2) motor function; and (3) pain and discomfort. A total score is calculated that correlates significantly with the MRC scale, which was shown in a study of 70 patients who had been treated for

nerve transection at the wrist or distal forearm level. The total score also correlated strongly with the patients' overall estimation of the impact of the injury on activities of daily living.[128]

Factors that affect outcome

General aspects

Ruijs *et al.* presented an excellent meta-analysis of 23 papers based on data from individual patients about motor and sensory recovery after microsurgical repair of the median and ulnar nerves.[125] Prognostic factors that have an impact on outcome varied for motor and sensory recovery. For motor recovery, age, delay before repair, level of injury, and type of injured nerve were important, and for sensory recovery, age and delay before repair were the most important.

Age

In several studies of digital nerve repairs, there was a close positive correlation between the younger age of the patient and the recovery of sensation.[132–134] For more proximal injuries of the median, ulnar, or radial nerves in the forearm, age also seems to be the factor that played the most important part in the outcome. Children (mean age 6 years) that were evaluated a minimum of 1 year after primary repair of injury to the median nerve were all considered to have regained normal function.[135] In comparison, 95 patients (age 15–55 years) with primary or secondary repair, or grafting, of injuries of the median and ulnar nerves[30] showed that only the younger patients who had primary distal repair had excellent results, with normal sensitivity and motor function. These findings are supported by other authors in similar case series.[127,136–138] Patients under 16 years are four times more likely to have satisfactory outcome in motor recovery, and also a significantly increased chance of satisfactory sensory recovery, with lower age.[126]

The superior results in children may, to some extent, be explained by better peripheral nerve regeneration and shorter regeneration distances. However, it is likely that a greater adaptability of the brain is of predominant importance for the functional outcome in children.[139,140] This hypothesis is confirmed by recent data that showed that early sensory re-education programs improve functional outcome in adults because of improvements in training-induced plasticity.[141]

More importantly, in a recent long-term follow-up, the age factor was extensively investigated indicating that children with injured median and ulnar nerves during childhood recovered significantly better than those injured during adolescence.[142] However, in spite of excellent clinical recovery among the children injured during childhood, the electroneurography response was poor,[143] indicating that a better cerebral plasticity is the crucial factor for outcome. Recently, a functional magnetic resonance imaging (fMRI) study showed that the children that had their median nerve injured at the age of 1–13 years had an activation pattern in the brain similar to healthy subjects and that changes in both cerebral hemispheres may explain differences in clinical outcome between children injured during childhood and adolescence.[144]

Digital nerves

In several studies of primary repair of the digital nerves, the results of immediate repair of digital nerves were "normal", "excellent", or "good" in 37–68% of the nerves repaired after a follow-up of 8–32 months.[132–134,145,146] In terms of static two-point discrimination (S2PD), "normal" sensory function has been defined in these studies as the equivalent to the uninjured digit or S2PD of 5 mm or less, whereas "excellent" function has been defined as a S2PD of 7–10 mm. To summarize, after microsurgical repair of a digital nerve injury, about half improve to have normal or fair sensation.

Nerve trunks

The motor outcome of lesions to the larger nerve trunks seems to be dependent on their target organ. This is indicated by the results in a series of 1837 nerve lesions that outcome after repair (primary suture, secondary suture, or graft repair) of the median nerve was superior to the outcome of repair of lesions to the radial nerve, which in turn was better than that after ulnar nerve repair.[147] The better outcome of motor function in median nerves than in ulnar nerves is also supported by others.[126,148,149] Recovery of sensation, on the other hand, has not been shown to differ between the median and ulnar nerves,[126] and combined median and ulnar nerve injuries.[126,150,151] The theoretical explanation may be that the ulnar nerve innervates the delicate intrinsic muscles of the hand, and the demand of an accurate innervation is theoretically greater than that of the median or radial nerves that innervate muscles that do not undertake delicate movements to the same extent. However, it is difficult to compare the outcome after injury to various nerve trunks due to their individual characteristics.

Level of injury

Lesions that are more proximal have a worse outcome than more distal lesions.[138] This may be explained by the fact that a proximal injury induces a more severe impact on the individual neuron, with higher risk of neuronal cell death, and that the axons have to regenerate over a large distance to reach the targets.[152,153]

Type of repair

In a study of 654 lesions of the ulnar nerve, the functional outcome (grade 3 or better) after suture repair (72%) was superior to that after graft repair (67%).[147,154] In the same series, neurolysis was done for patients with ulnar entrapment, and in comparison these patients achieved a functional outcome of grade 3 or better in 92% of the repairs, indicating the importance of preserving the continuity of nerve trunks if possible. A nerve repair therefore achieves better results than a nerve graft.[155]

Type of injury

Injuries with the nerve in continuity have a good prognosis, and so a nerve crush leads to better functional recovery than a transected nerve trunk. However, a transection injury can often be treated by a primary repair, whereas a crush injury, if it does not recover spontaneously, may require a nerve graft, which will lead to an impaired outcome.

Postoperative dysfunction

General aspects

Peripheral nerve injuries often have a dramatic impact on a person's capacity to function adequately, as the functional outcome often fails to reach the level of motor or sensory function present before the injury, at least in adults.[138,156] As most nerve injuries in the upper extremity are seen in young men,[34,157] there is a high probability of disability and subsequent social consequences.[8] The accompanying amount of post-traumatic stress after hand and forearm injuries has been evaluated and shown to be comparable with the psychological distress found among survivors of big disasters.[158] Other symptoms, such as pain, dysesthesia, and cold intolerance,[10] may also affect the outcome, and cause lifelong impairment of hand function. However, patients may have different strategies to cope with their injuries, whether it is a nerve injury or another serious hand injury.[159]

Complex regional pain syndrome

Complex regional pain syndrome (CRPS) is a clinical diagnosis that involves regional pain together with autonomic dysfunction, functional impairment, and atrophy. According to the classification, CRPS type 1 occurs with no evidence of peripheral nerve injury, whereas CRPS type 2 requires known damage to nerve structures. CRPS can be a disabling condition in many cases, and about half of patients with untreated symptoms for more than a year will have extensive residual dysfunction. Cigarette smokers and women are at increased risk of CRPS, and even though it may occur at any age, most patients are around 45 years. During operation, common sites of injury to peripheral nerves that may elicit CRPS are damage to the dorsal branch of the ulnar nerve, the palmar cutaneous branch of the median nerve, and the superficial branch of the radial nerve. However, CRPS may be initiated after any type of nerve injury. The symptoms are pain that is often described as burning or aching, and it is usually induced by a small stimulus that in the normal patient would not result in such a response to pain. It may affect the tissues surrounding the area of injury, or the whole extremity. In addition, there may be some kind of trophic changes, such as edema and stiffness, together with changes of the skin, nails, and hair. The limb may be perceived as different in temperature from the opposite side.

Other

Numbness, weakness, and abnormal pain with or without discoloration after exposure to mild to severe pain can be problematic after peripheral nerve injury.[160–162] In fact, cold intolerance is regarded by many authors as the most disabling symptom after nerve repair or other trauma to the upper extremity.[10,163–165] The mechanism behind hypersensitivity to cold is not known, but its presence has been inversely correlated to sensory recovery.[166–168] In addition, predictors associated with cold intolerance are coexisting injury to major vessels,[167,169,170] crush injury,[170,171] early postoperative pain,[162,172] and the level of the nerve injury.[164]

In a study by Ruijs *et al.* on 107 patients with median or ulnar nerve injury, or a combination of the two, numbness was reported as the most frequent symptom (80%). Other symptoms were stiffness (77%), weakness (72%), pain (63%), change in skin color (50%), and swelling (33%). Most of the patients (59%) were considered to have abnormal cold intolerance. In this group, a larger proportion (70%) had combined ulnar and median nerve injuries, whereas isolated nerve injuries were less common (median nerve 57% and ulnar nerve 56%). Even though there was no difference in sensory recovery between women and men, cold intolerance was more common in women than in men. Importantly, time since injury did not correlate with the presence of cold intolerance (follow-up time 2–10 years).[168] This is also supported by other investigators,[165] indicating that cold intolerance is a stationary condition when the maximum sensory recovery has been achieved.

There is currently no treatment available that is specifically directed against cold intolerance, although possible effects of treatment by Pavlovian conditioning, a behavioral treatment for digital cold sensitivity where whole-body cold exposure becomes associated with warm hands, has been reported recently in patients with hand injuries.[173] In addition, CRPS may be a severely disabling condition that may be treated with substances like gabapentin and pregabalin[174] and other strategies.[175] This poses a pedagogic challenge to the treating physician when addressing the patient's expectations of the final outcome after nerve repair.

Future directions

Nerve injuries, extending from minor digital nerve injuries up to severe injuries to the brachial plexus in the upper extremity as well as less common injuries in the lower extremity, represent one of the most challenging clinical problems for the treating surgeons and physicians. A variety of factors influence outcome and each individual nerve injury is unique in its entity; thus each case also requires consideration of factors such as motivation for rehabilitation and coping strategies of the patient. Efforts to improve diagnostic tools and treatment strategies have to be directed towards all components. In the future, improved imaging techniques, like three-dimensional high-resolution magnetic resonance imaging with diffusion tensor imaging and tractography and pre- and intraoperative high-resolution sonography, may improve the diagnostic accuracy; however, an initial and appropriate basic clinical examination is still the key for early treatment. Proper evaluation systems are needed to examine fully new surgical and rehabilitation techniques, such as the nerve transfers, end-to-side repair and the EMLA concept (see above), respectively. In addition, a continuous search for the secrets of intracellular signaling in neurons, Schwann cells, and other cells may provide the knowledge needed for the introduction of pharmacological treatment, not only of any neuropathic pain, but also to improve regeneration as an adjunct to surgical repair and reconstruction. Hopefully genomic and proteomic development may lead to improved repair and reconstruction strategies, with or without utilization of stem cells in the future.[176]

Acknowledgments

Financial support for this work was received from the Swedish Research Council (MEDICINE). We appreciate all the help from Professor Jørgen Tranum Jensen and his colleagues at the Panum Institute, University of Medicine and Dentistry, Copenhagen, Denmark.

Nerve transfers

Kirsty Usher Boyd, Ida K. Fox, and Susan E. Mackinnon

Access video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Nerve injuries are often devastating, with associated pain and impaired function.
- Motor nerve injuries must be managed expeditiously, because regenerating axons must reach target muscle prior to degeneration and fibrosis – "time is muscle".
- Nerve transfers offer an advantageous method of reconstruction by delivering regenerating nerve fibers to the target end organ more quickly, thus converting a proximal injury to a more distal injury.
- Nerve transfers allow for dissection outside the original zone of injury, providing a safer and more technically straightforward procedure.
- Unlike tendon transfers, the muscle–tendon biomechanical structure is preserved, thus excursion, origin, insertion, and length–tension relationships are undisturbed.
- Nerve transfers require time for the nerve to regenerate and extensive physical therapy for retraining.
- Intraneural dissection is technically demanding, and nerve transfers require intimate knowledge of nerve topography.

Key points

- Nerve transfers are a relatively recent development in peripheral nerve surgery.
- Nerve transfers can be performed to restore sensory or motor deficits.
- Nerve transfers essentially convert a proximal injury to a distal injury, providing a source of regenerating axons in close proximity to the end target.
- Nerve transfers are associated with minimal to no downgrade in donor function.
- Nerve transfers preserve the original biomechanical muscle–tendon relationship.
- Nerve transfers may provide superior results to tendon transfer, with the ability to restore individual and separate muscle function.
- Nerve transfers are replacing other techniques as the gold standard for brachial plexus and other peripheral nerve injury in the authors' practice.
- New applications of nerve transfers to pediatrics, lower extremity injury, partial injury (through supercharging or other end-to-side techniques), and central nervous system disorders (spinal cord injury and transverse myelitis) are exciting.

Introduction

While peripheral nerve reconstruction is an evolving field, nerve transfers have become a more broadly accepted reconstructive option.[1–3] As our understanding of internal nerve topography improves, we are able to recognize redundant or non-essential potential donor nerves and fascicles. Recent contributions in basic science are broadening options for nerve transfer with new and improved techniques. Clinical research focusing on outcomes, applications to novel populations, and areas of debate continue to advance the field. This chapter will outline the history and principles of nerve transfers as they pertain to upper extremity nerve reconstruction. The recent literature as it relates to current techniques, debates, and advances in nerve transfers will be reviewed. Current commonly performed nerve transfers are detailed with focus on both motor and sensory nerve transfers, their indications, rehabilitation and postoperative protocols, and a basic overview of selected surgical techniques[4] (see key points, above).

Table 33.1 appears online only.

Historical perspective

The classification of nerve injury is perhaps the single most important factor when determining management (Table 33.1). The six degrees of nerve injury have been well described. First- and second-degree injuries recover spontaneously, as do third-degree, albeit recovery is variable and less than normal, depending on scar tissue. Fourth- and fifth-degree injuries are significant and recovery is not expected. These injuries should be managed with prompt surgical intervention to prevent degeneration and fibrosis of the motor end plates. Sixth-degree injuries encompass a variety of nerve injuries within a single nerve, and the need to operate is determined on an individual basis.

Table 33.1 **Classification of nerve injury highlighting the six degrees of nerve injury and the anticipated rate and likelihood of recovery**

Degree of injury		Tinel's sign present	Recovery	Rate of recovery	Surgical procedure
I	Neurapraxia	No	Complete	Up to 12 weeks	None
II	Axonotmesis	Yes	Complete	1* per month	None
III		Yes	Varies*	1* per month	None or neurolysis
IV	Neuroma-in-continuity	Yes, but no advancement	None	None	Nerve repair, graft, or transfer
V	Neurotmesis	Yes, but no advancement	None	None	Nerve repair, graft, or transfer
VI	Mixed injury (I–V)	Some fascicles (II, III)	Some fascicles (II, III)	Depends on degree of injury (I–V)	Neurolysis, nerve repair, graft, or transfer

*Recovery can vary from excellent to poor depending on the amount of scarring and the sensory versus motor axon misdirection to target receptors.

Once surgical intervention has been deemed necessary, there are a number of surgical options. Traditionally nerve repair or grafting was used with tendon transfers to augment poor recovery or delayed presentation. The difficulty with proximal nerve injuries is that the distance from the injury to the motor end plate is significant, and recovery is prolonged. In addition, delayed intervention may result in denervation and fibrosis prior to muscle reinnervation. Axonal regeneration has been shown to occur at the rate of approximately 1 inch (2.5 cm) per month and reinnervation of denervated muscle is not possible after 12–18 months; therefore nerve transfers offer a valuable means of providing regenerating axons in closer proximity to the motor end plate. Essentially, a nerve transfer converts a proximal nerve injury to a distal one, enabling faster recovery and quicker return to function.

$$\text{Function} \propto \frac{\text{Number of nerve fibers}}{\text{Time of denervation}}$$

Nerve transfers were described very early; however they were traditionally reserved for otherwise unsalvageable root avulsions and proximal pan-plexus injuries. Approximately 20 years ago, nerve transfers were revisited and applied to a significantly broader patient population, with applications in partial plexus injuries to recreate specific essential functions in the upper extremity.[5–7] As our understanding of internal nerve topography has broadened, techniques and equipment for performing microsurgery have improved, and our diagnostic ability for brachial plexus and peripheral nerve injury has progressed, the field of nerve transfers has exploded. Nerve transfers have become the standard of care for treatment of peripheral nerve injuries in the authors' practice, and have largely replaced other modalities.

Basic science

There have been dramatic increases in our knowledge of nerve injury, healing, and regeneration. The majority will be touched on in Volume 1, Chapter 22, and Chapter 32 of this volume. The most relevant recent basic science advances pertaining to nerve transfers relate to end-to-side transfers (Fig. 33.1). End-to-side neurorrhaphy involves the coaptation of the distal end of an injured recipient nerve into the lateral aspect of an intact nerve, which serves as a proximal source of axons to regenerate into the injured nerve. Reports of end-to-side transfers occurred as early as the late 1800s and then made a resurgence in the 1990s. There has, however, been controversy regarding the success of these transfers, and sensory recovery has typically been more impressive than motor recovery. The sprouting of axons in an end-to-side coaptation, thus eliminating the need for a proximal nerve stump, makes nerve transfers an option for proximal nerve injuries and has been well demonstrated in the literature.[8,9] While sensory nerves are able to sprout spontaneously (collateral sprouting), donor nerve axonotmetic injury is required for motor neuronal regeneration (regenerative sprouting) across the end-to-side repair (Fig. 33.2).[8] An epineurotomy in the donor nerve is required, and partial axotomy will result in more significant regenerative sprouting into the recipient nerve, albeit at the potential expense of a measurable downgrade in donor nerve function.

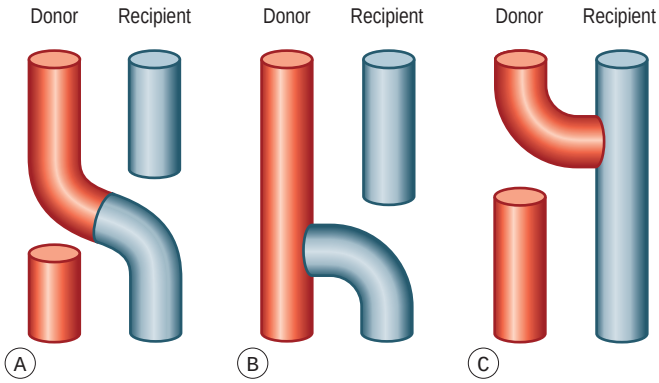

Fig. 33.1 The various options for coaptation in nerve transfer. **(A)** End-to-end coaptation between the donor nerve (red) and the recipient nerve (blue). **(B)** End-to-side coaptation, where the distal end of the divided recipient nerve (blue) is transferred to the side of the intact donor nerve (red). In this transfer, fascicles from the donor will "sprout" into the distal donor nerve. The recipient nerve essentially "pulls" the donor fascicles into the distal nerve. **(C)** Reverse end-to-side coaptation. In this transfer, the donor nerve (red) has been divided and transferred to the side of the intact recipient nerve (blue). The donor essentially "pushes" regenerating fascicles into the distal donor nerve. *(© Washington University in St. Louis.)*

Reverse end-to-side nerve transfers involve the complete transection of the donor nerve, which is then coapted into the side of the intact recipient nerve. This maximizes the potential number of available motor axons from the donor nerve. This procedure does not interrupt any recovery in the injured recipient nerve because the nerve remains in continuity; however the additional axons recruited from the donor nerve improve distal target reinnervation, a concept

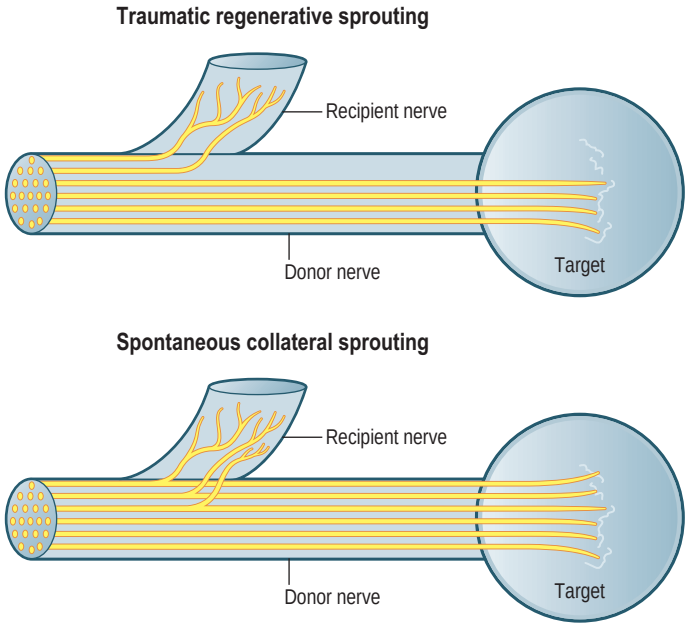

Fig. 33.2 The difference between regenerative and collateral sprouting. Traumatic regenerative sprouting occurs following injury to the proximal nerve. The damaged axons degenerate and then regenerate at the rate of 1 mm/day into the distal recipient nerve. Collateral sprouting occurs spontaneously, and does not require proximal nerve injury. Axons from the donor nerve simply sprout into the distal end of the recipient nerve. Only sensory nerves will undergo spontaneous collateral sprouting. Motor nerves require an axonotmetic injury to facilitate regenerative sprouting. *(© Washington University in St. Louis.)*

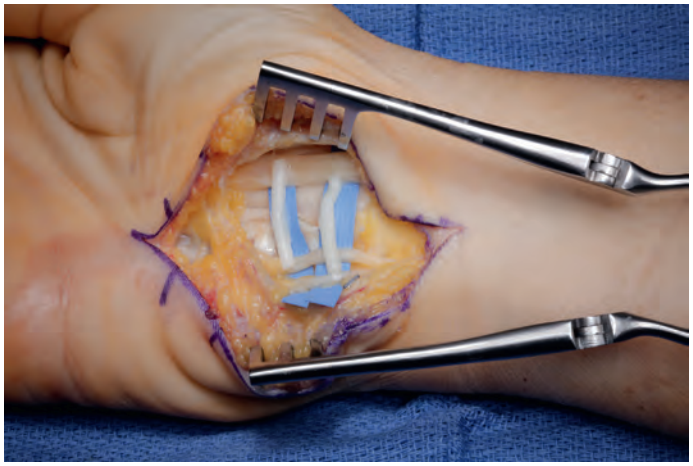

Fig. 33.3 A 62-year-old woman presented with ulnar nerve dysfunction. After an extended period of hand-intensive activity, she noted the onset of ulnar nerve distribution numbness and pain. She had subsequent weakness of extrinsic and absent intrinsic ulnar motor function. Electrodiagnostic testing revealed complete denervation without evidence of reinnervation at the intrinsic muscles. Nerve decompression and transposition at the elbow and decompression at the wrist was performed. Due to the significant distal abnormalities without evidence of recovery (at 3 months after onset of symptoms), side-to-side transfers were performed to restore and/or augment both motor and sensory function. This image depicts the intraoperative dissection of the distal median and ulnar nerves. The recipient ulnar nerve has been decompressed at Guyon's canal and is in continuity. The donor median nerve has been exposed at the upper aspect of the photo. Bridging acellularized allograft material is inlaid to provide side-to-side or "cross-grafting" reinnervation from the donor functional median nerve to the recipient non-functional sensory ulnar nerve branches. An additional coaptation of the pronator quadratus branch of the anterior interosseous nerve to the deep motor branch of the ulnar nerve in supercharge end-to-side fashion was also completed. This will provide an additional modicum of reinnervation as the ulnar nerve proper also, hopefully, recovers. *(© 2015 nervesurgery.wustl.edu.)*

known as "supercharging".[10] In a proximal partial nerve injury, with a long distance required for reinnervation, this technique can protect target muscles from denervation atrophy and fibrosis.[9,10] Clinically, the most relevant place to consider this strategy is for preservation of intrinsic hand function in proximal severe ulnar neuropathy with use of the end-to-side distal anterior interosseous (branch to pronator quadratus) to deep motor branch of ulnar nerve end-to-side coaptation.[10]

More recently, work on side-to-side, "cross-grafting" nerve transfers in animal models has also been completed and shows some role for preservation and protection of the denervated end organ (Fig. 33.3).[11] These strategies, however, remain under debate and deserve continued laboratory study and clinical evaluation.

Hints and tips

The end-to-side transfer can be considered as the recipient nerve "pulling" regenerating axons out of the intact donor, whereas the reverse end-to-side "supercharge" transfer can be considered as the donor nerve "pushing" regenerating axons out into the intact recipient.[11]

Diagnosis and patient presentation

The value of a complete history and physical examination in the patient with a potential brachial plexus or proximal nerve injury of the upper extremity cannot be overstated. Patients should be evaluated promptly after injury, both to provide a baseline for future serial examinations and to facilitate timing of surgical intervention where necessary.

Patient history

On history, details of the mechanism and timing of injury are crucial. When seeing a patient in a delayed fashion, it is also useful to ascertain any interval recovery of function. The mechanism of injury will determine timing of intervention, with prompt exploration of penetrating sharp trauma, and more expectant management of closed injuries and gunshot wounds. Specific patient symptoms such as loss of function, both sensory and motor, and pain should be precisely elicited, as this will help focus the subsequent physical examination. The pain diagram and questionnaire are particularly useful for eliciting this information (Fig. 33.4). Other factors, such as patient age, handedness, occupation, and comorbidities, will factor into management decisions. Attention to patient goals and expectations allows for individually tailored and nuanced approaches that may or may not involve nerve transfer surgery techniques, which form "a part of the armamentarium"[12] when caring for patients with complex upper extremity injury. Further information on steadily improving quality of life and other gradual but continuing changes over time after nerve transfer in brachial plexus injury patients may further influence treatment choices and patient preference-specific choices.[13]

Physical examination

A complete physical examination of the upper extremity includes assessment of sensory and motor function, joint suppleness, range of motion, and a functional assessment with attention paid to adaptive strategies and use patterns. Particularly in patients with late presentation, the presence of fixed joint contractures may preclude functional recovery. Perfusion, bony pathology, presence of edema, scar, previous incisions, and other soft-tissue trauma are factors that influence treatment choices.

Function should be graded at each joint. Manual muscle testing and examination by direct palpation is imperative for assessing the presence of redundant function when checking for expendable donor muscles. Shoulder function should be assessed by examining deltoid, supraspinatus, infraspinatus, trapezius, latissimus dorsi, serratus anterior, and pectoralis major. The patient's ability to abduct/adduct, flex/extend, and internally/externally rotate must be assessed. The elbow should also be assessed for flexion and extension. Here it is important to differentiate between flexion secondary to biceps brachii and brachialis (musculocutaneous nerve) and brachioradialis (radial nerve). The forearm and wrist should be assessed for flexion/extension and pronation/supination. Palpation of the individual tendons with wrist flexion is essential to determine which nerves are involved, as well as

Pain Questionnaire

Name: _____ Date: _____

Age: ____ Sex: Male ____ Female ____ Dominant Hand: Right ____ Left ____ Diagnosis: _____

1. Pain is difficult to describe. Circle the words that best describe your symptoms:

Burning	Throbbing	Aching	Stabbing	Tingling	Twisting	Squeezing
Cramping	Cutting	Shooting	Numbing	Vague	Stinging	Indescribable
Pulling	Smarting	Pressure	Coldness	Dull	Other:	

Level of symptoms: place a mark through the line to indicate the level of your pain, if zero is no pain and the end of the line is the most severe pain you can imagine having.

2. Mark your average level of pain in the last month

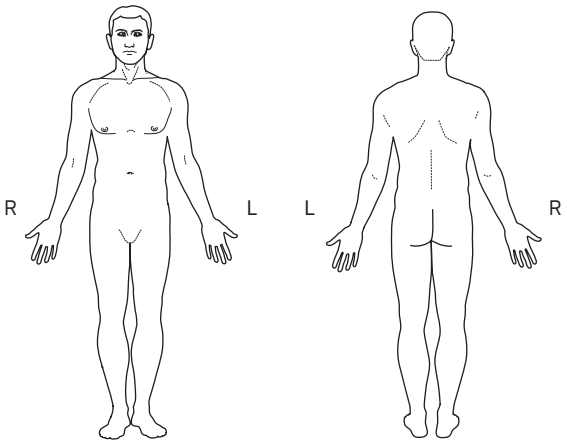
No pain — Most severe pain

3. Mark your worst level of pain in the last week

Right: No pain — Most severe pain

Left: No pain — Most severe pain

4. Where is your pain? (Draw on diagram)



Mark on this scale how your pain has affected your quality of life:

0% Very little — 100% A large amount

Mark on this scale how depressed you currently feel:

0% Not at all — 100% A large amount

Ⓐ

Fig. 33.4 The pain questionnaire is a valuable tool for qualifying and quantifying patient pain and the impact their injury is having on their life. This has uses both in obtaining baseline information, and also in tracking progress as patients recover. This questionnaire is filled out by every nerve patient at each office visit.

Continued

5. Mark your average level of stress in the last month?

At home 0 ⌊——————————————————⌋ 10

At work 0 ⌊——————————————————⌋ 10

6. How well are you able to cope with that stress?

At home Very well ⌊——————————————————⌋ Not at all

At work Very well ⌊——————————————————⌋ Not at all

7. How did the pain that you are now experiencing occur?

a. Sudden onset with accident or definable event
b. Slow progressive onset
c. Slow progressive onset with acute exacerbation without an accident or definable event
d. A sudden onset without an accident or definable event

8. How many surgical procedures have you had <u>in order to try to eliminate the cause of your pain?</u>

a. None or one
b. Two surgical procedures
c. Three or four surgical procedures
d. Greater than four surgical procedures

9. Does movement have any effect on your pain?

a. The pain is always worsened by use or movement
b. The pain is usually worsened by use and movement
c. The pain is not altered by use and movement

10. Does weather have any effect on your pain?

a. The pain is usually worse with damp or cold weather
b. The pain is occasionally worse with damp or cold weather
c. Damp or cold weather have no effect on the pain

Ⓑ

Fig. 33.4, cont'd

11. Do you ever have trouble falling asleep or awakening from sleep?
    a. No – Proceed to Question 12 b. Yes – Proceed to 11A & 11B

11A. How often do you have trouble falling asleep?
    a. Trouble falling asleep every night due to pain
    b. Trouble falling asleep due to pain most nights of the week
    c. Occasionally having difficulty falling asleep due to pain
    d. No trouble falling asleep due to pain
    e. Trouble falling asleep which is not related to pain

11B. How often do you awaken from sleep?
    a. Awakened by pain every night
    b. Awakened from sleep by pain more than 3 times per week
    c. Not usually awakened from sleep by pain
    d. Restless sleep or early morning awakening with or without being able to return to sleep, both unrelated to pain

12. Has your pain affected your intimate personal relationships?
    a. No b. Yes

13. Are you involved in any legal action regarding your physical complaint?
    a. No b. Yes

14. Is this a Workers' Compensation case?
    a. No b. Yes

15. Are you receiving or have you ever received psychiatric/psychological treatment?
    a. No b. Presently receiving psychiatric treatment c. Previous psychiatric treatment

16. Have you ever thought of suicide?
    a. No b. Yes c. Previous suicide attempts

17. Have you been a victim of emotional abuse?
    a. No b. Yes c. No comment

18. Have you been a victim of physical abuse?
    a. No b. Yes c. No comment

19. Have you been a victim of sexual abuse?
    a. No b. Yes c. No comment

20. Are you presently a victim of abuse?
    a. No b. Yes c. No comment

21. If you are retired, a student or homemaker, proceed to Question 21B

21A. Are you still working?

a. Work every day at the same pre-pain job
b. Work every day but the job is not the same as the pre-pain job, with reduced responsibility or physical activity
c. Work occasionally
d. Not presently working

21B. Are you able to do your household chores?

a. Do same level of household activities without discomfort
b. Do same level of household chores with discomfort
c. Do a reduced amount of household chores
d. Most household chores are now performed by others

22. What medications have you used in the past month?

a. No medications
b. List medications: _____

_____

_____

23. If you had three wishes for anything in the world, what would you wish for?

a. _____

b. _____

c. _____

Fig. 33.4, cont'd

the level and degree of injury and the availability of branches (flexor carpi ulnaris, flexor carpi palmaris, palmaris longus) for use as donor nerves. In the hand, a complete examination of extrinsic and intrinsic function again helps to delineate the level of injury.

Assessment of muscles and grouping the exam by peripheral nerve branch and/or by cervical root level pattern may be helpful, depending on the appropriate clinical scenario.

Sensation should be examined by both dermatome and peripheral nerve distribution, and can be helpful in distinguishing these injuries. The authors advocate the use of both two-point discrimination and the ten-test to evaluate sensory loss in the hand.[14] A Tinel's sign, the tingling sensation elicited with percussion over a regenerating nerve, will help to localize the level of nerve injury, and may also be followed on serial clinical examination to check for signs of advancement, indicating spontaneous recovery. An advancing Tinel's sign distal to the site of injury quite often precedes clinical motor recovery.

For completeness, the presence of Horner's syndrome and dysfunction of nerve branches that come off the proximal brachial plexus (dorsal scapular nerve to rhomboids, long thoracic nerve to serratus anterior) indicate a very proximal level of injury.

One of the most important components of the physical examination is the simple determination of what is functioning, and what function has been lost. Not only does this help to determine the level of injury, it can guide future surgical planning. In the presence of an injury requiring surgical intervention, it is important to examine the patient for putative nerve donors, both intraplexal and extraplexal (spinal accessory, medial pectoral, and thoracodorsal).

Hints and tips

Remember to check not only for what muscles have lost function, but also for potential nerve transfer donors.

Imaging

Imaging is primarily useful for confirming level of injury in more complex closed-mechanism nerve injury patients. For example, imaging such as computed tomography myelogram and magnetic resonance imaging provides additional confirmation of a nerve root avulsion pattern. Additional X-rays, such as shoulder films that demonstrate scapular notch-level trauma, may provide information of localized trauma that would make proximal transfer to the suprascapular nerve ineffective due to the extensive zone of injury. Other plain films such as chest X-ray might be used to evaluate pathology such as rib fractures or diaphragm dysfunction that might make the use of intercostal and phrenic nerves as donor nerves less palatable, although the former is debatable.[15]

Electrodiagnostic testing

Electrodiagnostic testing, performed by an experienced person, can be a useful adjunct to physical examination for serial assessment of reinnervation in closed nerve injuries. Electromyography records the electrical activity of muscle fibers, tested both at rest and activity, by the insertion of needles into the muscle. Denervated muscles will demonstrated fibrillations and positive sharp waves on needle insertion; however, the findings are not reliable until approximately 4 weeks after injury.[16] Initial electrodiagnostic testing should be deferred until a minimum of 6–8 weeks post-injury to assess for signs of both axonal injury and root-level avulsion. Serial testing will reveal signs of reinnervation with nascent potential and motor unit potentials in the affected muscle groups, often prior to clinical evidence of recovery.

Detailed testing of both putative functioning donors and non-functioning recipient muscles is important to confirm physical exam findings. This is particularly important because subtle abnormalities in donor muscles correlate with subsequent clinical results. In fact, abnormalities seen in the putative donor muscles may dictate a change to a different donor, if available, or an understanding that results may be detrimentally affected.

Conduction velocity is used to measure the integrity of a peripheral nerve (sensory nerve action potentials [SNAP] or compound motor action potentials [CMAP]).[16] A severed nerve will lose the ability to conduct a signal as Wallerian degeneration occurs; however, if measured too early, the distal aspect of the nerve will still conduct, leading to an inaccurate assessment. This is another reason for delaying initial electrodiagnostic studies. Preganglionic injuries will be associated with a loss of sensation but an intact SNAP and an absent CMAP.[16] Thus the level of injury can be confirmed with electrodiagnostic studies.

In patients with no evidence of recovery 3 months after a closed nerve injury, the balance should tilt towards consideration of surgical intervention.

Hints and tips

Order baseline electrodiagnostic studies at 6–8 weeks and subsequent testing as indicated by the injury:

- Electromyography (EMG) showing fibrillations (fibs) and positive sharp waves (PSW) suggest denervation. Motor unit potentials (MUP) and nascent units suggest reinnervation.
- Do not be confused by automated EMG reporting errors – "normal" may appear in some reports by default. If a muscle has fibs and PSWs but the MUP column says "normal" this may be a machine printout error – consult with your electrodiagnostician as it more likely that there are *absent* MUPS (not "normal" MUPS).
- When assessing for recovery over time, ask to check proximal muscles first (example flexor carpi ulnaris not first dorsal interosseous, when evaluating ulnar nerve recovery).
- Remember, the EMG provides qualitative information only (not quantitative).
- Above all, careful communication with the electrodiagnostician and correlation to clinical exam findings are imperative when interpreting these test results.

Overall, the complete picture, including history, physical examination, and adjunct testing, should facilitate surgical decision-making. Appropriate treatment for open injuries with nerve dysfunction begs for timely management with surgery on an urgent or semi-urgent basis. For these injuries, direct exploration and repair have historically been the

treatment of choice, but in very proximal injuries, distal nerve transfer can allow for more timely and successful reinnervation. In closed nerve injuries or in gunshot wounds, appropriate management demands a more measured approach and surgery should be delayed to allow for spontaneous recovery, which is often superior to that seen in patients treated with hasty surgery. These patients in particular may benefit from "supercharging" with reverse end-to-side nerve transfer procedures, which can more quickly deliver regenerating axons to the appropriate end organ, while still allowing slower spontaneous recovery.[10]

Patient selection

Hints and tips

When considering nerve transfers, be aware of the various advantages, disadvantages, and limitations:

- Nerve transfers may allow for an unprecedented level of timely and biomechanically appropriate return of function.
- A single donor nerve (from one muscle) can provide individual and isolated muscle function to more than one recipient through motor re-education and cortical adaptation.
- It will take months to years for maximal function to be achieved after nerve transfer (time for regeneration, relearning and strengthening) but function can continue to improve over years post-surgery.
- A distal nerve transfer will not directly address pain from a proximal neuroma or neuroma-in-continuity.
- No transfer, no matter how close to the target, can restore function after terminal muscle denervation has occurred (that deadline occurs somewhere between 12–18 months after nerve injury).

Nerve transfers have become increasingly popular for a number of reasons, the most compelling of which is the "time is muscle" issue. The biggest challenge facing peripheral nerve surgeons is that with increasing time since injury, the ability to achieve good motor function becomes increasingly limited. In fact, for any nerve injury where there is complete discontinuity with the motor end organ, no reinnervation procedure will be able to restore muscle once denervation and fibrosis have occurred, a process which occurs as early as 1 year. Nerve transfers, by bringing the regenerating motor fibers closer to the target end organ more rapidly, essentially convert a more proximal-level injury to a more distal-level injury, thus increasing the chance of achieving meaningful muscle function.

Another advantage of nerve transfers is that they enable surgical reconstruction outside the zone of the original injury, avoiding complex dissections and limiting injury to critical neurovascular structures. In patients with brachial plexus trauma, the proximity of vital structures (great vessels, thoracic duct, lung) makes the occurrence of potentially life-threatening complications a real possibility. In other cases, such as concomitant vascular injury, previous blast injury, or soft-tissue deficits requiring flap reconstruction, the ability to avoid doing a complex nerve exploration in the setting of dense fibrotic scar is particularly advantageous.

Nerve transfers allow for a very targeted intervention in cases of partial nerve injury such as in treatment of a sixth-degree or neuroma-in-continuity injury, where transfer can be done distal to the site of injury specifically to the non-functioning nerve branch. This allows for preservation of all intact function and restoration of only missing function. In addition, the ability to "supercharge" a recovering nerve is invaluable when it is unclear whether the nerve transfer or intrinsic recovery will be more beneficial.

Unlike tendon transfers, nerve transfers typically do not require immobilization, which is especially valuable in patients presenting with significant baseline stiffness. Nerve transfers also preserve the biomechanical properties of the musculotendinous unit, such as end organ origin, insertion, excursion, and length–tension relationships. Finally, nerve transfers can restore unique function such as pronation, which is incredibly difficult to restore by traditional surgical techniques.[17]

Thus nerve transfers are indicated in a number of situations (Table 33.2), for example, in proximal brachial plexus injury where grafting is not possible or the required distance for reinnervation will not allow motor axons to reach the target motor before denervation and fibrosis have occurred. In situations of extreme scarring, or major upper extremity trauma, a nerve transfer is preferable to risking damage to critical structures within the scarred region. Nerve transfers are also indicated in segmental nerve loss, and in partial nerve injury patterns with functional loss. Patients presenting in a delayed manner with inadequate time to reinnervate the distal targets are good candidates for distal nerve transfers. Also, patients with sensory nerve deficits in critical regions should be considered for nerve transfer to restore sensation.

The main reason a nerve transfer should not be performed is similar to the contraindication for any other traditional nerve repair/graft intervention, namely end organ unresponsiveness. An old peripheral nerve injury will not respond to the new "magic" of nerve transfers. Muscle that is in complete discontinuity with the nerve for greater than 1 year will not be reinnervated, no matter how elaborate the reinnervation strategy employed.

More relative contraindications for nerve transfer include issues such as the time required for regeneration, challenges of the surgery, the anatomic knowledge required, and problems of postoperative retraining and therapy, as these techniques are less familiar to hand therapists. There are some patients, such as the young manual laborer with a radial nerve

Table 33.2 Indications for nerve transfer

- Proximal brachial plexus injuries where grafting is not possible
- Proximal peripheral nerve injuries requiring long distance for reinnervation of distal targets
- Severely scarred areas with risk of damage to critical structures
- Segmental nerve loss
- Major upper extremity trauma4dc
- Partial nerve injuries with functional loss
- Delayed presentation with inadequate time for reinnervation of distal targets with grafting
- Sensory nerve deficits in critical regions

injury, who may prefer the more rapid recovery associated with tendon transfer at the expense of the independent fine motor control that could be achieved through the use of nerve transfers. The surgery itself is challenging because of the detailed knowledge of internal nerve topography required. Most surgeons are not formally trained in the intraneural dissection techniques required to perform nerve transfers and the results are not apparent until months down the line. This requires a significant leap of faith for surgeons who are more used to immediate gratification and a clear result in weeks, not months or years!

Direct nerve repair and nerve grafting also remain valuable tools for the peripheral nerve surgeon and should continue to be the treatment of choice in a variety of scenarios. These include cases of multiple nerve injuries where there is a paucity of nerve donor material for nerve transfer. Also, in distal single-function nerve injuries, direct or graft repair is preferable to nerve transfer because one-to-one function is preserved, no retraining is necessary, no donor function is sacrificed, and the distance to the end target is short.

Patient general health, comorbidities, and associated injuries factor into the decision to perform nerve transfers. These procedures can be lengthy, and are not without significant risk from anesthesia in the fragile patient. In addition, patient compliance is an integral part of the recovery process, and patients require education preoperatively about the prolonged recovery and therapy times associated with nerve transfer.

Examples of nerve transfer procedures for specific injury patterns

Hints and tips

- Avoid paralytics, or use only short-term paralytics with anesthesia induction to allow for nerve stimulation.
- Minimize or avoid tourniquet time to avoid interference with nerve stimulation.
- Use plain epinephrine in proximal incisions to minimize blood loss without lidocaine paralysis.
- Obtain wide surgical exposure to identify nerves and appropriate branches.
- Choice of optimal nerve donor is based on quantity of motor axons, proximity to target muscles, synergy of muscle function, and donor expendability.
- Conduct neurolysis with your "eyes", except at the site of actual transfer, to avoid prolonged dissection and increased trauma to nerve branches.
- Confirm no intraoperative stimulation in putative recipient before dividing donor.
- Divide donor nerve distally and recipient nerve proximally.
- Use 9-0 nylon and the operating microscope to perform tension-free epineurial repair.
- Use bupivacaine block at end of case for postoperative pain control.

Upper plexus injury

Specific patient exam findings

Patients with upper plexus injuries present with glenohumeral joint subluxation, loss of shoulder abduction and external rotation, and absent elbow flexion. When C7 is also involved, additional deficits in function may include loss of elbow extension and weakness of wrist and digit extension. Numbness over the corresponding dermatomes is noted.

Reconstruction techniques

Hints and tips

Priorities for upper plexus injuries include restoration of shoulder external rotation and abduction, as well as elbow flexion. Standard transfers include: (1) spinal accessory to suprascapular nerve; (2) medial triceps to axillary nerve; and (3) double fascicular nerve transfer.

Use of spinal accessory nerve (cranial nerve XI) to suprascapular nerve transfer (motor)

Restoration of shoulder stability and external rotation are facilitated by transferring the spinal accessory nerve (cranial nerve XI) to the suprascapular nerve. This transfer can be conducted by either an anterior or a posterior approach. In the posterior approach, the patient is positioned prone and surface landmarks are used to approximate the position of the nerves (Fig. 33.5A–D). The spinal accessory nerve runs parallel to the border of the trapezius and is localized 44% of the way along a line connecting the acromion to the dorsal midline at the level of the superior border of the scapula (Fig. 33.6). The suprascapular nerve is located midway between the medial border of the scapula and the acromion as it runs through the suprascapular notch.[18] Dissection is carried through the trapezius in a muscle-splitting fashion and an end-to-end coaptation, sparing the upper trapezius nerve branches.

For the anterior approach, a supraclavicular incision is made; the lateral aspect of the trapezius is released off of the clavicle and the spinal accessory nerve is identified on its anterior surface (Fig. 33.7). The suprascapular nerve sits at the superolateral aspect of the upper trunk, which is identified between the anterior and middle scalene muscles. An end-to-side approach with a partial neurectomy of the donor accessory nerve is preferred as this preserves some donor function. A short interpositional graft from the recipient suprascapular nerve to the donor spinal accessory nerve is required to avoid tension. A proximal crush injury to the donor nerve encourages axonal sprouting such that regeneration into the recipient suprascapular nerve occurs without loss of significant donor nerve trapezius function.[19]

Use of triceps to axillary nerve transfer (motor component)

Additional abduction of the shoulder is provided by transferring a branch of the triceps, usually from the medial head, to

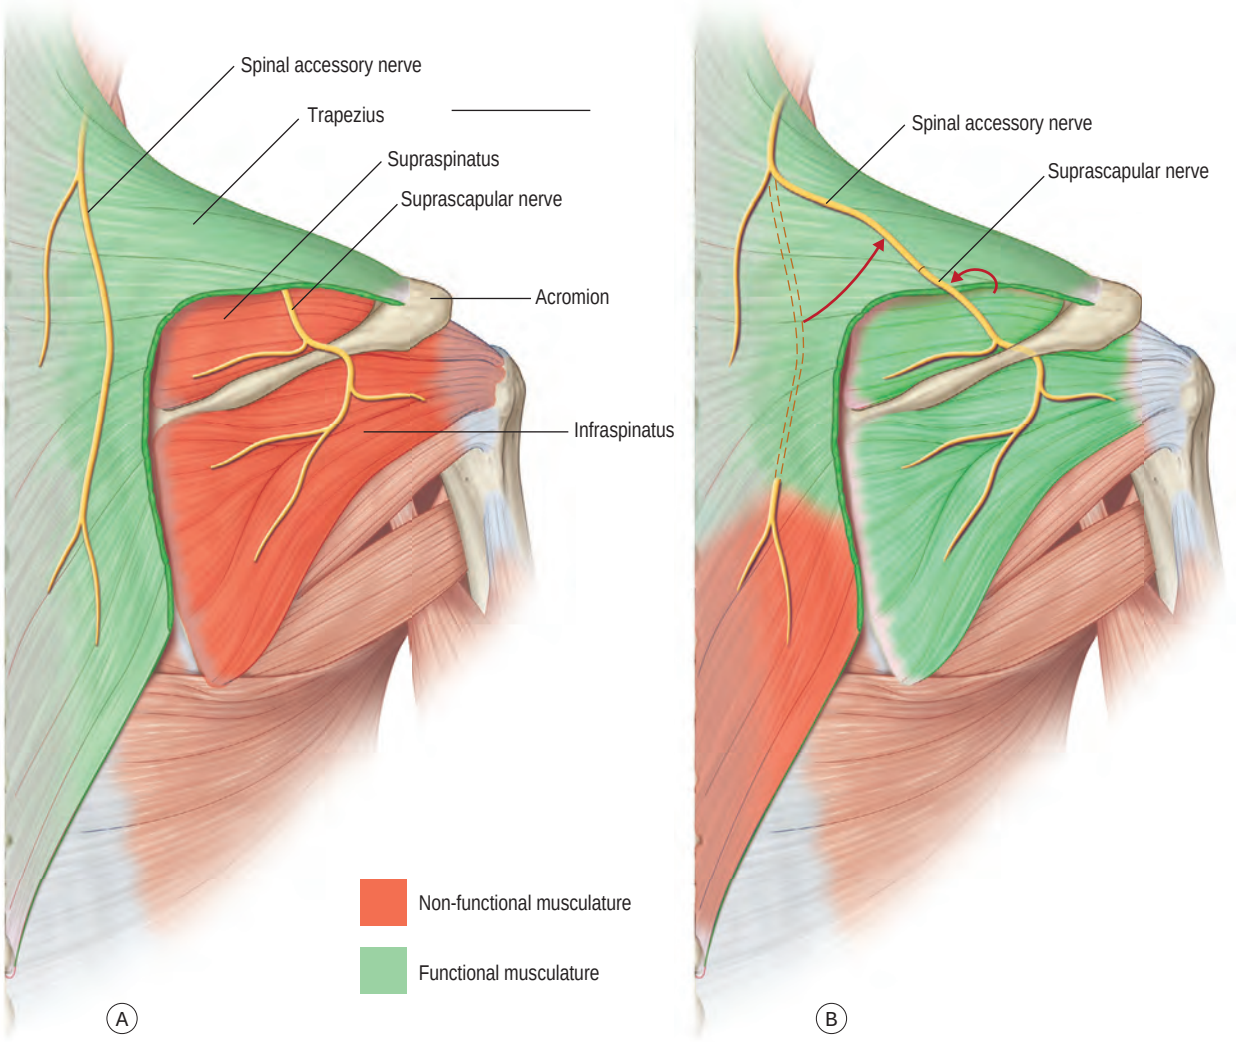

Fig. 33.5 The posterior approach for spinal accessory to suprascapular nerve transfers. **(A)** The nerves can be seen in their original orientation. **(B)** The end-to-end transfer has been completed. The transfer includes the functional spinal accessory nerve (donor) being transposed and coapted to the non-functional suprascapular nerve (recipient).

the axillary nerve (Fig. 33.8).[18,20] Better results in upper plexus injury patients are achieved by reinnervating both the suprascapular and axillary nerves.[21] A longitudinal incision is made on the posterior surface of the arm (Fig. 33.9). The axillary nerve is identified in the quadrangular space and dissected proximally to include the branch to teres minor, then divided proximally. The natural cleavage plane between the lateral and long heads of the triceps muscles is identified and blunt dissection is conducted to expose the donor radial nerve running along the humerus. The branch to the medial triceps sits superficially and medially on the surface of the radial nerve as a distinct branch. The donor triceps nerve is dissected as far distally as possible and then coapted to the axillary nerve (Fig. 33.10).

Use of the double fascicular (ulnar/median redundant branches to biceps brachii and brachialis branches of the musculocutaneous) nerve transfer (motor)

Restoration of elbow flexion is achieved with the double fascicular nerve transfer (Fig. 33.11). This transfer reinnervates both the biceps brachii and brachialis muscles using redundant fascicles from the ulnar and median nerves, if available.[22] However, in cases of limited donor availability, reinnervation of biceps alone may provide adequate antigravity elbow flexion.[23] A medial arm incision allows exposure of the musculocutaneous, median, and ulnar nerves. Dissection at the underside of the biceps brachii muscle allows exposure of the proximal biceps and distal brachialis

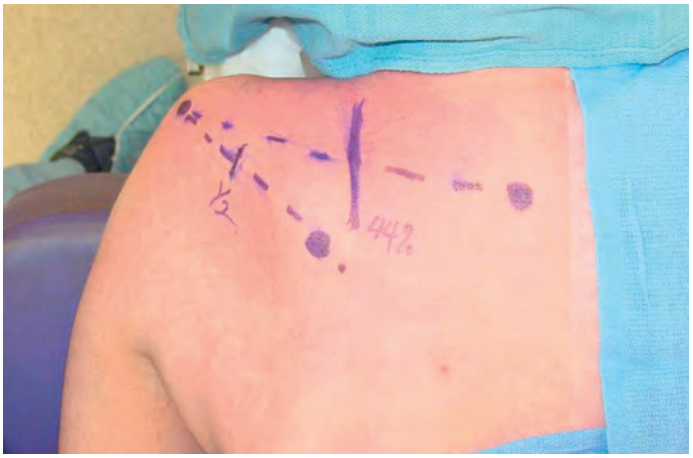

Fig. 33.6 Surface markings for posterior approach to spinal accessory to suprascapular. The spinal accessory nerve is located 44% of the way along a line connecting the dorsal midline to the acromion. The suprascapular nerve is located at the halfway point between the medial border of the scapula and the acromion on an obliquely oriented line at the superior aspect of the scapular spine. It runs in the suprascapular notch.

nerve branches, (Fig. 33.12), which are divided and draped over to the median and ulnar nerves to determine best donor–recipient pairings. The ulnar and median nerves are then neurolyzed at the appropriate level, and expendable fascicles to the flexor carpi ulnaris (FCU) (ulnar), flexor carpi radialis (FCR), flexor digitorum superficialis (FDS), or palmaris longus (median) are divided distally and coapted end to end. Reinnervation occurs at approximately 5–6 months postoperatively.

Other potential donors (medial pectoral nerve and thoracodorsal nerve)

Other potential donors that can be used to restore elbow flexion include the medial pectoral nerves and the thoracodorsal nerve. The medial pectoral nerves are identified by making an incision in the deltopectoral groove then dividing the pectoralis major tendon at the humeral head for exposure; the tendon can be reinserted using bone anchors or attaching to the remaining tendon insertion if the tendon is initially transected. While some advocate elevating the pectoralis minor to gain access to the nerves, we find that simple transection of the muscle belly affords the best exposure (Fig. 33.13). There are several branches to the pectoralis minor and these can be followed as distally as possible into the muscle to increase available donor nerve length.[24] Often a nerve graft will be required to reach the musculocutaneous recipient. The thoracodorsal nerve runs from the axilla along the lateral chest wall and can be exposed through an incision running along the free border of latissimus dorsi.

Lower plexus injury

Specific patient exam findings

Lower plexus injuries usually involve damage to C8 and T1 nerve roots. Patients have a resultant loss of the intrinsic hand function and variable loss of extrinsic hand and wrist function. Involvement of C7 can dramatically influence available options for nerve transfer.

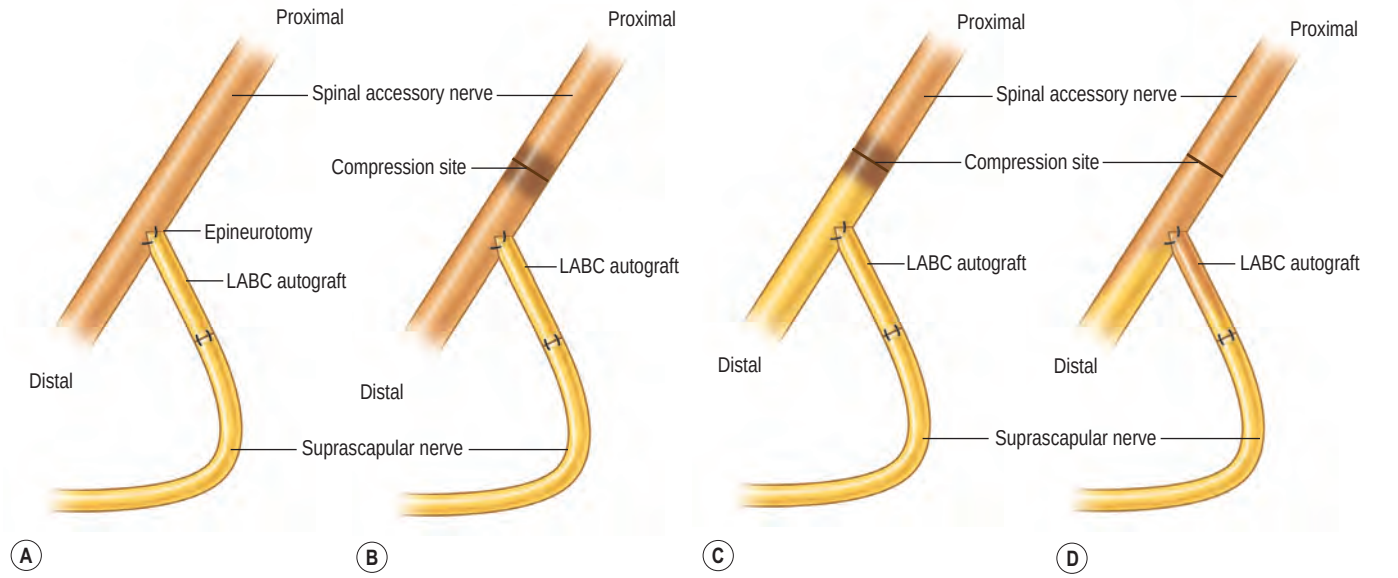

Fig. 33.7 In the anterior approach to the spinal accessory to suprascapular nerve transfer, upper trapezius function is preserved by performing the nerve transfer in an end-to-side manner. **(A)** To inset this transfer with no tension, an interpositional lateral antebrachial cutaneous nerve (LABC) nerve graft is used. **(B)** To facilitate regenerative sprouting, injury to the donor nerve is required proximally. This is accomplished by "crushing" the nerve with a hemostat to cause a second-degree nerve injury. **(C)** Wallerian degeneration occurs distal to the site of compression. **(D)** Axons regenerate from the level of the crush injury, with some axons following the donor nerve and restoring function to the upper trapezius muscle, and some axons diverting into the distal recipient nerve via the LABC graft.

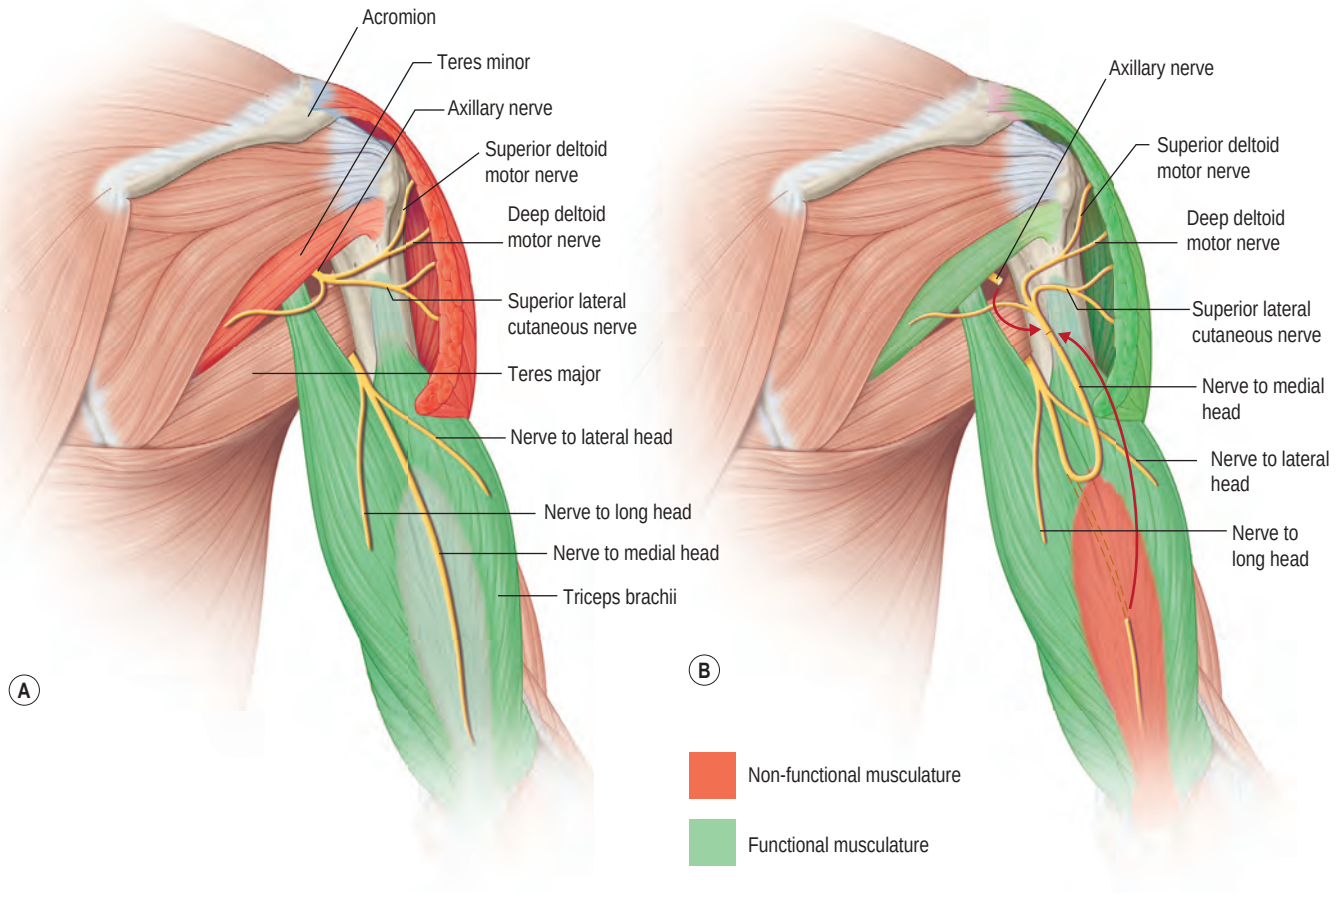

Fig. 33.8 The triceps to axillary nerve transfer via a posterior approach to the upper arm. **(A)** The axillary and radial nerves in their normal anatomical position. **(B)** The branch to the medial head of the triceps (donor) is transposed to meet the divided end of the axillary nerve (recipient). The branch to the medial head is coapted end to end to the axillary nerve.

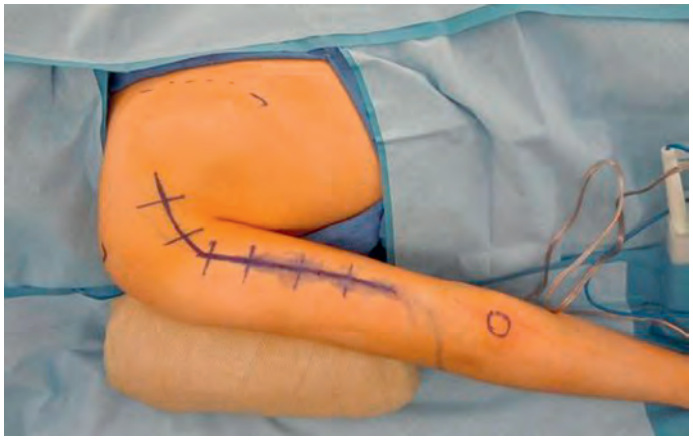

Fig. 33.9 Set-up and incision for triceps to axillary. The patient is positioned in the prone position and draped with the entire extremity free and the medial border of the scapula exposed. A line connecting the olecranon and the acromion is drawn on the posterior aspect of the arm and then extended in a curvilinear fashion just above the posterior axillary fold. Positioning is facilitated by placing a "bump" beneath the anterior shoulder preventing internal rotation and anterior subluxation. The arm is draped free so that distal function can be assessed with intraoperative nerve stimulation.

Hints and tips

Priorities for lower plexus injuries include restoration of hand extrinsic function. Restoration of hand intrinsic function is virtually unobtainable except in the very young pediatric patient.

Reconstruction techniques

There are few good direct nerve transfer options for lower plexus injury reconstruction. Strategies include transfer of the nerve to brachialis (a branch of the musculocutaneous nerve) to the anterior interosseous nerve (AIN) to regain thumb and finger flexion. The details of this technique are described under the median nerve injury section below. The brachioradialis (if function is preserved) may also be used as a donor to the AIN.[25] Additional options include the use of the supinator to the posterior interosseous nerve to restore thumb and finger extension.[26]

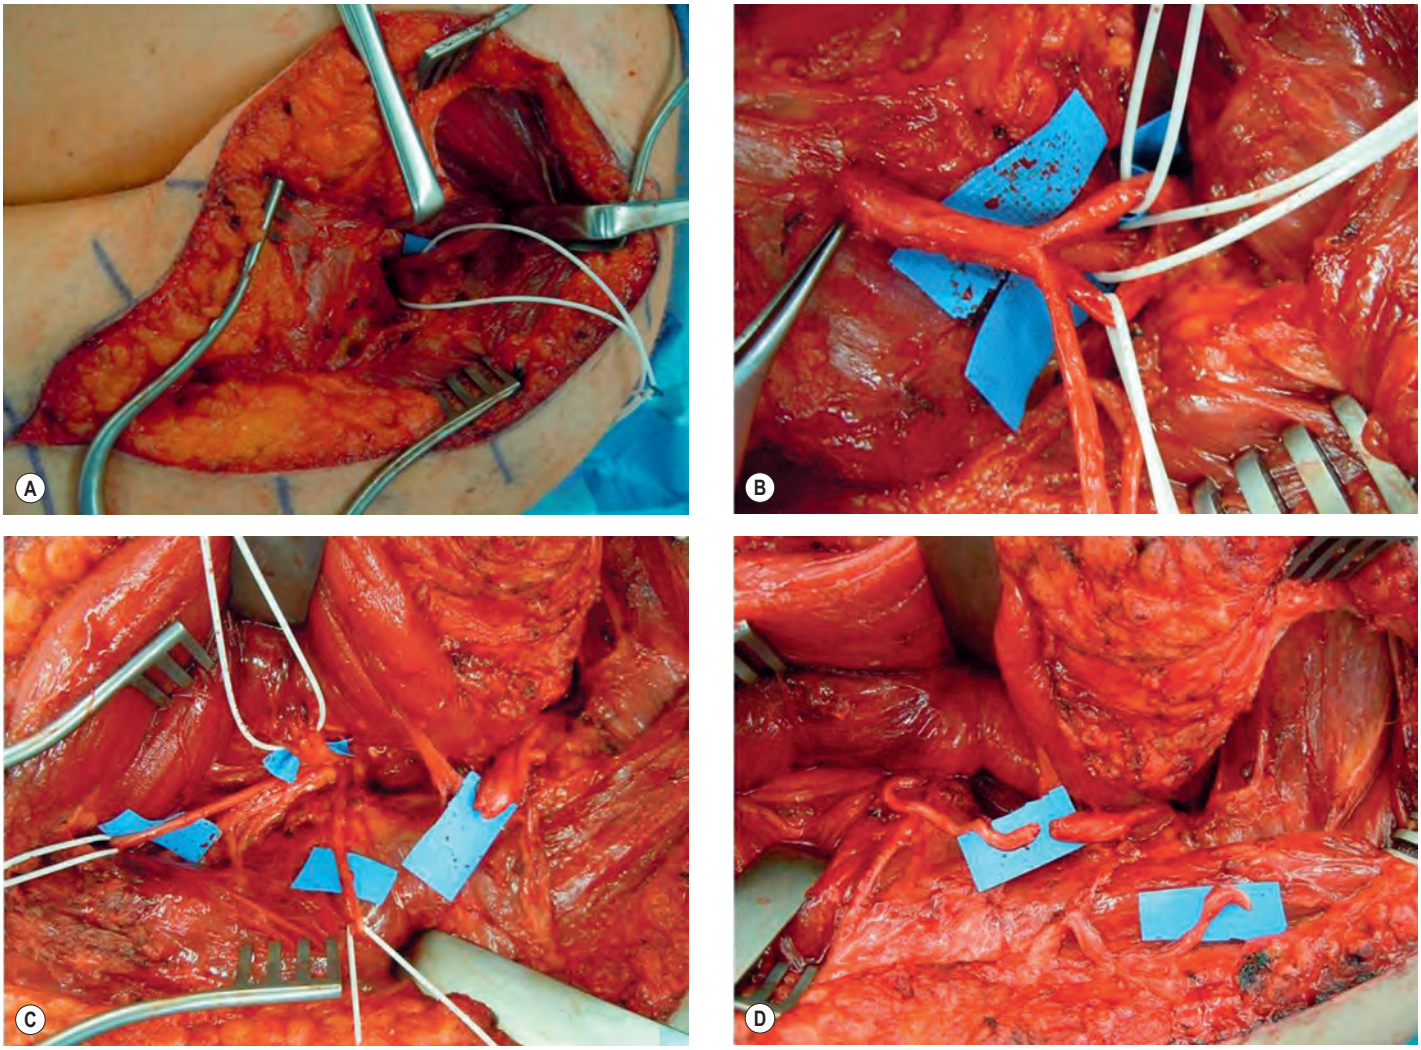

Fig. 33.10 A clinical example of the triceps to axillary nerve transfer. The patient is positioned with the head to the top right. The cross-hatchings of the posterior midline incision in the upper arm are visible and the quadrangular space is exposed. **(A)** The intact nerve *in situ* prior to division. A white vessel loop surrounds the entire nerve at that level. **(B)** The divided nerve transposed caudally with the proximal-most aspect held by the forceps. The branches are clearly visible with vessel loops around motor branches. The superior-most branch is the branch to teres minor. The sensory branch is the most inferior branch (no vessel loop) and can be visualized heading more superficially than the other branches. **(C)** The cut end of the recipient axillary nerve is visible on the most proximal blue background. The radial nerve is visualized at the base of the wound, with vessel loops around branches to the medial, long, and lateral heads of triceps. **(D)** The divided branch to the medial head (donor) is transposed proximally and coapted to the recipient axillary nerve.

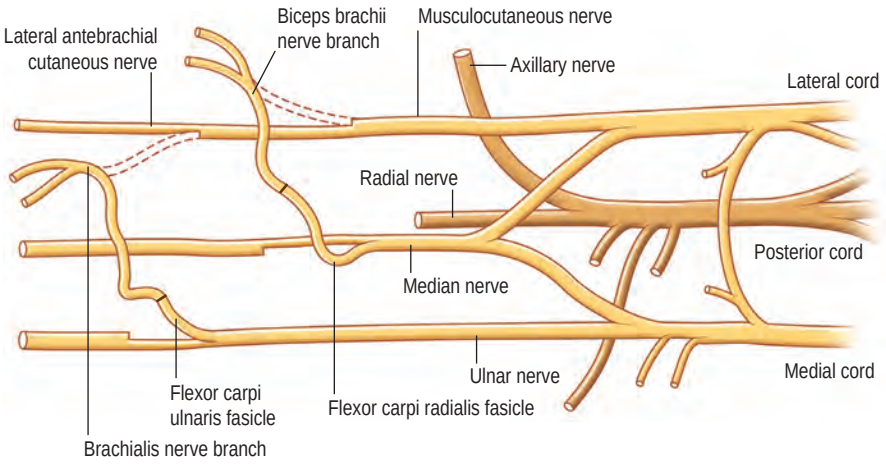

Fig. 33.11 A schematic of the double fascicular nerve transfer. The divided recipient branches of the musculocutaneous nerve (biceps brachii laterally and brachialis medially) are transposed medially to the median and ulnar nerves. In this example, a redundant fascicle to flexor digitorum superficialis (median donor) is transferred to the biceps brachii branch and a redundant fascicle of the flexor carpi ulnaris (ulnar donor) is transferred to the brachialis branch.

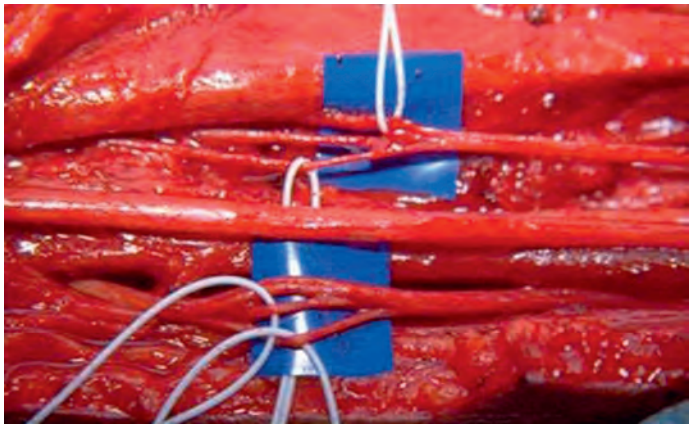

Fig. 33.12 Operative photo of double fascicular nerve transfer. A clinical example of the double fascicular nerve transfer. The superior nerve is the musculocutaneous nerve with vessel loops around the branch to biceps brachii (proximal and lateral) and branch to brachialis (distal and medial). The ulnar nerve is also neurolyzed at the level appropriate for transfer. Redundant fascicles determined by intraoperative nerve stimulation that can serve as potential donors are marked with vessel loops.

Complete/near-complete plexus injury

Specific patient exam findings

Complete, or near-complete, brachial plexus injury often results from high-velocity, penetrating, or crush-type mechanisms and result in devastating loss of function. These patients will typically have an insensate, flail upper extremity with glenohumeral joint subluxation and a positive sulcus sign. Most will lack shoulder stability, abduction, rotation, flexion and extension, elbow flexion and extension, wrist flexion and extension, finger flexion, extension, and intrinsic function.

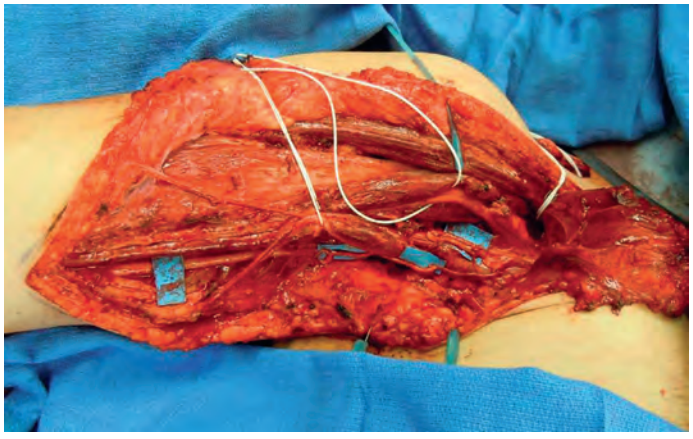

Fig. 33.13 Harvesting the medial pectoral nerve. Clinical photograph of a patient with medial pectoral nerve harvested as a donor. The divided pectoralis major muscle is flipped proximally and lying on the anterior chest wall. The medial pectoral nerves have been dissected from the deep surface of the pectoralis minor and divided distally. They have then been transposed towards the donor nerves in the arm and are lying on the most proximal blue background.

Reconstruction techniques

Hints and tips

Priorities for complete plexus injuries are to restore function in the following order of priority: (1) elbow flexion; (2) shoulder stability/external rotation; and (3) hand extrinsic function/grasp. Techniques include extraplexal to intraplexal nerve transfers. Most reconstructive approaches will require staged transfers due to the long distance to target, with banking of interposition grafts and subsequent free functional muscle reconstruction. Adjunctive fusion of selected joints (wrist, thumb) and other approaches may be completed. Contralateral C7 and phrenic nerve transfers are also described with varying and modest results.

Use of spinal accessory and intercostal nerves as donors (motor)

Reconstruction in this scenario has very different goals and outcomes from less traumatic injuries. Priorities include restoring elbow flexion, shoulder stability/external rotation, and hand extrinsic function/grasp. The extremity will often be a "helper" extremity at best. The severe damage to the brachial plexus means that options for nerve transfers are limited, and that extraplexal donors must be considered. Specifically, available extraplexal nerve donors may include the spinal accessory, medial pectoral, thoracodorsal, and intercostal nerves.

Donor nerves are isolated as follows: The spinal accessory nerve is harvested as described previously. Intercostal nerves are harvested through an L-shaped incision extending from the anterior axillary fold and curving anteriorly below the nipple–areolar complex. Rib periosteum is incised and peeled down to expose the neurovascular bundles running along the posterior inferior surface of each rib (Fig. 33.14). The motor

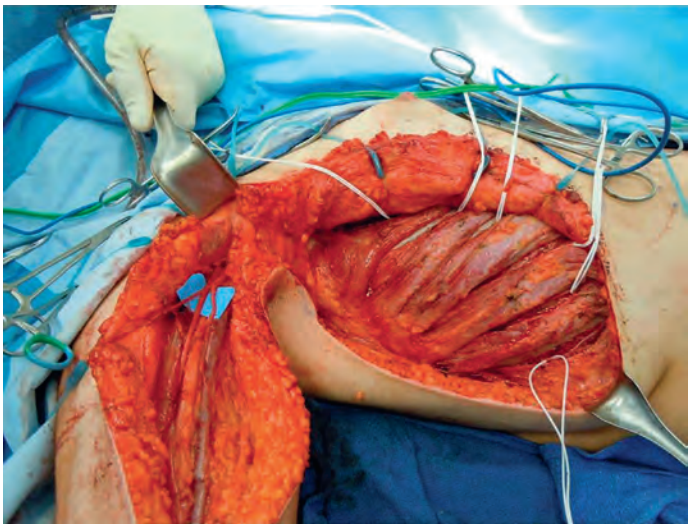

Fig. 33.14 Harvesting intercostal nerves. Clinical photograph of a female patient undergoing intercostal to musculocutaneous nerve transfer. The anterior subcutaneous flap has been turned over medially to expose the anterior chest wall. White vessel loops are around intercostal nerves at the inferior border of each rib. The recipient nerve is visualized in the upper arm on a blue background.

nerves are smaller and sit more superiorly than the sensory nerves. Often several are required. These are dissected as far medially as possible and then divided.

These extraplexal donor nerves can be transferred to a variety of potential recipients, depending on surgical goals. They can be used to establish shoulder stability and external rotation (suprascapular and axillary nerves), elbow flexion (musculocutaneous), or even to recreate elbow extension or finger flexion by neurotizing one or two free-functioning gracilis flaps.[27] This is often accomplished as a two-stage procedure.

Discussion of cross C7 transfer, phrenic nerve transfers (motor)

Contralateral C7 transfer has been described as a safe option in the literature[28,29] and has been met with varying levels of success and controversy. Approaches include prespinal tunneling, and complete and partial root harvest. However, evidence suggests that the degree of function obtained does not justify the donor complications, even with hemi-contralateral C7 harvest.[30]

The phrenic nerve has also been used, with some studies documenting no significant impact on respiration and others reporting decreased pulmonary capacity that goes on to improve. The senior author no longer uses either the phrenic nerve or the contralateral C7 as a potential nerve donor as results are, at best, Medical Research Council (MRC) grade 3 of 5 after several years for limited elbow flexion or poor finger flexion.

Median nerve injury

Specific patient exam findings

The median nerve proper supplies pronator teres (PT), FCR, palmaris longus, and FDS. The nerve then divides. The anterior interosseous nerve innervates flexor pollicis longus, flexor digitorum profundus (FDP) to the index finger and sometimes long finger, and pronator quadratus (PQ). The remainder of the nerve is largely sensory, with a small motor component contributing to the recurrent motor branch, which innervates the thenar muscles (abductor pollicis brevis, opponens pollicis and the superficial head of flexor pollicis brevis) and the two radial lumbricals.

Patients presenting with a median nerve injury will have numbness in the distribution of the median nerve. Depending on the level of injury, motor deficits will vary.

Hints and tips

Priorities with median nerve injury are to re-establish anterior interosseous nerve (AIN) function, thumb opposition, index and long finger flexion, and critical sensation to the first webspace. A combination of nerve and tendon transfers can be done. For reconstruction of proximal median nerve injuries, radial to median nerve transfers are used. For reconstruction of more distal median nerve or isolated AIN injuries, brachialis to AIN branch transfers can be done. This transfer is also useful for patients with lower plexus injuries.

Reconstruction techniques

Use of radial to median branch nerve transfers (motor)

Branches of the radial nerve may be used to restore median nerve function in a proximal median nerve injury.[17] Transfer of the extensor carpi radialis brevis branch (ECRB) of the radial nerve is used to restore PT function. Transfer of the supinator branch is used to restore anterior interosseous nerve (AIN) function (Fig. 33.15). A volar forearm incision with step lengthening of the PT and release of the deep head will facilitate visualization. The median nerve is identified and dissected to reveal the PT and AIN recipient branches. The nerve to supinator is identified on the posterior aspect of the radial nerve and the ECRB nerve is also identified. There are two fascicles to the ECRB and use of one branch is sufficient to restore pronation. Recovery of pronation occurs approximately 3–4 months postoperatively. If AIN function is required, the authors recommend using the nerve to brachialis (described below).

Use of brachialis branch to AIN branch nerve transfer

The brachialis branch of the musculocutaneous nerve may be used to restore AIN function (or, as noted above, in the setting of a lower brachial plexus injury) (Fig. 33.16).[31] A medial arm incision is made and the donor nerve to brachialis is then followed distally into the muscle as far as possible and divided. It is transposed over to the median nerve to identify the level for coaptation, and an internal neurolysis of the median nerve is performed (Fig. 33.17). Knowledge of the internal topography of the median nerve is crucial to performing this transfer. The lateral aspect of the median nerve is all sensory, and the medial aspect is motor. The AIN portion of the nerve is located at the posterior medial aspect of the nerve. Those performing this procedure for the first time may prefer to dissect the AIN out distally and then visually and, intermittently, physically neurolyze to confirm that the correct recipient fascicles have been identified. These recipient fascicles are neurotized and divided proximally. Of note, the nerve to the pronator can be included in this transfer to augment AIN function.

Sensory nerve transfer to restore critical sensation to the first webspace is also recommended (see below).

Use of adjunct tendon transfers to augment nerve transfers

Tendon transfers can be utilized to augment nerve transfers in median nerve injury. The most commonly performed tendon transfer would be to restore thumb opposition, as this is innervated by the most distal branches of the median nerve and will be slowest to recover. The authors' preference for restoration of thumb opposition is transfer of extensor indicis proprius tendon to abductor pollicis brevis. Another option is to use extensor digiti minimi.

Ulnar nerve injury

Specific patient exam findings

Patients presenting with an ulnar nerve injury will have numbness in the small and ulnar side of the ring finger.

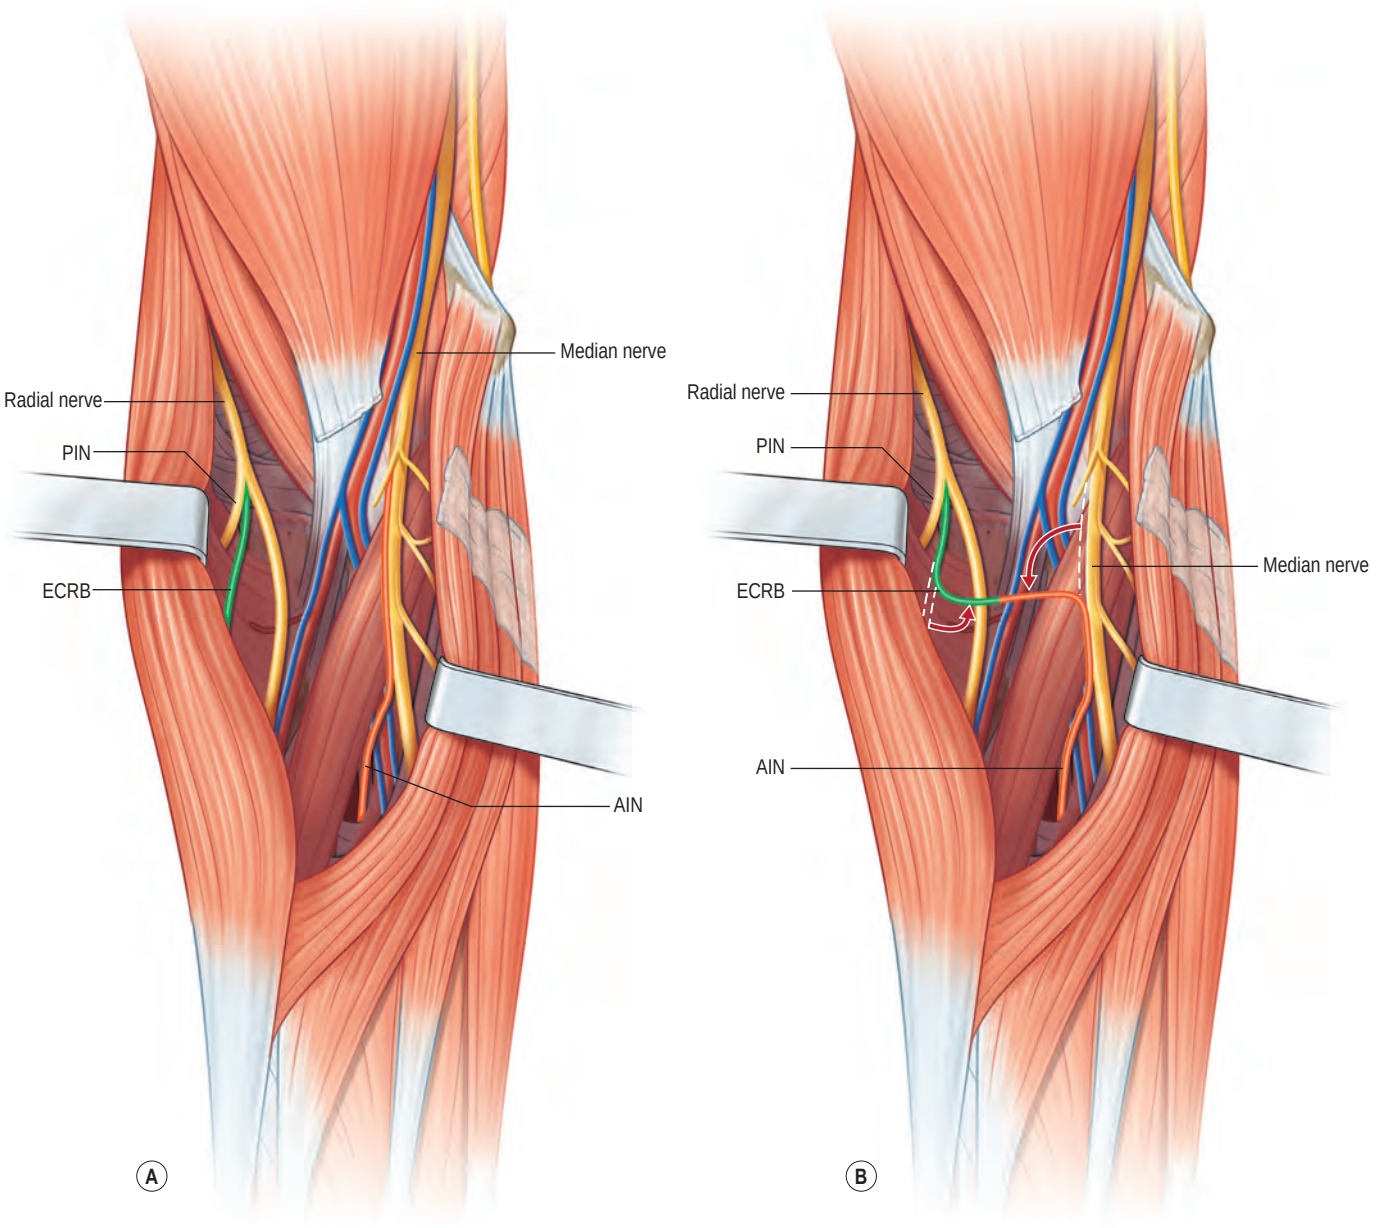

Fig. 33.15 A schematic of radial to median nerve transfers. **(A)** The radial nerve is visualized superiorly as it branches into three branches, from lateral to medial: posterior interosseous nerve (PIN), extensor carpi radialis brevis (ECRB), and radial sensory. The donor ECRB nerve is green. The median nerve is visualized inferiorly, with the non-functioning anterior interosseous nerve (AIN) illustrated branching off the lateral aspect of the nerve (red). Note that the AIN is the only branch to exit radially. **(B)** The donor ECRB nerve has been coapted end to end with the distal recipient AIN nerve.

Depending on the level of injury, sensation to the dorsum of the hand and wrist may also be affected. The motor deficits associated with ulnar nerve injury are particularly devastating. The deep motor branch of the ulnar nerve innervates all of the intrinsic muscles of the hand, and injury results in the inability to pinch, abduct, and adduct the fingers, and impairs power grasp. More proximal injuries will also further impair grip, with added losses of the FDP to the small and ring fingers and FCU.

Hints and tips

Priorities for ulnar nerve injury are to re-establish intrinsic muscle function, especially pinch, ring, and small finger flexion, and critical sensation to the ulnar border of the hand. A combination of nerve and tendon transfers can be done. For reconstruction of proximal nerve injuries, a direct end-to-end anterior interosseous nerve (AIN) to deep motor branch of ulnar nerve transfer is useful. For incomplete, or partial, nerve injuries where level of recovery is uncertain, reverse end-to-side AIN to deep motor branch "supercharging" should be considered.

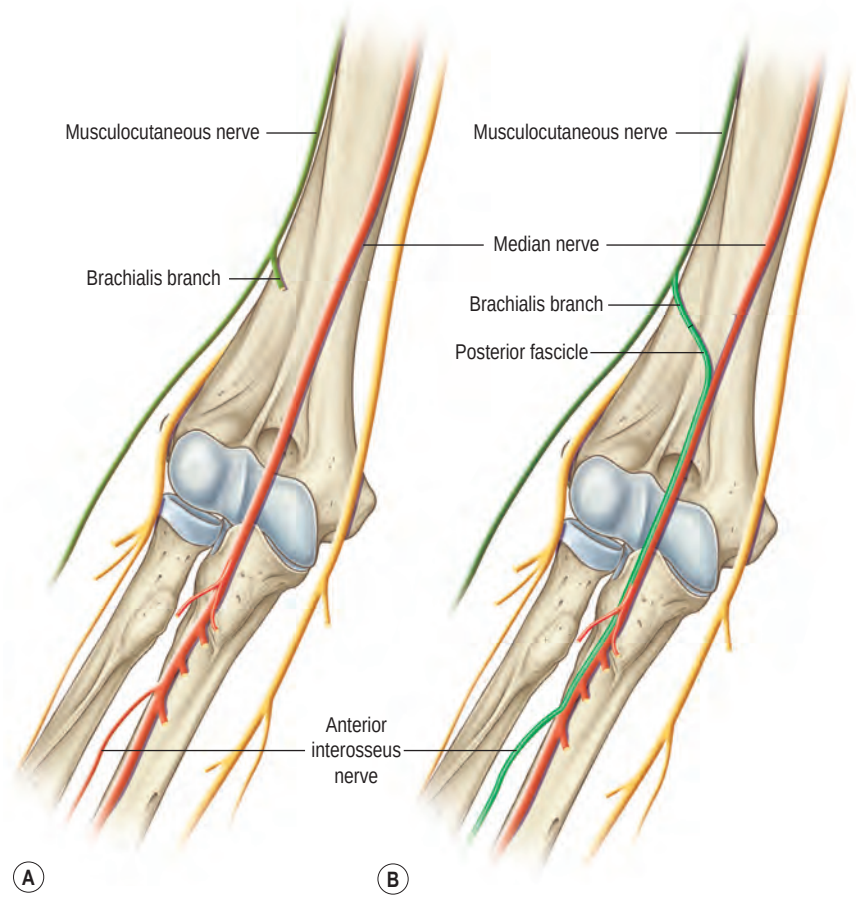

Fig. 33.16 A schematic of the nerve to brachialis to anterior interosseous nerve transfer. **(A)** The median nerve (pink) and musculocutaneous nerve (yellow) are shown in their normal anatomic position. Note that the branch to brachialis exits medially approximately 13 cm to the elbow crease. **(B)** The brachialis branch of the musculocutaneous nerve (donor) is coapted end to end with the divided distal end of the anterior interosseous nerve (recipient), which is located on the posterior medial aspect of the median nerve in the arm.

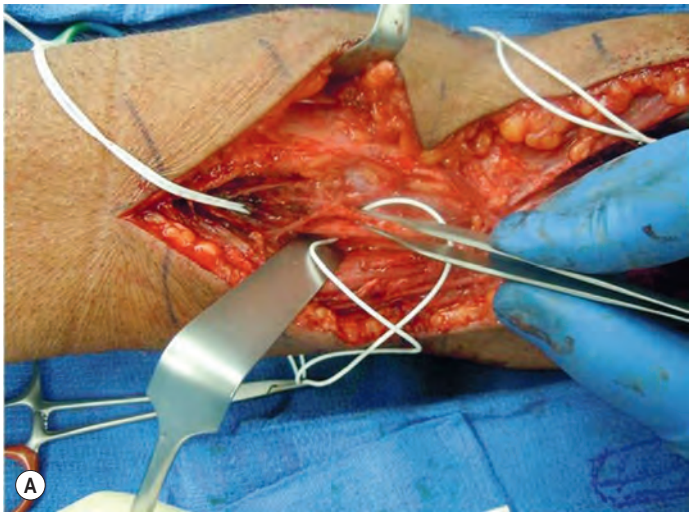
Reconstruction techniques

Use of median to ulnar branch nerve transfers (motor)

The median nerve may be used to restore ulnar nerve function, especially following very proximal injuries where time to regenerate to motor end plate becomes an issue. Both sensory and motor nerve transfers are utilized to restore optimal function. The sensory nerve transfers are described later. For restoration of intrinsic muscle function, the distal AIN nerve is transferred to the deep motor branch of the ulnar nerve at the distal forearm level (Fig. 33.18).[9,32] Release of the nerve through Guyon's canal, with particular attention to adequate release of the deep motor branch, is an essential component of this transfer.[9] Use of a volar forearm incision



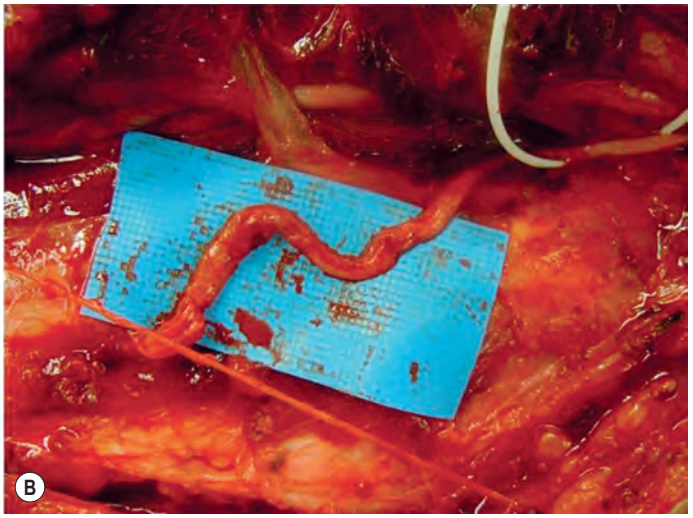


Fig. 33.17 Clinical photos of nerve to brachialis to anterior interosseous nerve. A clinical example of a nerve to brachialis to anterior interosseous nerve (AIN) transfer. **(A)** The median nerve is isolated with a vessel loop. Forceps are used to reveal the AIN nerve branching off the radial aspect of the median nerve. **(B)** A magnified view illustrating the branch to brachialis (marked with a vessel loop) divided and transposed over, to be coapted end to end with the recipient distal AIN.

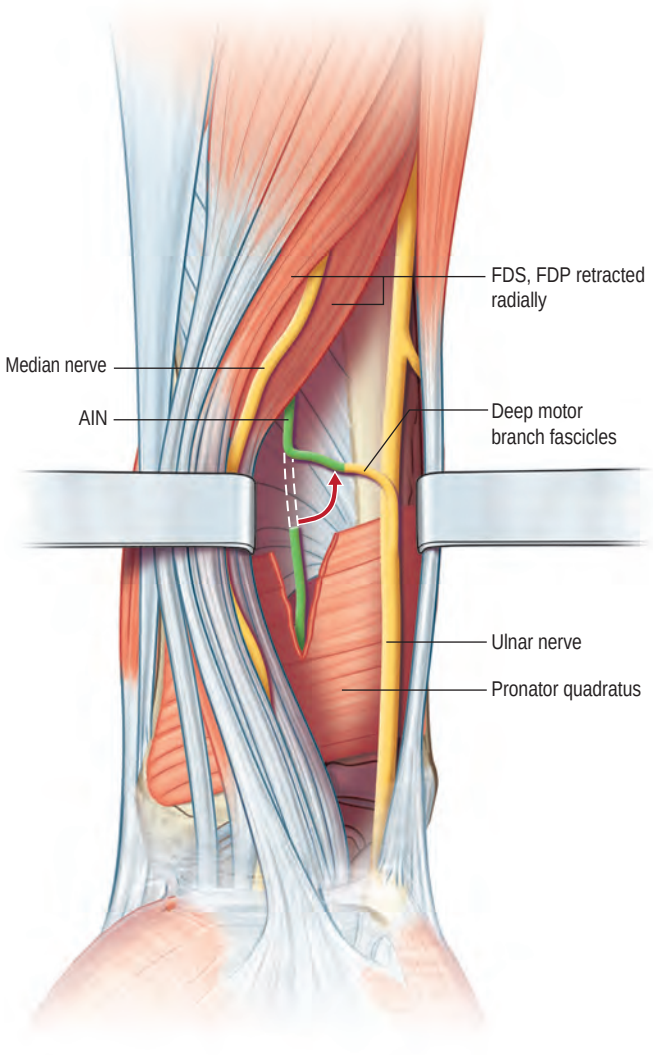

Fig. 33.18 Anterior interosseous nerve (AIN) to deep motor branch of ulnar nerve. A schematic of the distal AIN to deep motor branch transfer. The donor AIN (green) is seen divided under the pronator quadratus muscle and transposed over to the recipient deep motor branch of the ulnar nerve. At this level, distal to the take off the dorsal cutaneous ulnar branch, the motor fascicles are ulnar and the main sensory component of the nerve is radial. The coaptation is performed in an end-to-end manner. FDS, Flexor digitorum superficialis; FDP, flexor digitorum profundus.

and retraction of the flexor tendons radially allow visualization of the donor AIN as it enters into the deep surface of the PQ. The AIN is dissected distally into the mid-substance of the muscle and divided. It is transposed over to the ulnar nerve to identify the point where it can be coapted with no tension (Fig. 33.19). At this point, the neurolysis of the ulnar nerve is performed. Within the proximal forearm, prior to the take off the dorsal cutaneous branch, the topography of the ulnar nerve is sensory–motor–sensory. The medial-most sensory portion goes on to become the dorsal cutaneous ulnar branch (DCU) approximately 9 cm proximal to the wrist crease. As the nerve continues, the lateral sensory portion of the ulnar nerve is significantly larger than the more medial motor portion. Microforceps are used to tap along the surface of the nerve until they plunge into the natural cleavage plane between the sensory and motor portions of the nerve.[32] Visual neurolysis from the deep motor branch decompression at the leading edge of the hypothenar muscles confirms this. Once this plane is identified, the recipient motor fascicular group is isolated proximally and divided to allow for the appropriate motor nerve transfer.

Sensory nerve transfer to the ulnar border of the hand is recommended (see below).

Use of adjunct tendon transfers to augment nerve transfers

Tendon transfers are frequently performed to augment median to ulnar nerve transfers. The intrinsic muscles are so distal and are so important for function that these tendon transfers are often performed at the same time as the nerve transfers, even though their use might be considered redundant. Tenodesis of the ulnar nerve-powered ring and small FDP tendons to the median nerve-powered index and long FDP tendons is performed. Thumb adduction is also augmented using

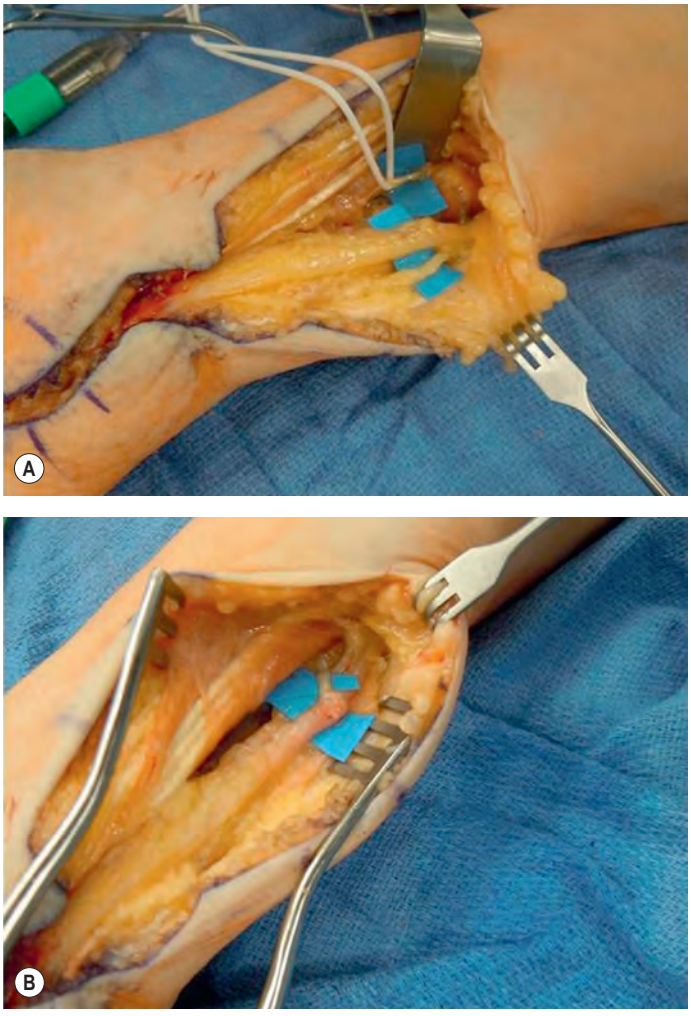

Fig. 33.19 Clinical photos of anterior interosseous nerve (AIN) to deep motor branch of ulnar nerve. Clinical example of an AIN to deep motor branch nerve transfer. **(A)** A vessel loop surrounds the distal AIN. The ulnar nerve is exposed on a blue background. The dorsal cutaneous ulnar branch is illustrated branching off ulnarly. **(B)** The donor AIN is divided distally and transposed over to the ulnar nerve. The dorsal cutaneous branch of the ulnar nerve is now located beneath the blue background, and a motor fascicle from the ulnar aspect of the main nerve is divided as the recipient and coapted end to end to the AIN nerve.

extensor indicis proprius to adductor pollicis tendon transfer. In patients with a prominent Wartenberg's sign, abductor digiti minimi is transferred to the extensor digitorum communis tendon of the small finger.[32]

Radial nerve injury

Specific patient exam findings

The radial nerve is a mixed motor and sensory nerve that receives contribution from C5, C6, C7, C8, and T1. The radial nerve proper innervates the three heads of the triceps muscle, anconeus epitrochlearis, brachioradialis, and extensor carpi radialis longus (ECRL). The nerve then branches into the posterior interosseous nerve (PIN) and radial sensory nerve (RSN). The PIN then innervates the ECRB, supinator, extensor carpi ulnaris, extensor indicis proprius, extensor digitorum communis, extensor digiti minimi, abductor pollicis longus, extensor pollicis longus, and extensor pollicis brevis. Of note, the ECRB branch can occasionally come off the radial nerve proper or branch off along with the radial sensory nerve, meaning that wrist extension can be variably affected in injuries at this level depending on individual anatomy.

Patients presenting with radial nerve injuries will have sensory defects in the distribution of the radial nerve. Motor deficits will depend on the level of injury. Isolated radial nerve injuries are typically distal to the triceps, so elbow extension is often preserved.

Hints and tips

Priorities with radial nerve injury are to re-establish wrist, finger, and thumb extension. Unlike tendon transfers, use of median-to-radial nerve transfers allows for individual and separate finger extension in addition to wrist and thumb extension.

Reconstruction techniques

Use of median to radial branch nerve transfers

The most commonly performed transfers include using redundant fascicles to FDS or FCR as donors to provide innervation to PIN and ECRB (Fig. 33.20).[33] An incision is made at the volar forearm and step lengthening of the PT may be performed to improve visualization. Knowledge of the internal topography of the median nerve is essential for this transfer, as protection of the branches to PT and AIN is mandatory. The most proximal branches, of which there are usually two, are to PT. Then, a branch to FCR and PL departs from the ulnar side of the nerve. The next two branches will be to the FDS and also depart ulnarly. The AIN departs from the median nerve on the radial side, and is the only branch to exit radially. The remaining sensory and thenar branches continue distally.

The recipient radial nerve branches are identified by retracting the brachioradialis laterally. The first nerve encountered will be the radial sensory branch, followed by the smaller branch to ECRB and the larger PIN located just deep and radial to the sensory branch. These recipient nerves are dissected as proximally as possible and then transected. Mobilization is facilitated by excluding the branch to the supinator, which comes off posteriorly. The recipient nerves are then transposed over to the median nerve to determine the level for neurolysis. The median nerve is dissected and redundant fascicles to FDS and FCR are divided and transferred. Motor reinnervation occurs at approximately 9–12 months postoperatively.

Use of adjunct tendon transfers to augment nerve transfers

The authors suggest augmenting median to radial nerve transfers with tendon transfer of PT to ECRB during the same procedure. This transfer provides earlier restoration of wrist extension, which is then enhanced once the nerve transfer becomes viable at 9–12 months.

Sensory nerve injury

Restoration of key sensory functions

Restoration of discriminatory sensation in critical areas can be accomplished using noncritical area donors. One of the newer developments in nerve transfer surgery is to maintain some donor territory protective sensation by use of adjunct end-to-side transfers. A number of studies have demonstrated that "collateral sprouting" occurs with an end-to-side sensory repair, and novel axonal regeneration from the donor nerve occurs into the recipient stump.[8] Only sensory axons sprout *de novo* without injury, whereas motor nerves require a proximal nerve injury to do so.[8] Making use of this principle, efforts are made to restore protective sensation to the donor region with end-to-side coaptation of the distal donor to an intact sensory nerve.

Use of ulnar to median branch nerve transfers (sensory)

A fourth webspace (ulnar) to first webspace (median) nerve transfer can be performed to restore critical first webspace sensation only. Alternatively, a triad of nerve transfers from the ulnar nerve can restore more extensive sensation and minimize donor deficits (Fig. 33.21). The DCU is transferred end to end to the radial portion of the median nerve to restore critical thumb and radial index sensation. The nerve to the third webspace is the most ulnar portion grouping of fascicles at this level (Fig. 33.22). It is coapted end to side to the main sensory component of the ulnar nerve for restoration of third webspace protective sensation. The distal end of the transected donor DCU is coapted end to side to the ulnar nerve to restore the donor deficit.[32]

Use of median to ulnar branch nerve transfers (sensory)

A third webspace (median) to ulnar small-finger nerve transfer can be used to restore sensation to the ulnar border of the hand. Alternatively, restoration of ulnar nerve sensation can be provided by a triad of nerve transfers from the median nerve (Fig. 33.23). The third webspace fascicle of the median nerve is transferred end to end to the main sensory component of the ulnar nerve (Fig. 33.24). End-to-side coaptation of the dorsal cutaneous ulnar branch to the sensory component of the median nerve is performed more proximally. The distal third webspace (median) donor is then coapted end to side to the remainder of the intact sensory portion of the median nerve to restore protective sensation to the donor defect.

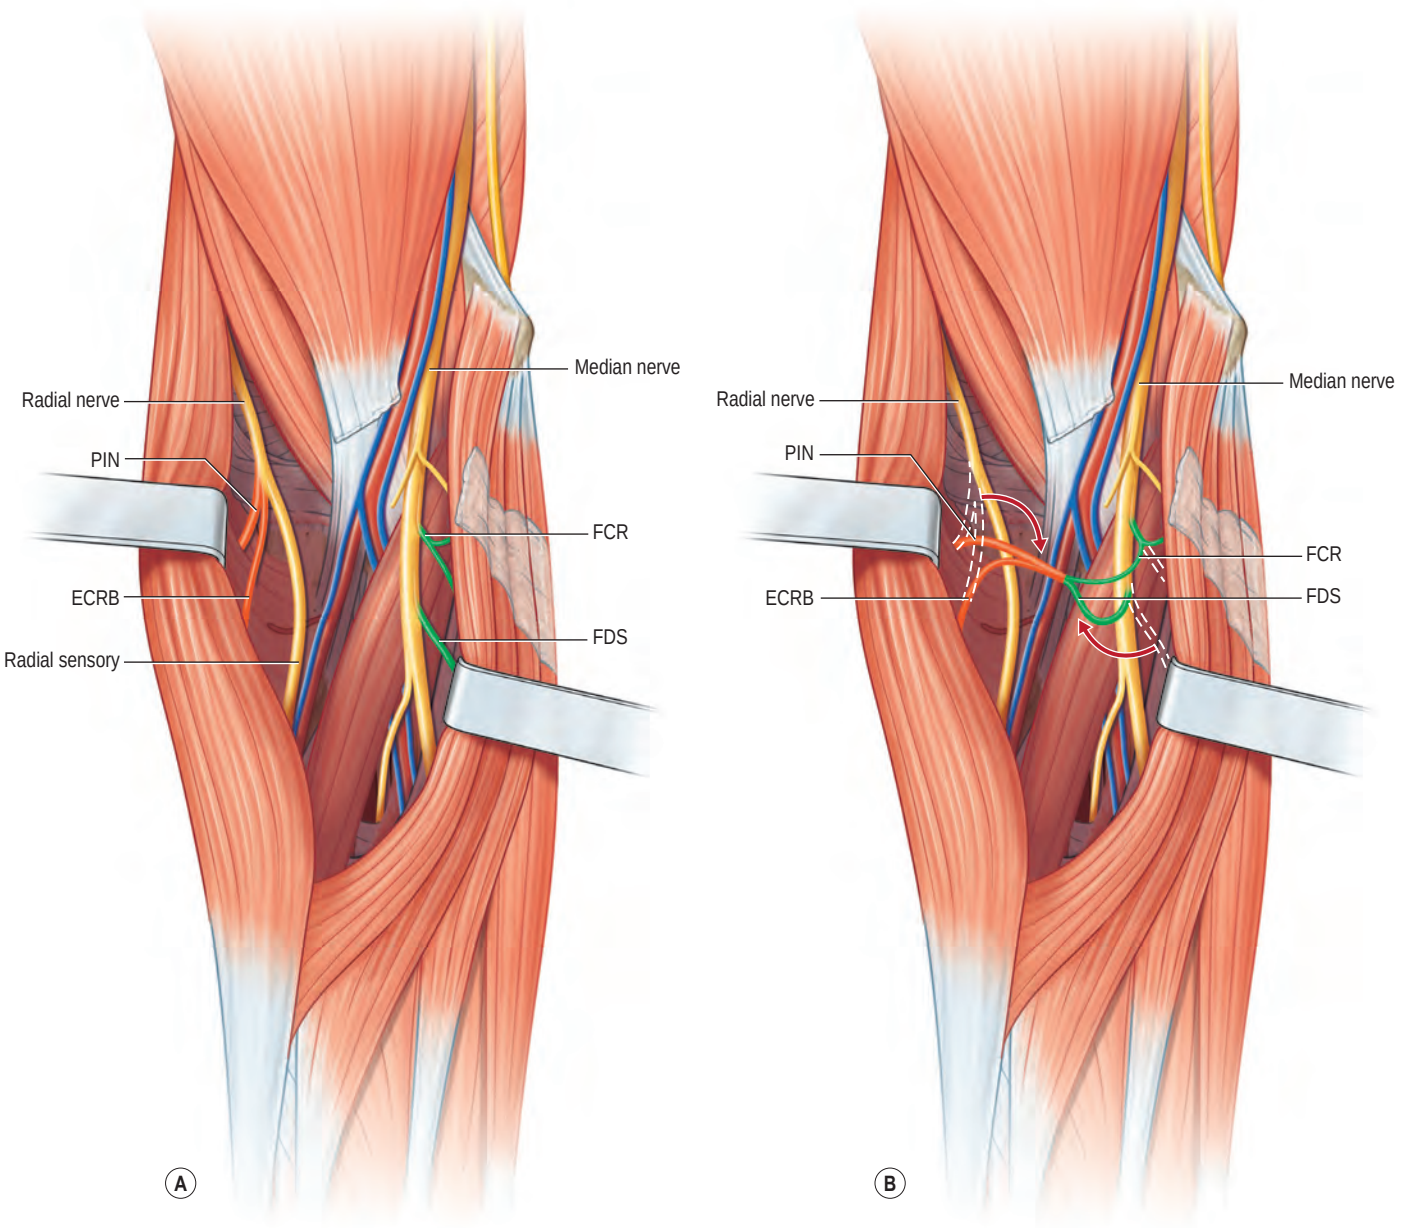

Fig. 33.20 Median to radial nerve transfers. A schematic diagram of median to radial nerve transfers. The redundant fascicles to flexor carpi radialis (FCR) and flexor digitorum superficialis (FDS) (donors) are transferred to the extensor carpi radialis brevis (ECRB) and posterior interosseous nerve (PIN) respectively.

Use of median and ulnar nerve transfers to restore first webspace sensation in C5–C6 root level brachial plexus injury (sensory)

In patients with an isolated upper trunk injury, sensation to the first and second webspaces will be absent. A combination of distal transfers at the level of the median and ulnar nerve proper can be used to reconstruct this deficit (Fig. 33.25). The third webspace nerve is transected and coapted end to end to the radial aspect of the median nerve to restore thumb and first webspace sensation. The distal end of the transected third webspace is coapted end to side to the ulnar nerve to restore protective sensation of the donor site. This effectively transfers intact sensation that originated from the C7 and C8 roots to the C5 and C6 level at a close-to-target end organ level.

Use of lateral antebrachial cutaneous nerve to radial nerve transfers (sensory)

Patients with radial sensory nerve injury have numbness on the dorsal radial aspect of the hand and wrist. Unfortunately, this injury is also commonly associated with excruciating phantom pain due to this nerve's exquisite sensitivity to denervation. The lateral antebrachial cutaneous nerve runs superficial and medial to the brachioradialis and is in close proximity to the radial sensory nerve. It is also a close size match. Coaptation of the expendable lateral

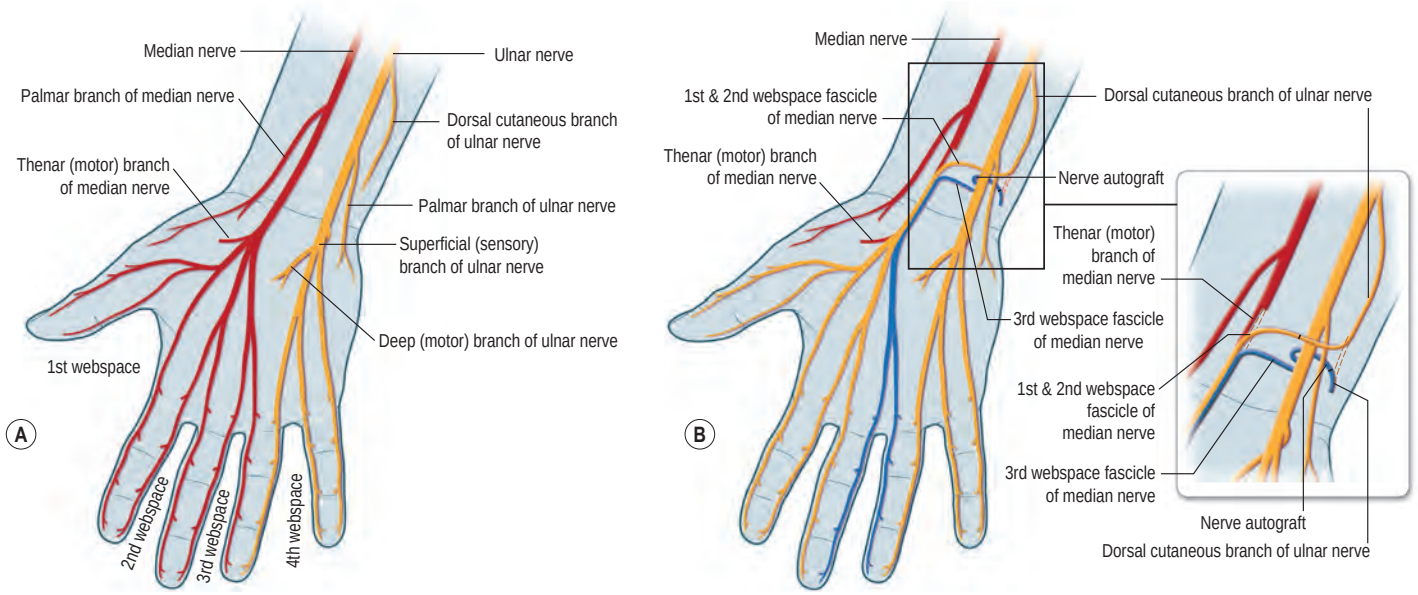

Fig. 33.21 A schematic of the triad of transfers used to restore sensation in a median nerve deficit. **(A)** The non-functional median (red) and the functioning ulnar nerve (yellow). **(B)** The triad of nerve transfers from ulnar to median (inset) is a magnification of the transfers showing the dorsal cutaneous branch of the ulnar nerve (donor) coapted end to end to the radial side of the median (recipient) to restore first webspace sensation, the distal third webspace (recipient) end to side to the ulnar sensory (donor), and the distal dorsal cutaneous branch of the ulnar nerve end to side to restore sensation to the donor deficit. The third webspace fascicle is shown in blue.

antebrachial cutaneous nerve (LABC) to the denervated radial sensory nerve territory may not restore completely normal sensation, but can significantly interrupt the neuropathic pain cycle.

Use of radial to axillary nerve transfers (sensory)

Patients with axillary nerve injury have numbness on the lateral aspect of the shoulder. To treat this, the sensory portion of the axillary nerve can be transferred end to side to a functioning intact nerve such as the radial. At this level, the internal topography of the radial nerve is such that the lateral aspect is sensory.

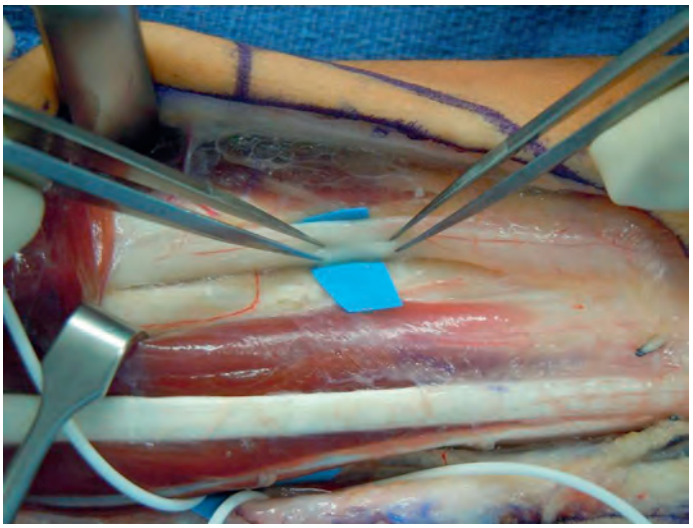

Fig. 33.22 Identifying the fascicle to the third webspace. This clinical photograph demonstrates identifying the third webspace fascicle at the proximal wrist level. Microforceps were walked along the surface of the nerve until they plunged into the natural cleavage plane. The division is also marked with a prominent vessel on the surface of the nerve.

Postoperative care

Postoperative wound care

Patients are initially placed into a bulky soft dressing for comfort. Patients are encouraged to move their extremity early to promote nerve gliding, as all nerve transfers are performed under no tension.[34] Concomitant tendon transfers may also dictate splinting and therapy regimens and will supersede the minor restrictions required for post nerve transfer patients. If the insertion of the pectoralis major muscle was disinserted to allow access to the medial pectoral nerve, the tendon is reapproximated and the shoulder is immobilized for a full 4 weeks.[34]

Complications

Complications specific to nerve surgery include temporary pain, paresthesias, or motor neurapraxia secondary to retraction or manipulation of nerves; neuroma; and inadequate functional recovery. The complication rate associated with nerve transfer should be significantly less than that seen with operating within a scarred and hostile zone of injury. Nerve transfers are performed remote from the time of injury, thus ensuring that patients have been stabilized, appropriately evaluated and educated, serially clinically examined, and perhaps most importantly, that surgery takes place during regular, scheduled hours with a staff familiar with the procedure, as opposed to exploratory repair in a trauma or after-hours situation.

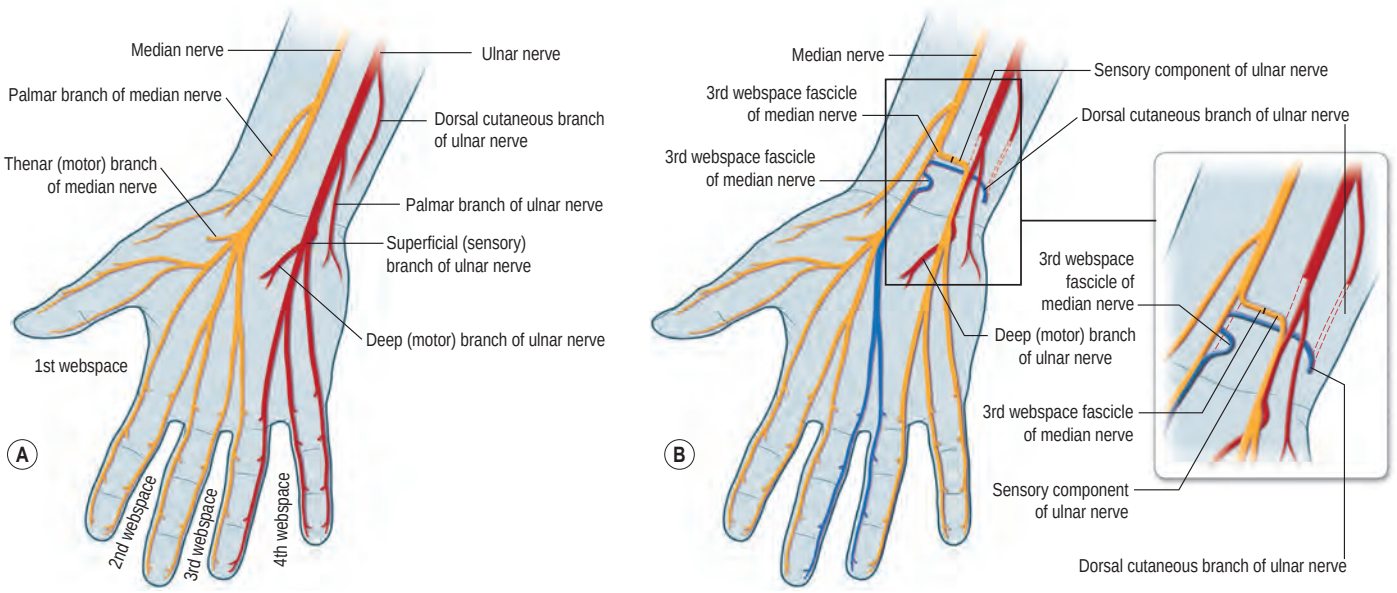

Fig. 33.23 Sensory nerve transfers to restore ulnar nerve deficit. A schematic of the triad of nerve transfers used to restore ulnar nerve sensation. **(A)** The functioning median nerve is shown in yellow and the non-functioning ulnar nerve is shown in red. **(B)** The triad of nerve transfers to restore sensation. (Inset) A magnified view of the nerve transfers illustrating the third webspace fascicle (donor) coapted end to end with the ulnar sensory (recipient), the distal dorsal cutaneous branch of the ulnar nerve (recipient) coapted end to side to the sensory side of the intact median nerve (donor), and the distal third webspace nerve coapted end to side to the median sensory to restore donor sensory loss.

Rehabilitation

All patients are introduced to our hand therapists prior to surgery and referrals for therapy are given at the first postoperative visit. Patients are instructed about wound and scar management, the need for protective splinting or sling use, and pain management. Wrist cock-up splints are used in patients with radial nerve injuries until reinnervation occurs. Supportive braces for patients with painful humeral subluxation at the glenohumeral joint due to loss of deltoid function can also be used. Education about their nerve transfer is provided, and retraining is discussed in the early postoperative period, long before clinical recovery will have occurred, to keep the motor cortex prepared for reinnervation.[34,35] The long-term focus of rehabilitation is on re-education, as the cortical command required to initiate target muscle function will differ from before. The patient will "relearn" motor control of the reinnervated target muscle by activating the nerve to the donor muscle, similar to the re-education required following tendon transfer. For restoration of sensation, as patients perceive input stimulus from the reinnervated territory, cortical remapping occurs. Patients are provided with written instructions about exercises as well as an anticipated timeline for recovery.

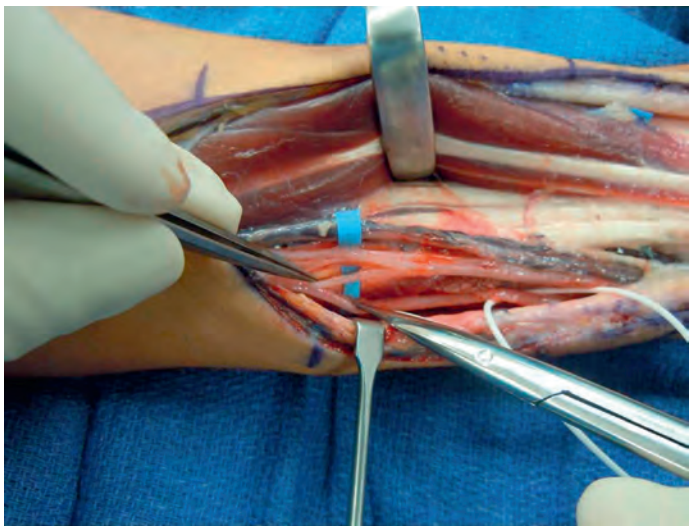

Fig. 33.24 Internal topography of the ulnar nerve in the distal forearm. A clinical photograph illustrating the internal topography of a neurolyzed ulnar nerve at the wrist. The tenotomy scissors are displacing the dorsal cutaneous branch of the ulnar nerve ulnarly, the microforceps are separating the deep motor branch fascicles ulnarly, and the remainder of the radial portion of the nerve is sensory. At this level, the topography of the ulnar nerve is sensory–motor–sensory in a radial to ulnar direction.

Prior to reinnervation, the focus is on maintaining full active and passive range of motion and on prevention of pain syndromes related to musculoskeletal imbalances associated with lost or impaired muscle strength. Therapists also work to optimize strength of uninvolved and donor muscles following transfer.

Once reinnervation has occurred, therapy is focused on strengthening. Maintaining full passive range of motion throughout is paramount. Patients may start by "strengthening the donor" and then advance to co-contracture activities as reinnervation proceeds. For example, this would include finger and wrist flexion with elbow flexion in double fascicular nerve transfer patients. Specific strategies involve repetitive motor co-contraction of the donor and recipient muscles, with and without passive assistance. The incorporation of resistance into the exercises is progressive as tolerated, starting with gravity completely eliminated and then against

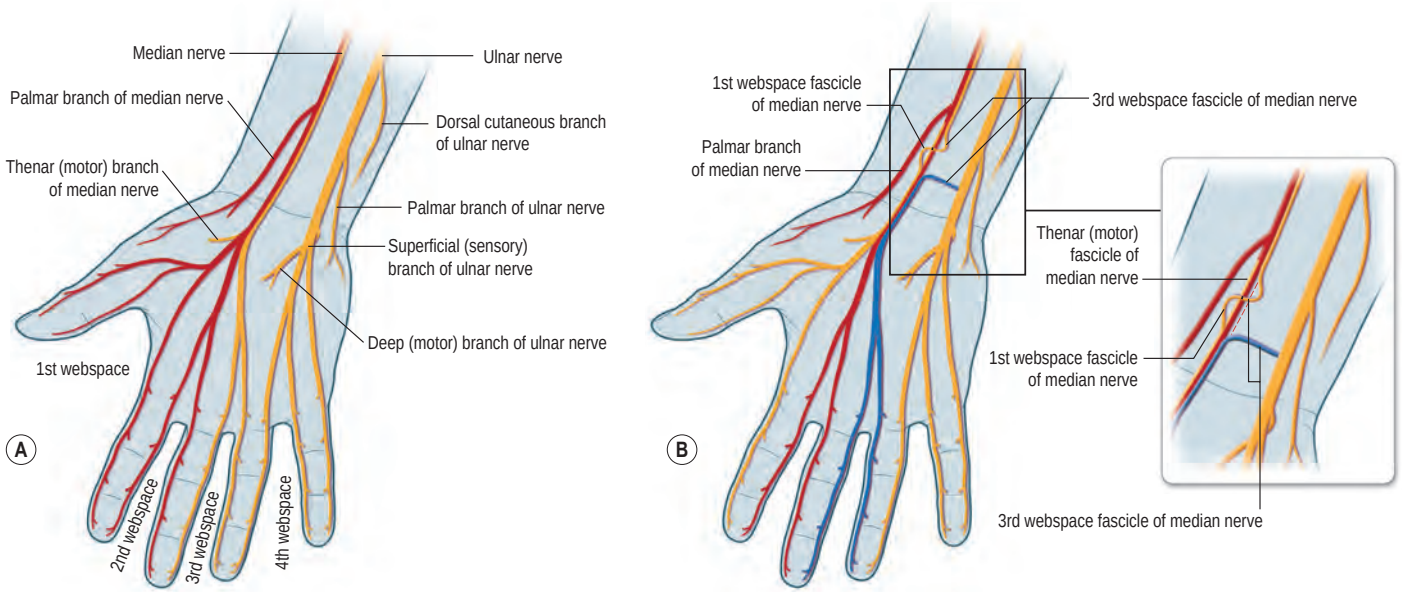

Fig. 33.25 Sensory nerve transfers to restore C5/C6 deficit. A schematic of sensory nerve transfers used to restore sensation to the first webspace following C5/C6 root injuries of the brachial plexus. **(A)** The non-functional nerves are visualized in red and the functioning nerves are yellow. **(B)** The ulnar and median nerves are used to restore sensation to the first webspace and the radial border of the thumb. (Inset) A magnified view of the nerve transfers illustrating end-to-end coaptation of the third webspace nerve (donor) to the first webspace nerve (recipient). The distal third webspace nerve is then coapted end to side with the sensory portion of the ulnar nerve to restore sensation to the donor third webspace.

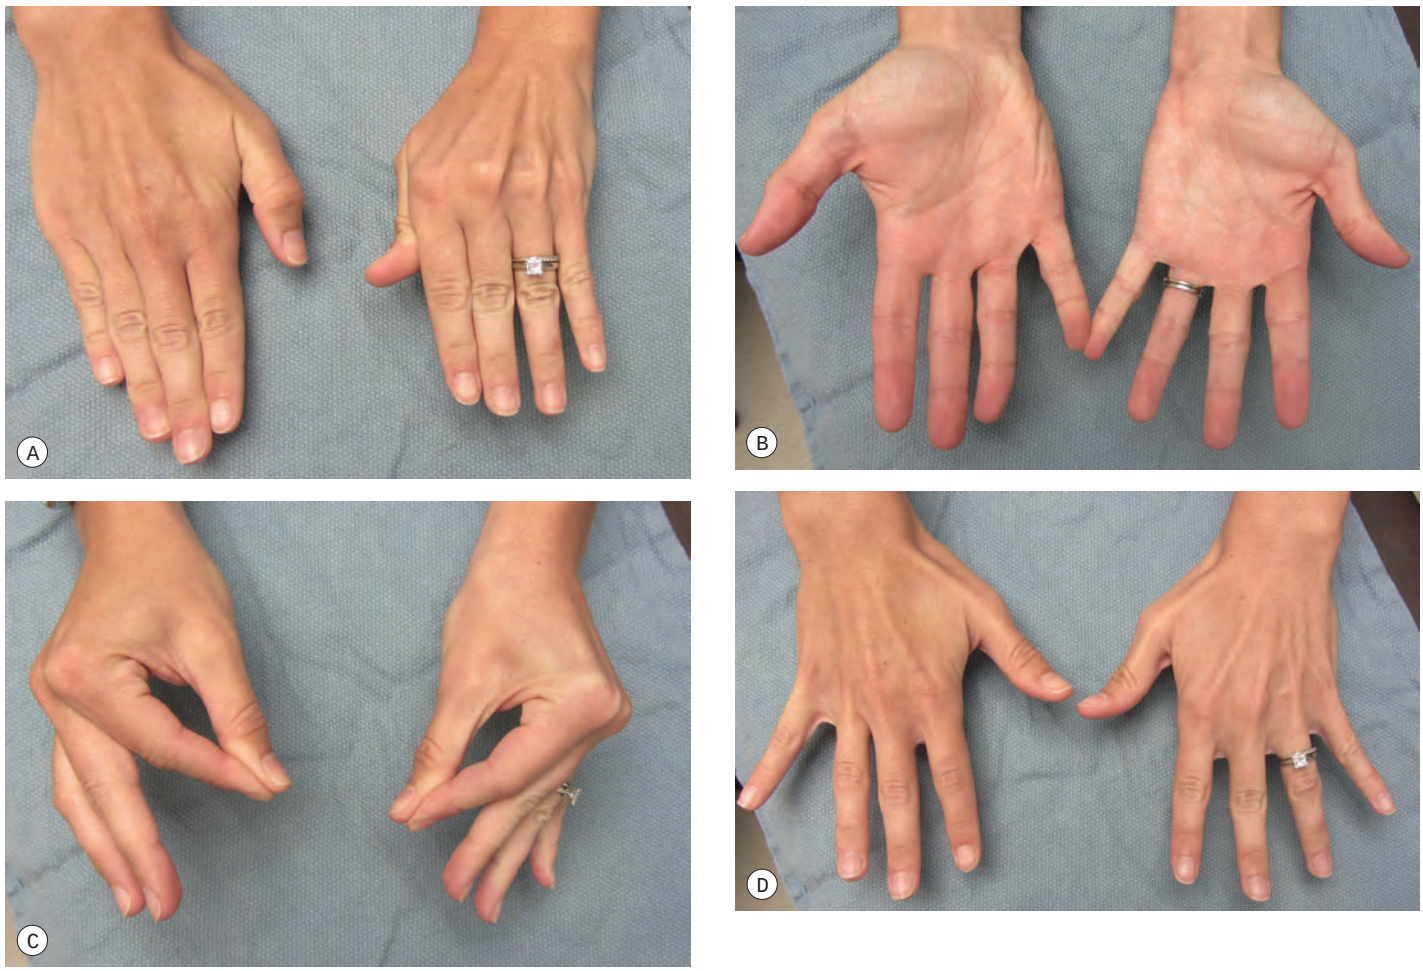

Fig. 33.26 (A–D) A 25-year-old right-handed female with a traumatic proximal ulnar nerve laceration. She underwent primary repair of the ulnar nerve transection at the time of initial injury by another surgeon. For timely restoration of intrinsic function, she underwent a distal nerve transfer procedure at 1 month post-injury. A distal anterior interosseous nerve (to pronator quadratus) to deep motor branch of ulnar nerve end-to-end coaptation was performed. At nearly 2 years post-injury, she has no significant clawing, improved strength (pinch of 18 on the right, 12 on the left; grip of 70 on the right, 60 on the left), and reasonable intrinsic function (intact abduction, adduction with simultaneous lumbrical plus positioning), residual Froment's sign and inability to cross the fingers. She has resumed all of her baseline work (desk job) and leisure (weightlifting) activities and is not interested in further surgery. *(© 2015 nervesurgery.wustl.edu.)*

gravity, and finally against resistance. Place-and-hold exercises facilitate strengthening. Resisted exercises are introduced much later, after good movement against gravity is obtained, to avoid overfatiguing the transfer and discouraging the patient.

In severe injuries, hand therapists can instruct patients in adaptive strategies for handedness retraining and performing activities of daily living with their impaired extremity. We have found that hand therapy is an integral part of the success of our nerve transfers.

Outcomes and prognosis

The evaluation of outcomes following brachial plexus and peripheral nerve reconstruction lacks standardization and objectivity, largely given the extent and variation of nerve injuries.[34] In addition, the expected outcomes vary with the initial injury, given that nerve transfer for a partial, distal nerve defect would be anticipated to have near-complete function following surgery compared to a pan-plexus type of injury presenting with a flail extremity, where expectations are significantly lower. Due to these difficulties, it is difficult to compare different surgical approaches with regard to patient outcome and prognosis; however, there have been numerous articles reporting favorable outcomes on an increasing number of nerve transfer options.

We feel shoulder function is best improved by reinnervation of both suprascapular and axillary nerves, confirmed in a large meta-analysis of 1088 nerve transfers.[21] Variable levels of transfer and incomplete inclusion of all the branches of the axillary nerve (to teres minor and the anterior, middle, and posterior deltoid) may, in part, explain the continued debate in the literature about the variable conclusions regarding the superiority of transfer versus direct repair or interposition grafting.[36–38] In a recent study by Garg *et al.*, the use of dual nerve transfers to restore shoulder and elbow function in C5/C6-level injuries was superior to the results of traditional nerve grafting.[39] In a clinical series of seven patients undergoing nerve transfer from triceps to axillary nerve, all patients recovered MRC 4/5 power. Five of the patients had excellent recoveries and 2 showed good results.[40]

The double fascicular nerve transfer has been evaluated with long-term follow-up in more than one study, and all patients were noted to achieve at least MRC grade 4 of 5 function with no appreciable donor deficit. Innervation was noted at a mean of 5.5 months postoperatively.[22]

In medial pectoral to musculocutaneous nerve transfers with an interpositional lateral antebrachial cutaneous nerve graft, three of four patients achieved MRC grade 4 of 5 elbow flexion, and the last, MRC grade 3 of 5. Reinnervation was first noted at 6–8 months postoperatively.[5]

Restoration of radial nerve function in the forearm using expendable branches of the median nerve has demonstrated predictable results, with MRC grade 4 of 5 wrist and finger extension by 1 year.[41]

In another series, eight patients undergoing transfer of the distal AIN to the deep motor branch of the ulnar nerve were evaluated. All patients had reinnervation of the ulnar intrinsic muscles facilitating grip and lateral pinch strength. No patient required anticlaw procedures. None of the patients had a deficit in pronation associated with AIN transfer (Fig. 33.26A–D). A single patient required a secondary tendon transfer to improve small-finger adduction.[9]

Inevitably, the literature contains much controversy regarding the outcomes following nerve transfers, and longer follow-up is required to assess the success of these novel procedures. This is particularly true because the continued effect of cortical remodeling as demonstrated with functional MRI studies as well as gradual strengthening and incorporation of the restored function has been shown to continue for as long as 5 years or more post-transfer surgery. It seems clear, however, that the exponential increase in publications related to nerve transfers demonstrates that nerve transfers can no longer be considered experimental, and are rivaling other procedures in the treatment of severe brachial plexus and many other peripheral nerve injuries.

Secondary procedures

Given the devastating nature of brachial plexus and proximal nerve injuries, it is inevitable that nerve transfers are not successful in every circumstance. Where concern exists regarding the likelihood of functional recovery, adjunct procedures are performed to augment the nerve transfer.

In the event of a failed nerve transfer and the necessity of further secondary procedures, there are several important considerations. When planning nerve transfers, one must consider the possible salvage procedures required should the transfer fail. Thus, when deciding on donor nerve, it is prudent to ensure that options are left for later (for example, avoiding the harvest of redundant fascicles to both flexor carpi radialis and FCU). A donor for tendon transfer requires MRC grade 5 of 5 strength because following transfer it will be downgraded by a minimum of one grade. This becomes especially challenging in patients with multiple nerve injuries, and illustrates the importance of an accurate and detailed physical examination at preoperative assessment.

Hints and tips

Avoid using a donor nerve that may be required for a secondary procedure such as a tendon transfer down the road. Prior to cutting a donor nerve, make sure the rest of the nerve performs all essential functions with fastidious intraoperative nerve stimulation.

Tendon transfers have the benefit of not being restricted by time, given that distal motor denervation and fibrosis do not affect the outcome. For this reason, there is no harm in attempting a nerve transfer as a primary procedure (as long as it is completed within the timeframe to achieve motor reinnervation, which is approximately within 12 months post-injury), and reserving the tendon transfer for a secondary procedure if the functional outcome is less than desired.

Nerve transfers should not be attempted if there are not suitable, redundant, available donors, as in the setting of a multinerve injury. In this setting, nerve grafting combined with tendon transfer, or even arthrodesis, may be warranted.

In our experience, secondary procedures are rarely required following nerve transfer. However, we are diligent about considering options when planning our initial procedure.

Future directions

Nerve transfer techniques have proved to be a powerful tool to restore meaning function. More recent work expands their application in a variety of directions.

In peripheral nerve and brachial plexus injury, novel combinations of sensory and motor transfers[42–45] based on the principles of expendable donor, appropriate recipient and knowledge of internal topography continue to expand the literature. Early reports of adaptation to lower extremity nerve injury patterns,[46–49] while more limited by the greater distances to target, are encouraging. Broadened applications to pediatrics[50,51] and central nervous system disorders such as spinal cord injury[52–59] and transverse myelitis[60] will require a cautious approach and ongoing study to avoid potential harms in these complicated and vulnerable patients.

Tendon transfer for reconstruction of the wrist and hand

Neil F. Jones

SYNOPSIS

- Tendon transfers in the upper limb are indicated to restore function to paralyzed muscle and tendon following nerve injury, direct muscle or tendon injury, and to restore balance to hands affected by neurological disease.
- In selecting donor tissue, the surgeon has to consider expendability of the muscle–tendon unit, the native strength of donor and paralyzed muscle, and the direction of transfer and integrity of the muscle.
- The timing of tendon transfers can be classified as early, conventional, or late.
- Upper extremity neurological injury can be subdivided into radial nerve palsy, low and high median nerve palsy, low and high ulnar nerve palsy, and combined nerve injuries.

Introduction

Tendon transfers are reconstructive techniques that will restore motion or balance to the hand lost secondary to impaired or absent function of the extrinsic or intrinsic muscle–tendon units of the forearm and hand. In a typical tendon transfer, the tendon of insertion of a functioning muscle is detached, mobilized, and then reattached to another tendon or bone to substitute for the action of a non-functioning muscle–tendon unit. Very occasionally, both the tendon of origin and the tendon of insertion are detached and then reattached at different locations. Unlike a tendon graft, the transferred donor tendon remains attached to its parent muscle. A tendon transfer also differs from a microsurgical free muscle transfer in that the neurovascular pedicle to the muscle of the transferred tendon remains intact.

There are three general indications for tendon transfers in the upper extremity:

1. To restore function to a paralyzed muscle due to injuries of the peripheral nerves, the brachial plexus, or the spinal cord.
2. To restore function following closed tendon ruptures or open injuries to the tendons or muscles.
3. To restore balance to a deformed hand due to various neurological diseases.

Tendon transfers are best conceptualized as a means to restore a lost "function", rather than a means of substituting for a specific muscle, i.e., restoring strong pinch as opposed to restoring function of the flexor pollicis longus. Tendon transfers are performed predominantly following peripheral nerve injuries and therefore will be discussed according to the three specific nerve palsies. However, the general principles described in this chapter apply to all transfers (Table 34.1).

General principles

Bone and soft-tissue healing

Steindler[1] first suggested that tendon transfers cannot glide through edematous or scarred soft tissues, nor can they flex or extend stiff metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints. He therefore advocated that tendon transfers be delayed until "tissue equilibrium" had been restored. Before a tendon transfer is performed, all fractures should be healed or rigidly fixed by internal fixation. Chronic scarred skin and subcutaneous tissues or skin grafts in the projected line of pull of a tendon transfer should be excised and the defect resurfaced with a flap that itself is allowed to heal and the new scars become mature. If secondary tendon transfers are likely to be necessary, initial split-thickness skin grafting of soft-tissue defects of the hand and forearm, simply to achieve a healed wound, should be avoided if possible. Instead, a pliable flap ideally of skin and subcutaneous tissues should be considered, either as a delayed primary coverage using pedicled flaps such as the groin flap and reverse radial forearm flap or free flaps such as the lateral arm flap, contralateral radial forearm flap, scapular flap, and latissimus dorsi flap. Occasionally, silicone rods can be placed

Table 34.1 Basic principles of tendon transfers
Soft-tissue "equilibrium"

Adequate amplitude of donor muscle
Direct line of pull
Single function for each transferred tendon
Synergy of transfer

at the time of flap coverage, either beneath or through the subcutaneous fat of a transferred flap to create a smooth tunnel through which a tendon transfer may be later passed. The span of the thumb–index finger webspace should be maintained by splinting, especially following median nerve injuries. If a secondary adduction contracture has developed, this should be released by a Z-plasty, skin grafting, or transposition flap, and release of the adductor pollicis if needed, prior to any opposition tendon transfer. Full passive range of motion of the MCP and PIP joints should be achieved by physical therapy and dynamic splinting prior to any tendon transfer. Preliminary capsulotomies of the MCP and PIP joints or tenolysis of adherent flexor or extensor tendons may occasionally be required if dynamic splinting fails to achieve adequate joint mobility.

Selection of donor muscle–tendon

Expendability

The muscle–tendon unit selected as a potential donor for transfer must be expendable. Its sacrifice must not create an important new deficit. For example, the ring finger flexor digitorum superficialis (FDS) tendon may be used to correct MCP hyperextension (claw deformity) in patients with a low ulnar nerve palsy, but it is not expendable in patients with a high ulnar nerve palsy who have no functioning flexor digitorum profundus (FDP) tendon to the ring finger. The selection of a muscle–tendon unit as a tendon transfer may also be influenced by the patient's occupation. For example, the flexor carpi radialis (FCR) may be a more appropriate transfer to provide finger extension in a working man rather than the more conventional flexor carpi ulnaris (FCU) transfer, since the FCU provides the important function of flexion and ulnar deviation of the wrist needed in work activities such as hammering. More importantly, if multiple tendon transfers are required, a minimum of one wrist flexor, one wrist extensor, and one extrinsic flexor and extensor tendon to each digit should always be retained.

Clinical tips

- Full passive range of motion of the MCP and PIP joints should be achieved before considering any tendon transfers.
- The selected donor muscle–tendon unit must be expendable.
- One wrist flexor, one wrist extensor, one extrinsic flexor, and one extrinsic extensor tendon to each digit should always be retained.

- Potential amplitude of donor muscle–tendon units:
  - Finger flexors – 70 mm;
  - Finger extensors – 50 mm;
  - Wrist flexors and extensors – 33 mm.

Strength

In selecting the most appropriate donor muscle–tendon, the surgeon must consider not only the strength of the muscle to be transferred, but also the native strength of the now paralyzed muscle or muscles and the strength of the antagonist muscle.[2] Brand[3,4] has emphasized that the maximum potential force of a muscle is directly proportional to its physiologic cross-sectional area. It has been calculated that a muscle can produce a force of 3.65 kg per square centimeter of its cross-sectional area. This potential force is maximal when the muscle is at its resting length which is defined as the position midway between the length when it is fully stretched passively and when it is fully contracted.

Amplitude

The potential amplitude or excursion of a donor muscle–tendon unit must also be sufficient to restore the specific lost function. The finger flexors have an amplitude of 70 mm, the finger extensors 50 mm and the wrist flexors and extensors 33 mm. The tenodesis effect of wrist flexion or extension may also increase the effective amplitude of a tendon transfer by 25 mm (Fig. 34.1). Excursion of a donor muscle may also be increased by extensive release of its surrounding fascia and is best exemplified by transfer of the brachioradialis (BR) muscle. The distal portion and tendon of the brachioradialis muscle are surrounded by dense fascia. Release of these fascial attachments will add an additional 2–3 cm of passive excursion.

Clinical tips

- The potential amplitude of a donor wrist extensor tendon may be increased by 20 mm to produce an effective amplitude by the tenodesis effect of wrist extension.
- The potential amplitude of a donor wrist flexor tendon can be increased by 20 mm to produce an effective amplitude by the tenodesis effect of wrist flexion.

Direction of transfer and integrity

A tendon transfer should pass in a direct line from the origin of the donor muscle to its new insertion. Unless early tendon transfers are being performed, when there is still a chance of reinnervation following nerve repair, the recipient tendons should be divided proximal to the site of the tendon juncture to create a more direct line of pull (end-to-end) rather than producing a Y- shaped end-to-side juncture. Tendon transfers should only act across one joint and only perform one single function. This maintains the "integrity" of the muscle. However, a transfer may be inserted into several recipient tendons as long as they each perform the same function in adjacent digits. Finally, the donor muscle selected should

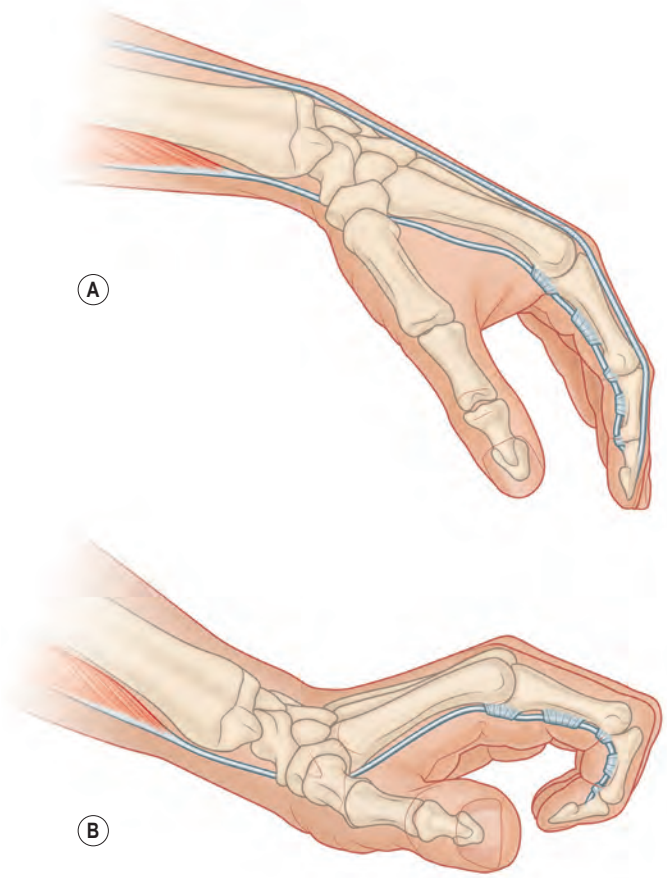

Fig. 34.1 **(A)** The wrist tenodesis effect: Wrist flexion will increase the potential amplitude of a tendon transfer to restore finger extension by 20 mm. **(B)** Similarly, wrist extension will increase the potential amplitude of a tendon transfer to restore finger flexion by 20 mm.

preferably be synergistic with the function of the muscle to be restored or at least be potentially retrainable.

The surgeon has to determine the specific functions to be restored, select the appropriate donor muscle–tendon units, and decide on the timing of the tendon transfer. To make this selection, every muscle still functioning in the forearm and hand should be tested by manual muscle testing to document which ones are functioning and their strength graded. From this list of functioning muscles, only those that are expendable are available as donor transfers. The specific functions of the hand that need to be restored are then listed in order of priority. The final step is to match the available donor muscles with the functions that need to be restored, based on the force, amplitude, and direction of the various muscles available. Arthrodesis of a more proximal joint such as the wrist may occasionally need to be considered to release a wrist flexor or extensor tendon for transfer. Transfers that require postoperative immobilization with the wrist in flexion are usually performed at a first stage. Those transfers requiring postoperative immobilization with the wrist in extension are performed at a second stage.

Clinical tips

- Document which muscles are functioning and their individual strengths.
- Only the expendable muscles in this group of functioning muscles can be considered as potential donor transfers.
- List the specific hand functions that need to be restored, in order of priority.
- Match the available expendable donor muscles with the hand functions to be restored.

Timing of tendon transfers

Timing of tendon transfers may be classified as early, conventional, or late. A conventional tendon transfer is usually performed after reinnervation of the paralyzed muscle fails to occur by 3 months after the expected time of reinnervation based on the rate of nerve regeneration of 1 mm/day. Brand,[3] Omer,[5] and Burkhalter[6] have advocated "early" tendon transfers in certain circumstances, in which a tendon transfer is performed simultaneously with the nerve repair or before the expected time of reinnervation of the muscle. This "early" tendon transfer therefore serves as a temporary substitute for the paralyzed muscle until reinnervation occurs, by acting as an "internal splint". If reinnervation is suboptimal, the "early" tendon transfer acts as a helper to augment the power of the muscle and if reinnervation fails to occur it then acts as a permanent substitute.

Surgical techniques

The success of any tendon transfer depends entirely on preventing scarring or adhesions along the path of the transferred tendon. Incisions should be carefully planned prior to elevation of the tourniquet so that the final tendon junctures lie transversely beneath skin flaps rather than lying immediately beneath and paralleling the incisions. The donor muscle should be carefully mobilized to prevent damage to its neurovascular bundle which usually enters in the proximal third of the muscle. The transferred tendon should glide in a tunnel through the subcutaneous tissues and not cross bone devoid of uninjured periosteum nor pass through small fascial windows. Only the distal end of the tendon should be grasped with surgical instruments and care taken to prevent desiccation of the tendon or the surrounding tissues. Tendon junctures are performed using a Pulvertaft weave technique when possible. The donor and recipient tendons are sutured under normal tension and after one or two non-absorbable sutures have been inserted, the tension of the transfer is checked by observing the flexion and extension of the digit during tenodesis of the wrist. Postoperatively the hand is immobilized in the desired position for 3–4 weeks, at which time gentle active range of motion exercises are started, usually under the supervision of a therapist, but the hand is protected for a further 3 weeks in a lightweight protective splint.

Clinical tips

- Carefully design the incisions not only to allow dissection of the donor muscle–tendon unit, but also so that the tendon junctures lie beneath an elevated skin flap, rather than immediately beneath the incision, to prevent adhesions that will restrict gliding of the tendon transfer.
- The recipient tendon should be fully distracted to produce maximal function of the recipient tendon and the donor tendon transfer should be sutured at its resting length to the recipient tendon using a Pulvertaft weave technique.
- Correct tensioning of the tendon transfer is checked by observing flexion and extension of the digits or abduction and adduction of the thumb during tenodesis of the wrist.

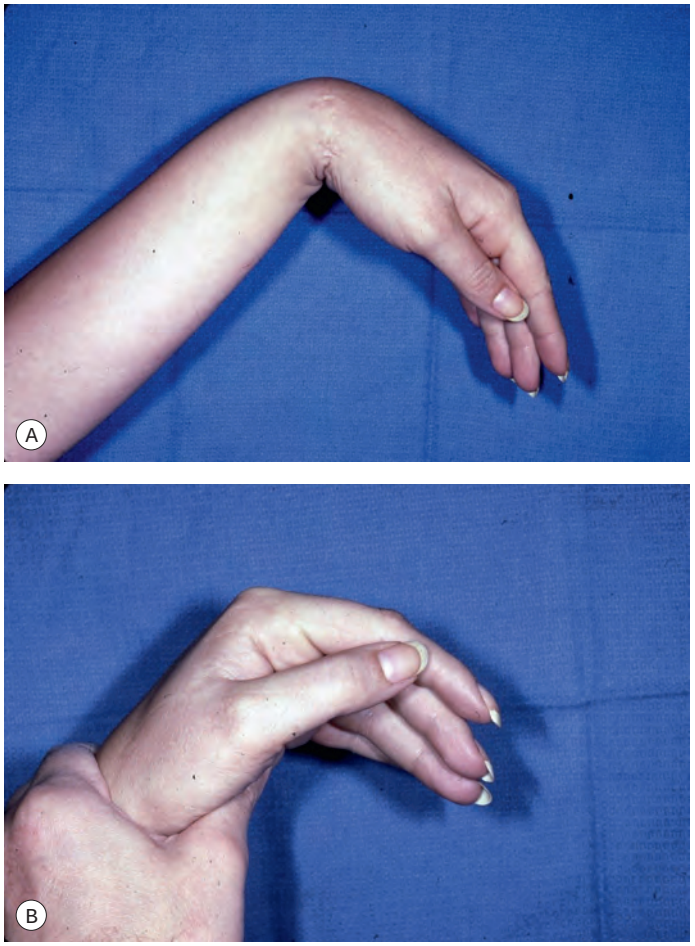

Fig. 34.2 **(A)** Typical appearance of a patient with radial nerve palsy with wrist drop. The fingers extend at the proximal interphalangeal joints through the tenodesis effect. **(B)** Even with the wrist supported in extension, the patient is unable to actively extend the fingers at the metacarpophalangeal joints or extend the thumb.

Radial nerve palsy

Indications

The functional motor deficit in radial nerve palsy consists of inability to extend the wrist, inability to extend the fingers at the MCP joints, and inability to extend and radially abduct the thumb (Fig. 34.2). However, the most significant disability is that patients are unable to stabilize their wrist, so that transmission of flexor power to their fingers is impaired resulting in marked weakness of grip strength.

Tendon transfers are therefore required to provide wrist extension, extension of the fingers at the MCP joints, and extension and radial abduction of the thumb. Unlike the median and ulnar nerves, sensory loss following radial nerve injury is not functionally disabling unless the patient develops a painful neuroma.

Timing

Timing of tendon transfers for radial nerve palsy remains controversial. The two options are either to perform an "early" tendon transfer simultaneously with repair of the radial nerve to act as an "internal splint" to provide immediate restoration of power grip; or more conventionally, to delay any tendon transfers until reinnervation of the most proximal muscles, brachioradialis and extensor carpi radialis longus fails to occur within the calculated time limit. The more proximal the nerve injury, the less likely that functional muscle reinnervation will occur.[3,6] If the nerve remains in continuity, most surgeons would suggests that 3 months of observation are indicated to await spontaneous recovery in peripheral nerve palsies.

Ring *et al*.[7] reviewed 24 patients with a complete radial nerve palsy associated with a high-energy humeral fracture. Six of 11 open fractures had a transected radial nerve and none of the five patients who underwent primary repair of the radial nerve recovered any function. All eight nerves that were explored and found to be intact and 9 of 10 unexplored nerves recovered completely, with initial signs of recovery at an average of 7 weeks and full recovery at an average of 6 months. The authors concluded that primary repair of a transected radial nerve associated with a high-energy humerus fracture was very poor, but the prognosis for full recovery of an intact radial nerve, whether the fracture is open or closed, was very good. Mayer and Mayfield[8] reported 39 cases of posterior interosseous nerve (PIN) neurorrhaphy with complete recovery in 28 and partial recovery in 11 patients. Young *et al*.[9] studied 51 patients with PIN palsy and only 11 had resolved by 3 months. Of the remaining 40 patients, 20 of the 23 who underwent neurolysis and 10 of the 12 who underwent nerve grafting had excellent or good results. A conflicting study of radial nerve injuries demonstrated useful function in 65%, but only 38% of patients who underwent nerve grafting obtained useful motor function.[10] These studies demonstrate that injury and repair of the radial and PIN nerves can provide significant return of function and should be considered. With extensive nerve gaps or associated soft-tissue injuries or in older patients, the chances of successful reinnervation are much less predictable and it may therefore be more appropriate for these patients to undergo the full set of tendon transfers early.[11] In a patient awaiting return of nerve function, it is important to maintain supple MCP joints capable of full extension and adequate radial abduction of the thumb with appropriate splinting and therapy.

Operations

Franke provided one of the earliest descriptions of tendon transfers for radial nerve palsy using the FCU to extensor digitorum communis (EDC) transfer through the interosseous membrane.[12] Capellen in 1899 described the FCR to extensor pollicis longus (EPL) transfer. The pronator teres (PT) to extensor carpi radialis longus (ECRL) and the extensor carpi radialis brevis (ECRB) transfer for wrist extension was first reported in 1906 by Sir Robert Jones. Zachary[13] emphasized the importance of retaining at least one wrist flexor, preferably the FCR to facilitate wrist control. Other authors have suggested that FCU is not an expendable tendon and therefore prefer to use the FCR as the donor tendon to restore finger extension.[14] The advantage of using FCR is that it preserves the important vector of wrist flexion and ulnar deviation which is so important for power grip in a working man. This is particularly true in the patient with a posterior interosseous nerve (PIN) palsy, in which ECRL function is preserved but extensor carpi ulnaris (ECU) activity is lost. This leads to radial deviation of the wrist with attempted wrist extension. Use of the FCU in this setting will therefore increase the radial deviation of the wrist, since only radially deviating wrist motors are preserved.

Several different tendon transfers have been reported for radial nerve palsy but three patterns of transfer have evolved.[15,16] The use of pronator teres (PT) to provide wrist extension has become universally accepted, the only remaining controversy being whether to insert pronator teres into extensor carpi radialis brevis (ECRB) alone or into both extensor carpi radialis longus (ECRL) and extensor carpi radialis brevis. The three patterns of tendon transfer differ therefore only in the technique of restoring finger extension and thumb extension and radial abduction (Table 34.2).[13,17–19]

Standard FCU transfer (Figs. 34.3–34.5)

In the patient with a radial nerve palsy, the FCU transfer is the author's preferred technique; in the patient with a PIN palsy, the FCR transfer is preferred. Through an inverted J-shaped incision over the ulnar–volar aspect of the distal forearm, the FCU tendon is transected at the wrist crease and released extensively from its fascial attachments up into the proximal third of the forearm, taking care not to damage the neurovascular pedicle, using a second incision in the proximal forearm if necessary (see Figs. 34.4 & 34.6). Through the same distal incision, the palmaris longus (PL) tendon is transected at the wrist crease and the muscle mobilized into the middle third of the forearm (see Figs. 34.5 & 34.6). An S-shaped incision is then made beginning over the volar-radial aspect of the middle third of the forearm and passing dorsally and ulnarly over the radial border of the forearm. The tendon of pronator teres is elevated from the radius in continuity with a 2–3 cm strip of periosteum (see Fig. 34.3). The ECRB is transected at its musculotendinous junction if there is no chance of future reinnervation of the wrist extensors. The pronator teres is then re-routed around the radial border of the forearm superficial to the brachioradialis and extensor carpi radialis longus in a straight direction to its insertion into ECRB (see Fig. 34.3). The FCU tendon is passed through a subcutaneous tunnel made with a Kelly clamp from the

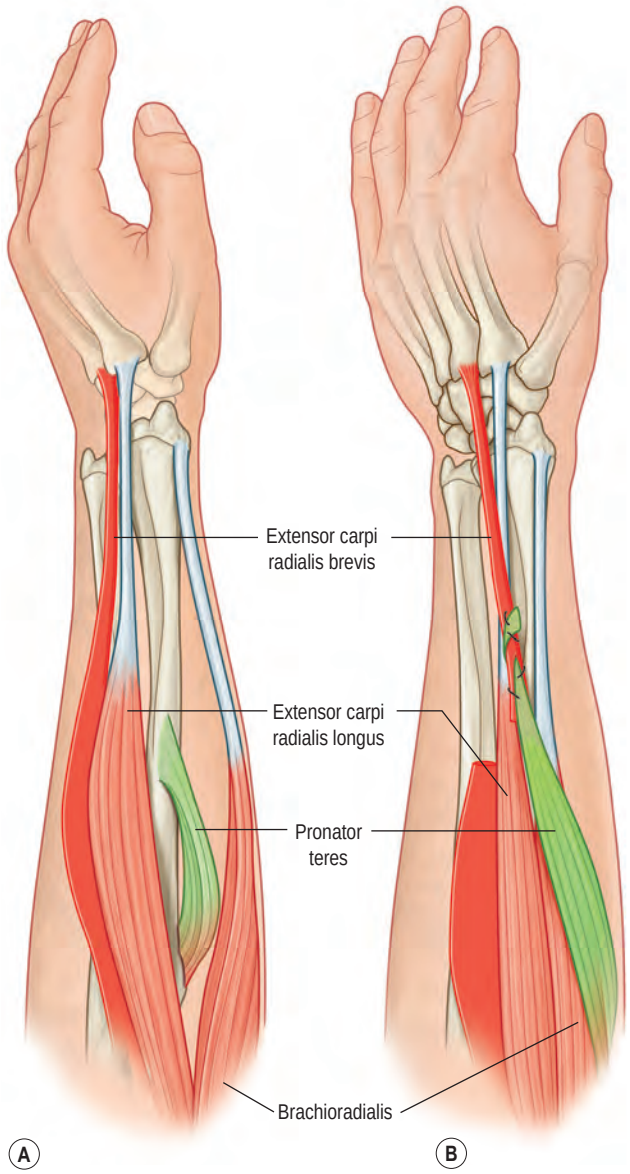

Fig. 34.3 **(A)** The insertion of pronator teres is released from the radius, if necessary, extended by a strip of periosteum. **(B)** The pronator teres is passed around the radial border of the forearm superficial to brachioradialis and sutured to the transected tendon of extensor carpi radialis brevis.

Table 34.2 Tendon transfers for radial nerve palsy

Standard FCU transfer	FCR transfer	Boyes superficialis transfer
PT to ECRB	PT to ECRB	PT to ECRB
FCU to EDC	FCR to EDC	FDS of ring finger to EDC long, ring, and small fingers
PL to EPL	PL to EPL	FDS long finger to EIP and EPL (FCR to APL and EPB)

APL, Abductor pollicis longus; ECRB, extensor carpi radialis brevis; EDC, extensor digitorum communis; EIP, extensor indicis proprius; EPB, extensor pollicis brevis; EPL, extensor pollicis longus; FCR, flexor carpi radialis; FCU, flexor carpi ulnaris; FDS, flexor digitorum superficialis; PL, palmaris longus; PT, pronator teres.

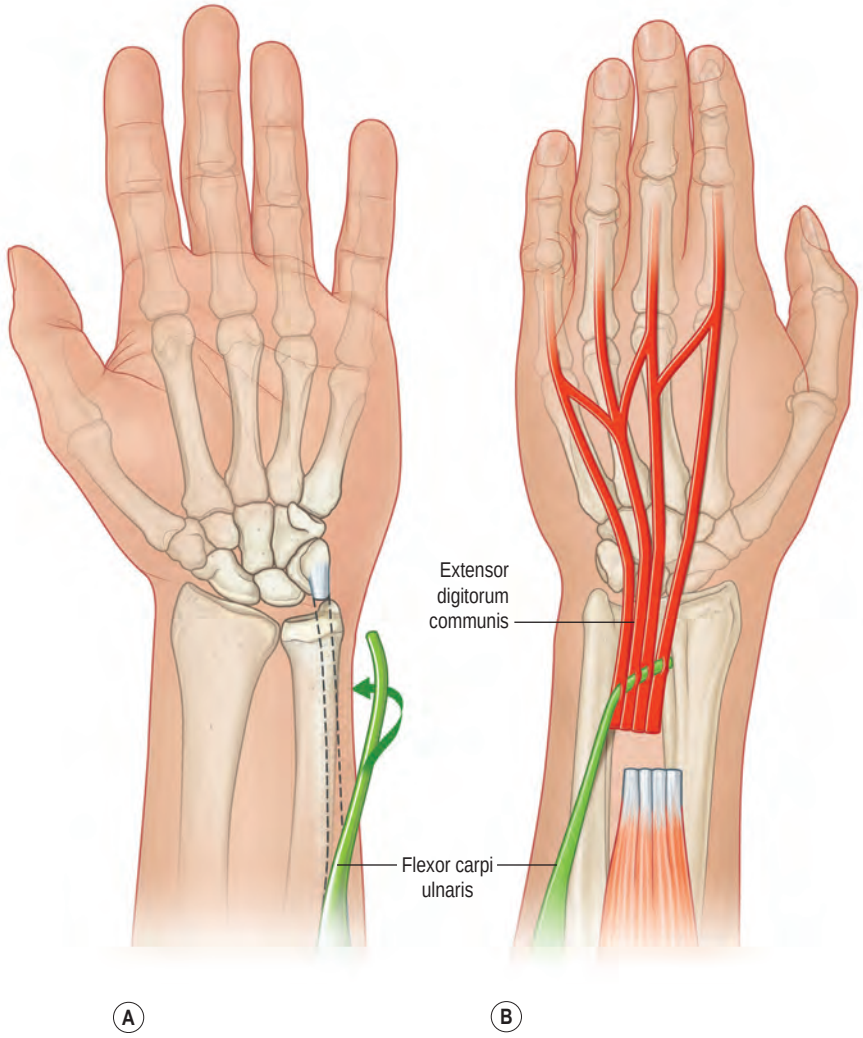

Fig. 34.4 (A) The flexor carpi ulnaris tendon is transected and passed around the ulnar border of the distal forearm and **(B)** woven into the combined extensor digitorum communis tendons proximal to the extensor retinaculum.

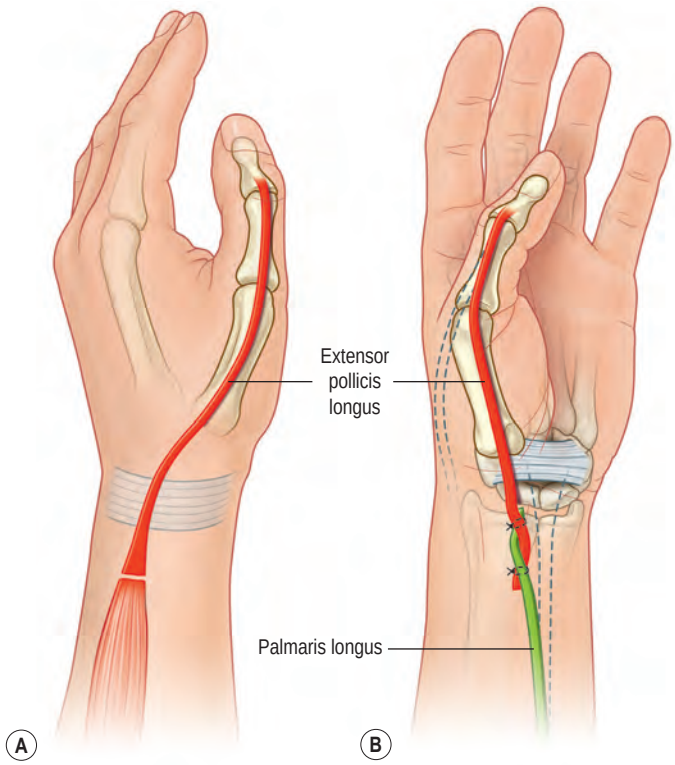

Fig. 34.5 (A) The extensor pollicis longus tendon is transected at its musculotendinous junction, **(B)** re-routed into the anterior aspect of the distal forearm and attached to the palmaris longus, if present, to provide both thumb extension and some radial abduction.

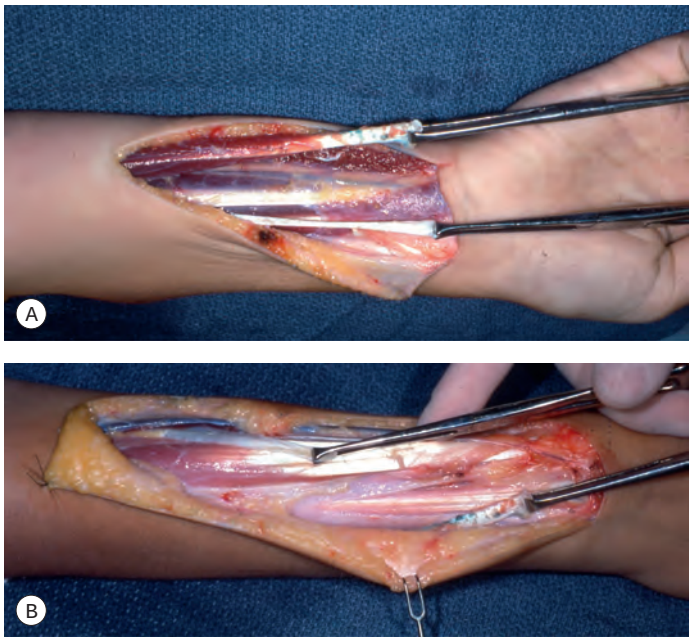

Fig. 34.6 (A) Through a volar incision in the distal third of the forearm, the flexor carpi ulnaris (FCU) tendon and its distal muscle and the palmaris longus tendon are isolated. **(B)** The pronator teres tendon is passed around the radial border of the forearm and sutured to extensor carpi radialis brevis. The FCU tendon is passed around the ulnar border of the distal forearm and sutured to the extensor digitorum communis tendons.

proximal incision used to mobilize FCU, around the ulnar border of the forearm into the dorsal incision, to lie obliquely across the EDC tendons proximal to the extensor retinaculum (see Fig. 34.6). Alternatively, the FCU tendon may be passed from the palmar incision to the dorsal incision through a window in the interosseous membrane.[20] If no return of EDC function is to be expected, the EDC tendons can be transected at their musculotendinous junctions so that a more direct line of pull can be achieved. Otherwise an end-to-side juncture is performed. The extensor pollicis longus (EPL) tendon is divided at its musculotendinous junction, removed from the third dorsal extensor tendon compartment, and passed through a subcutaneous tunnel from the base of the thumb metacarpal to the volar wrist incision (see Fig. 34.5). If the PL is absent, the EPL tendon is included with the EDC tendons and the FCU transfer provides both finger and thumb extension. To prevent a collapse flexion deformity at the carpometacarpal joint of the thumb, tenodesis of the abductor pollicis longus may be necessary. After transection of the APL tendon in the distal forearm, it is looped around the brachioradialis proximal to the radial styloid and sutured to itself with the thumb metacarpal held in extension with the wrist in 30° of extension.

The proper tension in radial nerve tendon transfers should be tight enough to provide full extension of the wrist and digits but without restricting full flexion of the digits when the wrist is fully extended. The pronator teres at its resting tension is woven through the ECRB tendon with the wrist in 45° of extension. The distal ends of the four EDC tendons to the index, long, ring and small fingers are sutured to the FCU tendon proximal to the extensor retinaculum. The extensor digiti minimi is usually not included unless there is still an extensor lag when proximal traction is applied to the EDC tendon to the small finger. With the wrist in neutral and FCU under maximal tension, each individual EDC tendon is sutured to provide full extension at the MCP joint, starting with the index finger and finishing with the small finger. Appropriate tension is then evaluated by checking that all four digits extend synchronously when the wrist is palmar flexed and most importantly that all four digits can be passively flexed into a fist when the wrist is extended. Finally, palmaris longus and extensor pollicis longus are interwoven over the radiovolar aspect of the wrist with the thumb in maximal extension and the wrist in neutral with the PL tendon at its resting tension. The wrist is immobilized in 45° of extension in a volar splint with the MCP joints positioned in slight flexion and the thumb in full extension and abduction.

Active flexion and extension of the fingers and thumb are started at 3½ to 4 weeks and active exercises of the wrist begun at 5 weeks. Protective splinting is continued until 6 to 8 weeks postoperatively. Results have been uniformly good (Fig. 34.7).

FCR transfer (Fig. 34.8)

The skin incision begins from the radiovolar aspect of the mid-forearm and extends dorsally over the third and fourth extensor tendon compartments. The pronator teres is transferred to the extensor carpi radialis brevis and the palmaris longus is transferred to the extensor pollicis longus exactly as described in the standard FCU transfer. The FCR tendon is divided at the wrist crease and mobilized approximately to the level of the mid-forearm and re-routed around the radial border of the forearm. The four EDC tendons, and if necessary the EDM, may be woven through the donor FCR tendon proximal to the extensor retinaculum, but more usually the extensor tendons need to be re-routed superficial to the extensor retinaculum to obtain a straighter line of pull (see Fig. 34.8). To prevent a bulky tendon juncture, the small finger EDC and EDM may be sutured side-to-side to the ring finger EDC and the index finger EDC sutured side-to-side to the long finger EDC under appropriate tension. Then only the two EDC tendons to the long and ring fingers require weaving through the FCR tendon. As with the standard FCU transfer,

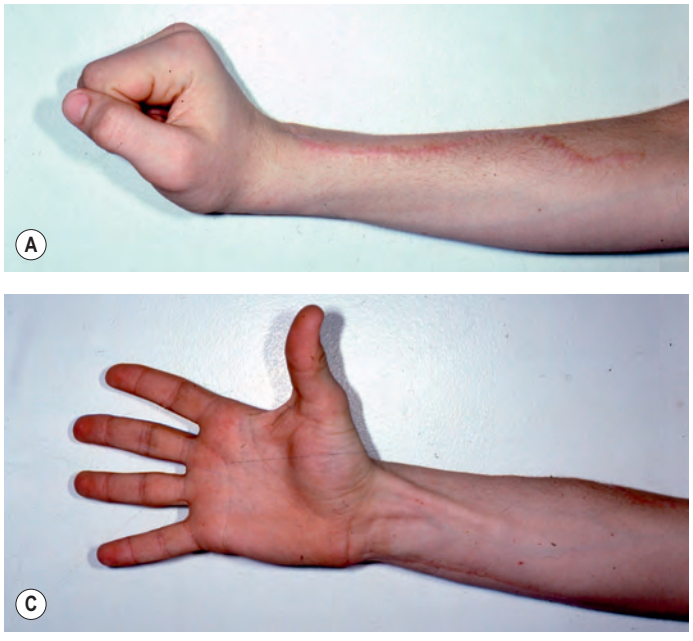

Fig. 34.7 **(A)** The patient 3 years following pronator teres to extensor carpi radialis brevis transfer showing wrist extension and satisfactory finger flexion; **(B)** full extension of the fingers at the metacarpophalangeal joints; and **(C)** excellent thumb extension and radial abduction.

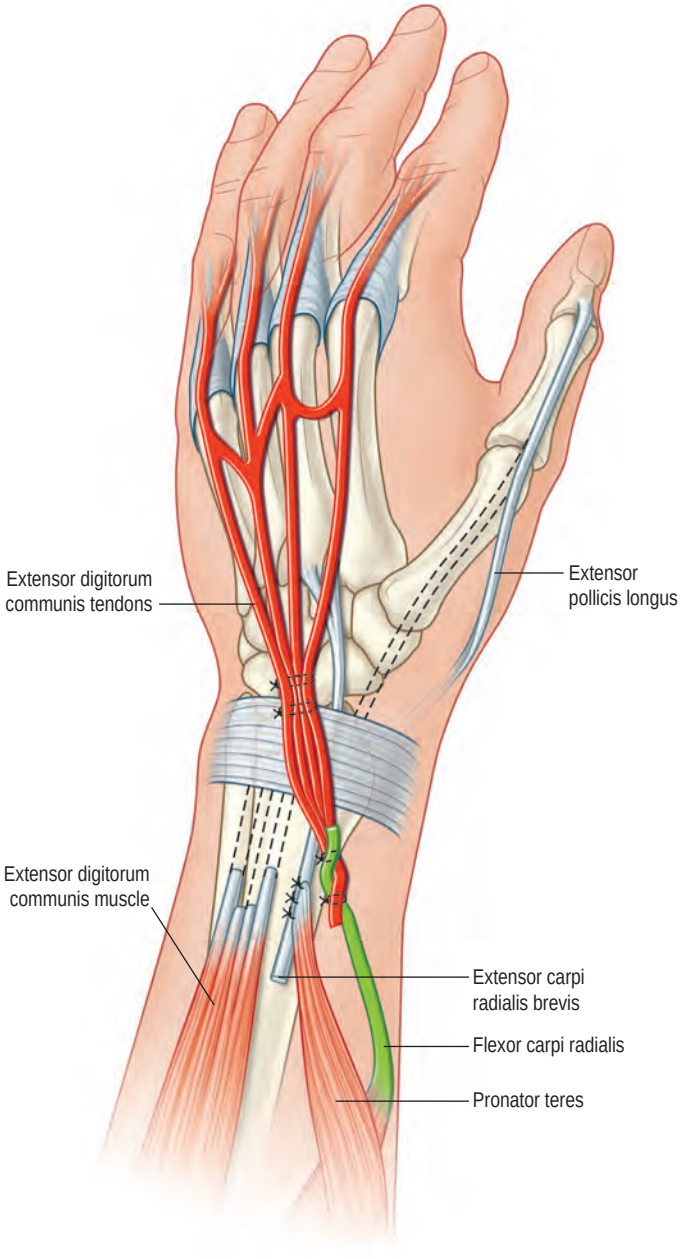

Fig. 34.8 Flexor carpi radialis transfer to the combined tendons of extensor digitorum communis. The tendon juncture may have to lie superficial to the extensor retinaculum. Tendon transfers of pronator teres to extensor carpi radialis brevis and palmaris longus to extensor pollicis longus are the same as in the flexor carpi ulnaris transfers.

these tendon junctures are performed with the wrist in neutral and the MCP joints in full extension with the FCR tendon under maximal traction. Postoperative management is similar to that for the FCU transfer. Chandraprakasam *et al.*[20] described a modification of the modified Jones transfer in which the pronator teres is transferred to ECRB; the FCR is transferred to the finger extensors and the palmaris longus transferred to EPL; all through a single incision along the radial aspect of the distal third of the forearm curving obliquely to end at Lister's tubercle.

Boyes flexor digitorum superficialis transfer (Fig. 34.9)

Boyes[17] was the first to suggest that neither FCU nor FCR have sufficient amplitude (30 mm) to produce full excursion of the finger extensor tendons (50 mm) without the potential increase in amplitude obtained with the tenodesis effect of wrist flexion. He therefore advocated using the flexor digitorum superficialis (FDS) tendons to the long and ring fingers, which have an amplitude of 70 mm, to act as donor tendons to restore finger extension.[17,18] The advantages of the Boyes transfer are that this transfer will potentially allow simultaneous wrist and finger extension; secondly, it may allow independent thumb and index finger extension; and finally, it does not weaken wrist flexion. However, the long and ring fingers are deprived of superficialis function and this may result in weak grip. Harvesting of the superficialis tendons may also lead to the subsequent development of either a "swan neck" deformity or a flexion contracture at the PIP joint.

The FDS tendons to the long and ring fingers are exposed between the A1 and A2 pulleys either through one transverse incision at the base of the fingers or two separate longitudinal incisions. The FDS tendons are divided just proximal to their decussation and then withdrawn proximally into a longitudinal incision over the volar aspect of the middle third of the forearm. The tendon of pronator teres can be transected and re-routed through this same incision as described previously. Blunt dissection on either side of the flexor digitorum profundus (FDP) muscles allows a window to be excised in the

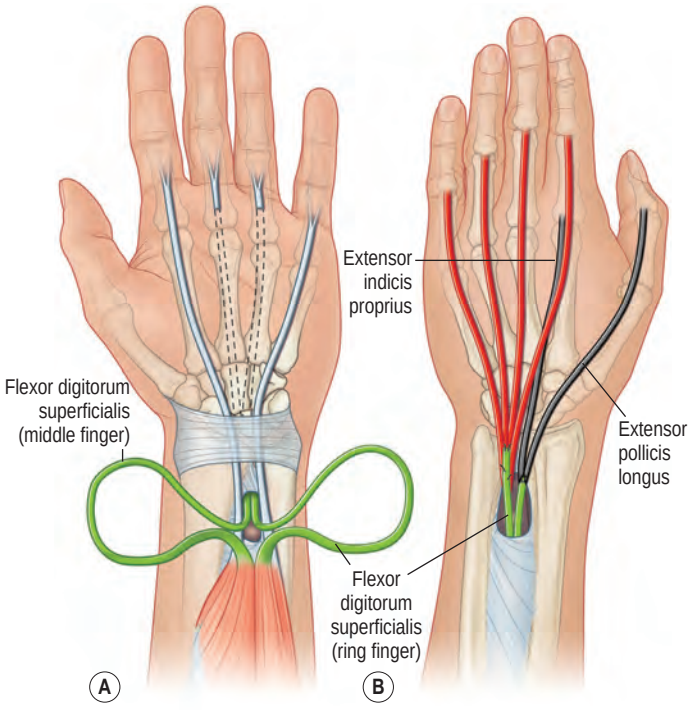

Fig. 34.9 In the Boyes tendon transfer, the long and ring finger flexor digitorum superficialis tendons, FDS_L and FDS_R are transferred either through a window in the interosseous membrane **(A)** or around the radial and ulnar border of the forearm to restore extension of the extensor digitorum communis tendons to the long, ring, and small fingers and the extensor indicis proprius and extensor pollicis longus tendons **(B)**.

interosseous membrane just proximal to the pronator quadratus (see Fig. 34.9). This window should be made as large as possible at least 4 cm long and as wide as the interosseous space, so that the muscle bellies of the two FDS tendons can be passed through this window to minimize the development of adhesions. It is important to pass the FDS tendons of the ring and long fingers to their respective sides of the median nerve to prevent scissoring over the nerve and compression.

Thomsen and Rasmussen[21] prefer to transfer the two FDS tendons around the radial and ulnar borders of the forearm through subcutaneous tunnels. Through a J-shaped incision passing transversely across the dorsum of the wrist and then extending proximally along the dorsum of the ulna, the extensor tendons are isolated as well as extensor carpi radialis brevis. In Boyes' original description, pronator teres was sutured to both ECRL and ECRB,[17] but in order to prevent excessive radial deviation, pronator teres should only be woven end-to-end into ECRB with the wrist in 30° of extension. The long finger FDS is then passed to the radial side of the FDP muscles and the ring finger FDS to the ulnar side through the interosseous window into the dorsal incision. After transection of the EPL and EIP tendons, they are woven end-to-end into the long finger FDS tendon. Similarly, the transected EDC tendons to the index, long, ring, and small fingers are woven end-to-end into the ring finger FDS tendon, although this arrangement can be reversed. The tendon junctures are performed proximal to the extensor retinaculum with resting tension in the donor FDS tendons and full extension at the MCP joints.

If necessary, abductor pollicis longus (APL) is transected at its musculotendinous junction and passed through a subcutaneous tunnel from the base of the thumb into the volar forearm incision. Either palmaris longus or flexor carpi radialis are transected at the wrist crease and woven end-to-end with the APL tendon to provide abduction of the thumb and prevent a collapse deformity of the thumb metacarpal. The tourniquet should be deflated prior to the closure of the incisions because of the likelihood of bleeding from the anterior or posterior interosseous arteries.

Outcomes

Tendon transfers for radial nerve palsy are generally predictable. Tsuge[22] described the evolution of his technique in 69 patients over a 25 year period. Using the FCU transfer and insertion of pronator teres into both ECRL and ECRB in the initial 41 patients, he reported "fairly satisfactory" results, but felt that there were three problems: development of radial deviation of the wrist, restriction of wrist flexion, and marginal thumb abduction. Because of these concerns, pronator teres was transferred only to ECRB and the FCR was transferred through the interosseous membrane for finger extension, leaving the FCU intact leading to good results in 24 of 27 cases. A long-term functional study of the FCU transfer in six patients by Raskin and Wilgis[23] revealed adequate wrist motion and power to perform daily activities, and a work-simulation protocol showed patients were able to perform tasks without significant difficulty. Problems of inadequate ulnar deviation, grip strength, and wrist instability were not seen. A subjective outcome study by Riordan[24] also revealed satisfaction with the standard FCU transfer. Long-term evaluation of the FCU transfer for radial nerve palsy at a mean follow up of 9.5 years revealed 11 excellent, two good, one fair, and one bad result, with the main problems being loss of power grip and development of a radial deviation deformity.[25] This resulted in an evolution in the author's technique to use pronator teres to restore wrist extension, FCR to restore finger extension, and palmaris longus to restore thumb extension with tenodesis of the abductor pollicis longus to brachioradialis to restore thumb abduction. Gousheh and Arasteh[26] transferred only the FCU to the finger extensors and EPL in 108 patients. At a mean follow-up of 4 years, wrist extension was less than the opposite side, but extension of the fingers was similar to the normal hand and most patients were able to return to their previous job. According to the authors, there was no obvious difference between the results using a single FCU tendon transfer compared to their previous results using the conventional three tendon transfers for reconstruction of radial nerve palsy. Altintas *et al*.[27] compared the long-term results after tendon transfers for radial nerve palsy, using the FCU in 58 patients and the FCR in 19 patients. Wrist extension averaged 73% of the opposite side, finger extension 32%, and thumb extension 80%. Grip strength was reduced to 49% and pinch strength to 28% of the opposite hand and the mean total DASH score was 16. Eighty-nine percent of patients remained employed after tendon transfers for radial nerve palsy.

Chuinard *et al*.[18] studied 21 patients who had undergone the Boyes FDS transfers with excellent results in 10, good in six, and only a fair result in five patients. Subjectively, 13 patients felt that they had obtained an excellent result and eight a good result. Complications requiring a second procedure were reported in five patients and included adhesions, dehiscence of the transfer, MCP and wrist extension contractures, and problems with correct tensioning of the transfers. A report by Fujiwara[28] of 13 patients with radial nerve palsy and five patients with PIN palsy documented generally good results with the Boyes transfers. No patient in either of these studies developed postoperative median nerve compression despite the potential for this complication with this transfer. Krishnan and Schackert[29] evaluated the function of 29 patients who had undergone a Boyes transfer of the FDS tendons to the long and ring fingers through the interosseous membrane for radial nerve palsy. Near-normal wrist extension was achieved in 22 of 25 patients. Finger extension simultaneously with wrist extension was achieved in 12 patients, but in 17 patients full finger extension was only possible with the wrist in neutral. Selective extension of the index finger and thumb powered by the FDS tendon from the long finger was achieved in all patients.

All three techniques have been reported to yield good results, but there are few quantitative studies to substantiate the reported outcomes, and no prospective comparison of the three different techniques. The FCU transfer is perhaps the simplest technique and provides reproducibly good results in patients with radial nerve palsy.

Low median nerve palsy

Anatomical considerations

The functional deficit following injury to the median nerve distal to the innervation of the extrinsic forearm flexor muscles consists primarily of loss of opposition of the thumb and

absent sensation over the thumb, index, long, and radial half of the ring finger.

Opposition is a composite motion that occurs at all three joints to position the thumb pad opposite the distal phalanx of the partially flexed long finger. Abduction, pronation, and flexion occur at the carpometacarpal joint, abduction and flexion at the metacarpophalangeal joint, and either flexion or extension at the interphalangeal joint. Approximately 40° of abduction of the thumb metacarpal occurs at the carpometacarpal joint and 20° of abduction of the proximal phalanx occurs at the metacarpophalangeal joint. From a starting position of full extension and adduction, the thumb pronates approximately 90° during opposition to the long finger. Extension of the thumb interphalangeal joint is required for pulp-to-pulp pinch, whereas slight flexion of the interphalangeal joint allows tip-to-tip pinch. Of the three intrinsic thenar muscles, the flexor pollicis brevis (FPB) muscle typically, although not always, receives a dual innervation from both the median and ulnar nerves. Because the flexor pollicis brevis may remain innervated by the ulnar nerve in approximately 70% of median nerve injuries, patients may not notice any significant functional loss, but careful testing will reveal decreased strength of abduction and lack of pronation.

Prior to any opposition transfer, patients with median nerve injuries should be instructed to prevent the development of an adduction or supination contracture of the thumb by a program of passive abduction exercises. A static thumb–index finger webspace splint may be used at night, but this usually interferes with the already compromised function of the hand if used during the day. Care should be taken to insure that such splints abduct the thumb metacarpal rather than the proximal phalanx; otherwise the median nerve palsy will be compounded by attenuation of the ulnar collateral ligament of the metacarpophalangeal joint. If patients present with an established adduction or supination contracture of the thumb, release of the thumb–index finger webspace skin, fascia over the first dorsal interosseous muscle, or even the first dorsal interosseous and adductor muscles themselves may be required prior to any opposition tendon transfer.

Bunnell[30] first emphasized that the pull of an opposition tendon transfer should be in an oblique direction from the thumb metacarpophalangeal joint to the region of the pisiform, and secondly, that in order to produce pronation, the transfer should be inserted into the dorso-ulnar base of the proximal phalanx. Opposition transfers that are directed along the radial aspect of the palm will produce a greater component of palmar abduction, whereas transfers that pass from the pisiform will produce both abduction and pronation. The more distal the transfer passes across the palm, the greater the power of thumb flexion. Several methods of insertion of opposition transfers have been advocated including attachment to the dorso-ulnar base of the proximal phalanx (Bunnell[30], Royle-Thompson[31,32]), insertion into the abductor pollicis brevis tendon (Littler[33]), dual insertion into the abductor pollicis brevis and continuation distally into the MCP joint capsule and extensor pollicis longus tendon (Riordan[24]), insertion into the abductor pollicis brevis, dorsal joint capsule and adductor pollicis (Edgerton and Brand[34]), and finally utilization of a distal-based extensor pollicis brevis tendon (Phalen and Miller[35]). However, a biomechanical study has shown that opposition tendon transfers inserted into the abductor pollicis brevis (APB) tendon alone will produce full abduction and pronation.[36] Therefore the more complex dual insertions should probably be reserved for combined median and ulnar nerve palsies.

Timing

Several factors influence the likelihood of useful motor and sensory return following median nerve injury including patient age, level of injury, length of nerve defect and interposition nerve graft; and period of preoperative delay. The best results are realized in distal injuries in young patients requiring only primary repair. Associated injuries such as vascular injury, tendon injury, and concomitant ulnar nerve transection portend a worse prognosis. The chances of reinnervation of the thenar muscles following group fascicular repair of a distal median nerve laceration should be reasonably optimistic. Therefore, conventional timing of an opposition tendon transfer may only be required in those patients who fail to demonstrate signs of reinnervation within the usual calculated time interval. For older patients or those with poor prognostic comorbid factors, early tendon transfers should be considered.

Careful observation of thumb function following either a low or high median nerve palsy will reveal whether an "early" tendon transfer for thumb opposition is necessary. Flexor pollicis brevis remains innervated by the ulnar nerve in approximately 70% of median nerve injuries so that thumb function may not be significantly compromised. Consequently an "early" opposition transfer may not be necessary. Other patients, however, will adapt to their loss of opposition and abduction by substitution of the abductor pollicis longus to provide thumb abduction, but this can only be achieved with the hand positioned in pronation. This places the patient at an even greater disadvantage in that not only do they have absent sensation in the median nerve distribution, but with the forearm in pronation they cannot even see the palmar surface of their hand to compensate for their loss of sensation. Therefore, if the surgeon or therapist observes the patient attempting to grasp objects by radial abduction of the thumb with the forearm in pronation, an "early" opposition tendon transfer should be strongly considered. If, however, the patient is able to pick up an object with the forearm in neutral or grasp an object with the forearm in supination, it is likely that flexor pollicis brevis remains innervated by the ulnar nerve and consequently the decision for performing an "early" opposition tendon transfer can be delayed.

Operations

Burkhalter extensor indicis proprius transfer (Fig. 34.10)

The extensor indicis proprius (EIP) transfer[37] is the author's preferred technique, except in elderly patients with thenar atrophy secondary to severe carpal tunnel syndrome (see Fig. 34.10). The EIP tendon is transected through a small transverse incision just proximal to the MCP joint of the index finger. The distal stump of the EIP tendon is then repaired to the extensor digitorum communis tendon of the index finger to prevent extensor lag at the metacarpophalangeal joint. The EIP tendon is mobilized through two small transverse incisions one proximal and one distal to the extensor retinaculum and the

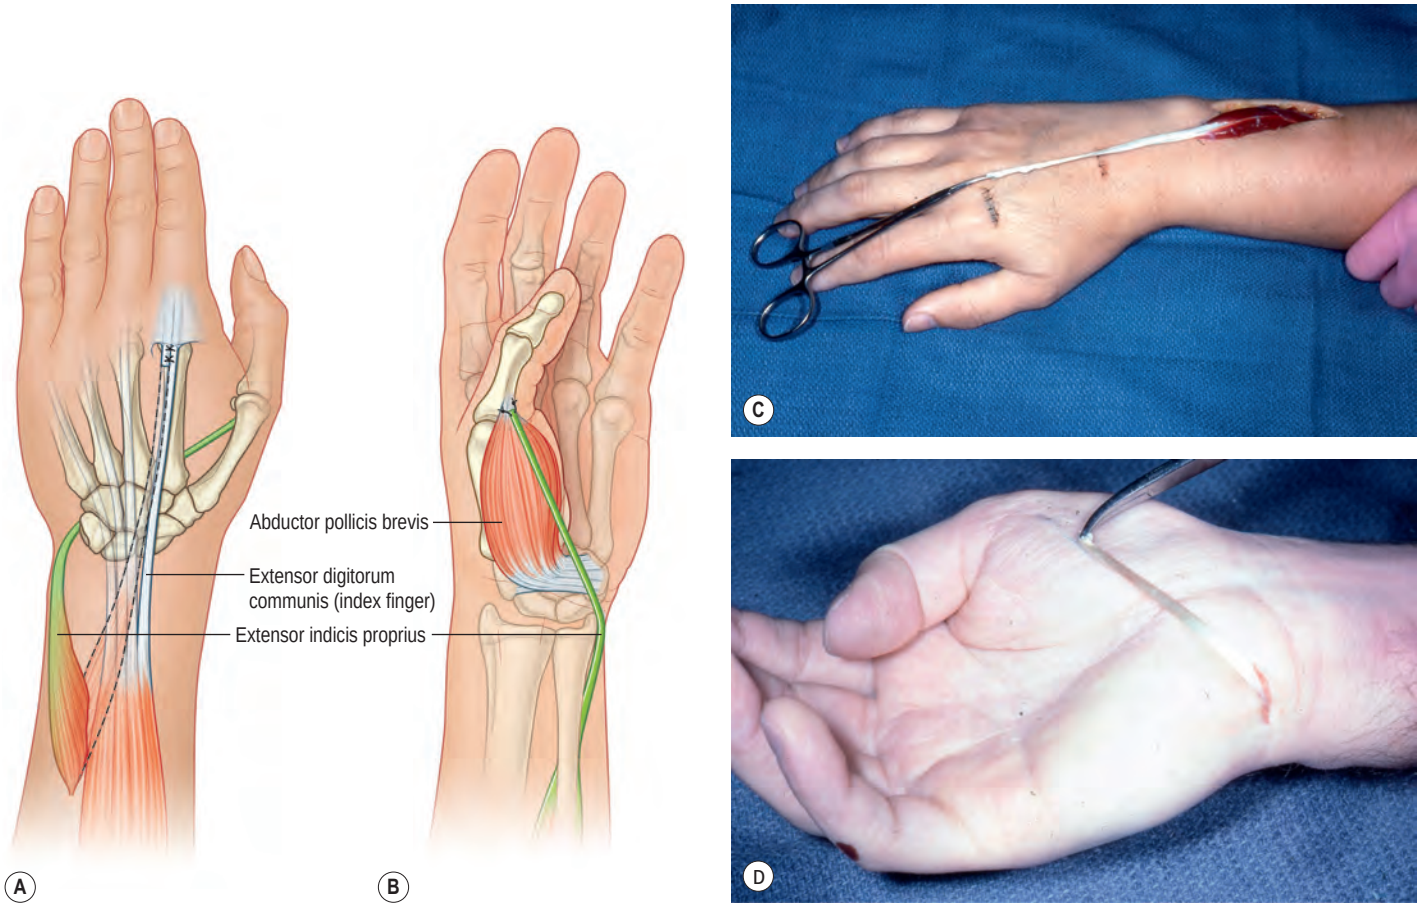

Fig. 34.10 (A,B) In the Burkhalter opposition tendon transfer, extensor indicis proprius (EIP) is transected at the level of the metacarpophalangeal (MCP) joint of the index finger and **(C)** mobilized through a dorsal-ulnar incision in the distal forearm. The EIP tendon is passed around the ulnar border of the distal forearm and **(D)** passed obliquely across the palm from the level of the pisiform to the radial aspect of the MCP joint of the thumb and sutured to the insertion of abductor pollicis brevis.

muscle belly mobilized through a longitudinal incision over the ulnar aspect of the dorsum of the mid-forearm (see Fig. 34.10C). A transverse incision is made just proximal to the pisiform bone and a subcutaneous tunnel developed to connect this incision to the dorsal forearm incision. The EIP tendon is then passed subcutaneously around the ulnar border of the distal forearm superficial to the extensor carpi ulnaris tendon into the pisiform incision. The abductor pollicis brevis tendon is identified through a small incision over the radial aspect of the MCP joint of the thumb and a subcutaneous tunnel made connecting this incision with the pisiform incision. The tendon transfer is passed obliquely across the palm (see Fig. 34.10D) and woven into the tendon of abductor pollicis brevis under maximum tension with the wrist in neutral position and the thumb in maximal palmar abduction. The tension of the transfer is then tested by the tenodesis effect of the wrist. Wrist flexion should allow the thumb to be passively adducted. If wrist extension produces excessive flexion or extension of the thumb at the metacarpophalangeal joint, this indicates that the transfer has been inserted either too far volarly or too far dorsally and should be adjusted accordingly. The thumb is immobilized in full abduction with the wrist in slight palmar flexion for 4 weeks, at which time active abduction and opposition movements are begun with protective splinting for a further 3–4 weeks. The only potential disadvantage with this tendon transfer is that the EIP tendon is only just long enough to reach the abductor pollicis brevis tendon. The postoperative results have been very predictable (Fig. 34.11).

Bunnell ring finger flexor digitorum superficialis transfer (Fig. 34.12)

In the flexor digitorum superficialis transfer described originally by Bunnell,[30] the ring finger FDS tendon is isolated through a small transverse incision just distal to the distal palmar crease. The tendon is transected between the A1 and A2 pulleys and delivered into a proximal incision made over the volar aspect of the distal forearm (Fig. 34.13A). The flexor carpi ulnaris tendon is split longitudinally to create a distal-based strip of the radial half of the tendon. This is then passed through a slit in the flexor carpi ulnaris tendon just proximal to the pisiform and sutured to itself to create a pulley (see Fig. 34.13B,C). The distal end of the ring finger FDS tendon is passed through this pulley and through an oblique subcutaneous tunnel across the palm into an incision over the radial aspect of the MCP joint of the thumb. All the other incisions are then closed and the tension on the tendon transfer adjusted as described previously.

Simple looping of the ring finger FDS around the FCU tendon rather than using a fixed pulley rapidly becomes ineffective and the transfer becomes converted to a flexor of the

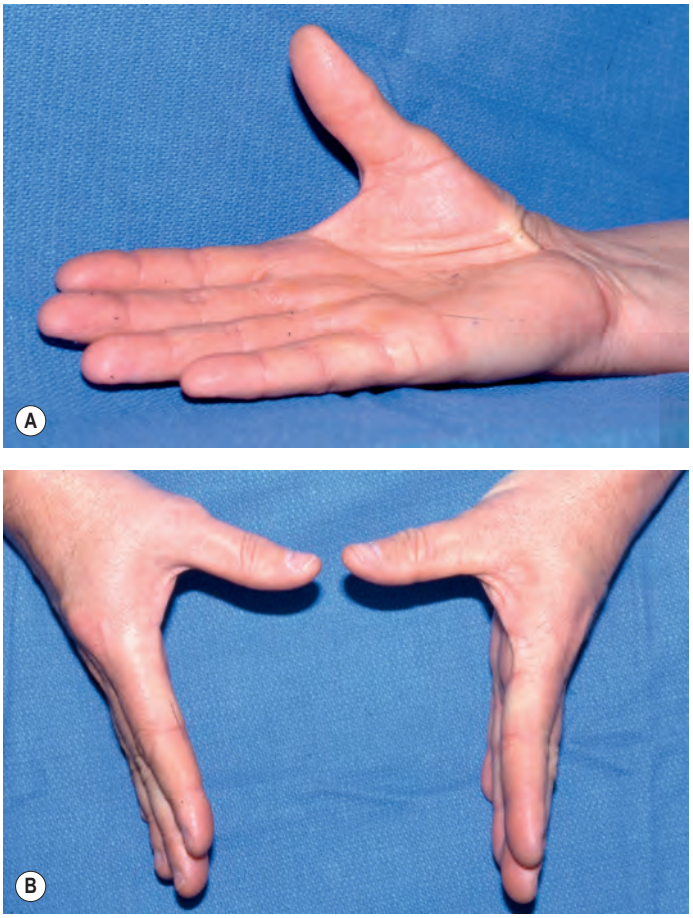

Fig. 34.11 **(A)** Postoperative opposition of the right thumb has been restored after a Burkhalter extensor indicis proprius transfer. **(B)** Thumb abduction is symmetrical with the normal thumb.

MCP joint rather than a true opposition transfer. Other pulleys for the ring finger FDS transfer include passing the tendon through Guyon's canal or through a window in the transverse carpal ligament (Snow–Fink).

Compared with the EIP transfer, the ring finger FDS is relatively stronger and has greater length. This is perhaps the strongest of the opposition transfers (Fig. 34.14C,D). However, the ring finger FDS is not available as a donor tendon in a high median nerve palsy or in low median nerve injuries in which there have been associated injuries to the flexor tendons. The ring finger FDS transfer should also not be selected in combined low median and high ulnar nerve palsies since the ring finger FDS is the only remaining flexor tendon in the ring finger. In low median–low ulnar nerve palsies, the ring finger FDS may be required for correction of clawing. In addition, harvesting of the FDS tendon may result in either a flexion contracture or a "swan neck" deformity of the PIP joint of the donor finger.

Camitz palmaris longus transfer (Fig. 34.15)

The palmaris longus (PL) donor tendon in the Camitz transfer[38–41] will provide abduction of the thumb but little pronation or flexion and is particularly indicated in elderly patients with thenar atrophy due to long-standing carpal tunnel syndrome. A strip of palmar fascia is dissected in continuity with the distal palmaris longus tendon through a standard carpal tunnel incision in the palm extending proximally into the distal forearm (Fig. 34.16A). A subcutaneous tunnel is developed from the radial aspect of the distal forearm incision along the thenar eminence into a mid-axial incision on the radial aspect of the MCP joint of the thumb (see Fig. 34.16B). The fascial extension of the palmaris longus tendon is passed through this subcutaneous tunnel and sutured to the abductor pollicis brevis tendon under maximal tension with the wrist in neutral position (see Fig. 34.16C).

Other opposition tendon transfers

Huber[42] and Nicholaysen[43] described transfer of the abductor digiti minimi (ADM), which may occasionally be indicated in patients with a combined median and radial nerve palsy and also in children with congenital anomalies affecting the thumb. Since the muscle originates at the pisiform, this

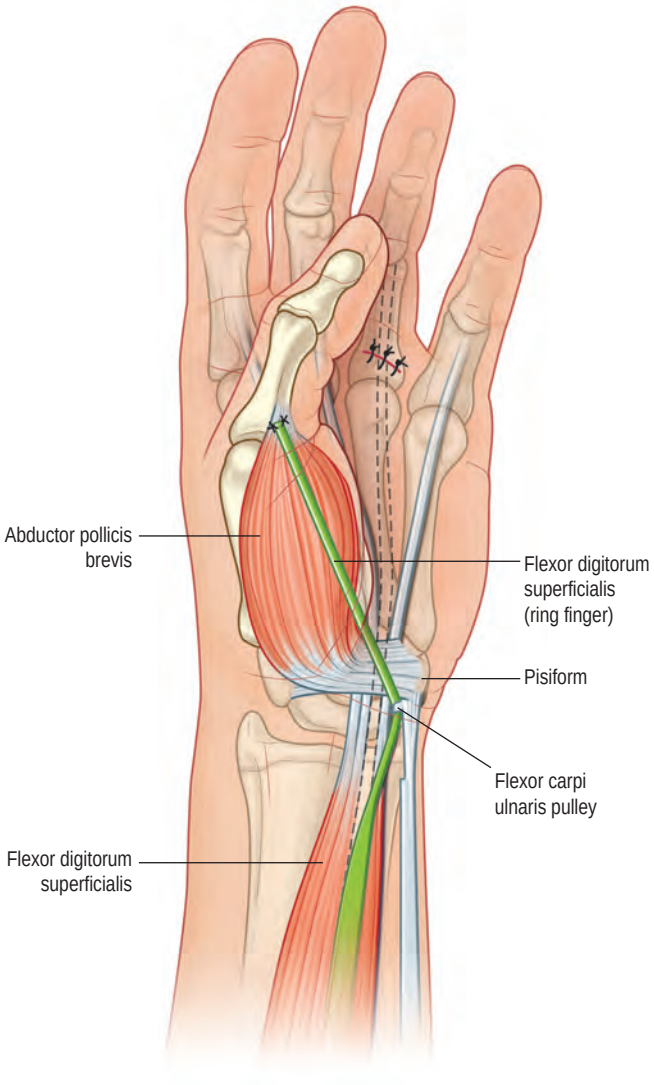

Fig. 34.12 Bunnell transfer using the flexor digitorum superficialis of the ring finger passed through a pulley of the flexor carpi ulnaris tendon to restore opposition of the thumb.

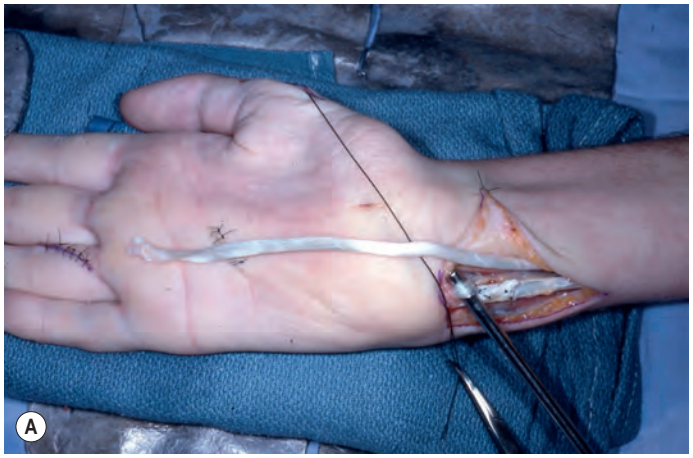

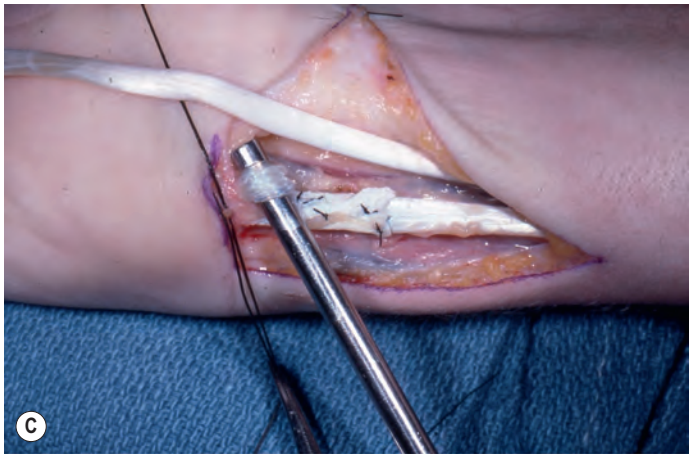

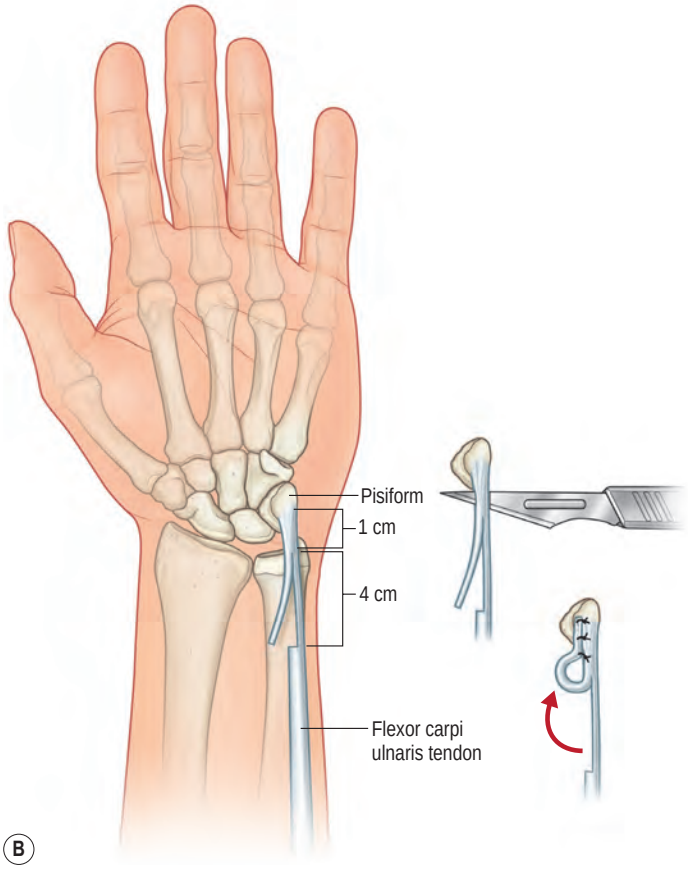

Fig. 34.13 (A) Harvesting the flexor digitorum superficialis (FDS) tendon from the ring finger. **(B,C)** A sucker tip is used to create a pulley for the FDS from a distal-based slip of flexor carpi ulnaris just proximal to the pisiform.

Fig. 34.14 (A) Preoperative appearance of a patient with Charcot–Marie–Tooth disease with severe thenar atrophy and inability to oppose either thumb. **(B)** Postoperatively after a Bunnell transfer, the patient is able to oppose their right thumb to the tip of the small finger.

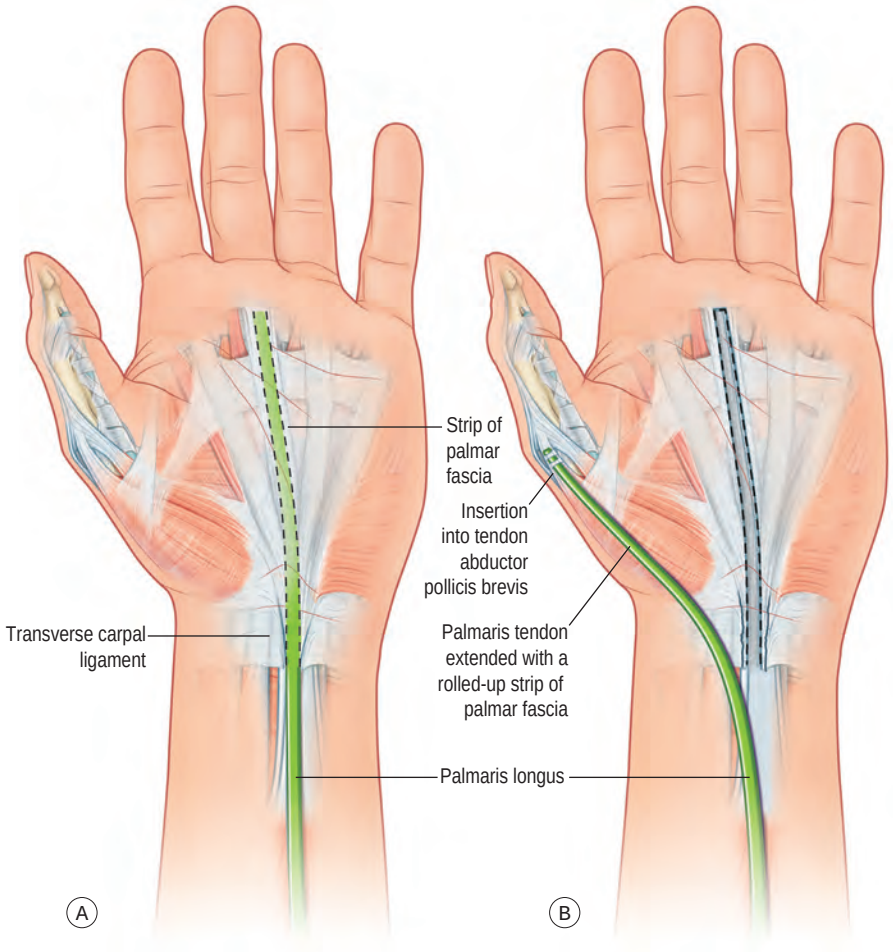

Fig. 34.15 Camitz opposition transfer using the palmaris longus tendon extended with a strip of palmar fascia and transferred to the insertion of abductor pollicis brevis.

transfer provides excellent flexion and pronation of the thumb but little palmar abduction. The insertion of the abductor digiti minimi tendon is transected from the ulnar lateral band through an ulnar midaxial incision along the proximal phalanx of the small finger. The incision is then extended proximally along the radial aspect of the hypothenar eminence and the muscle elevated in a distal to proximal direction taking care to protect the neurovascular bundle which enters the muscle just beyond the pisiform. A wide subcutaneous tunnel is dissected between the hypothenar incision and the insertion of

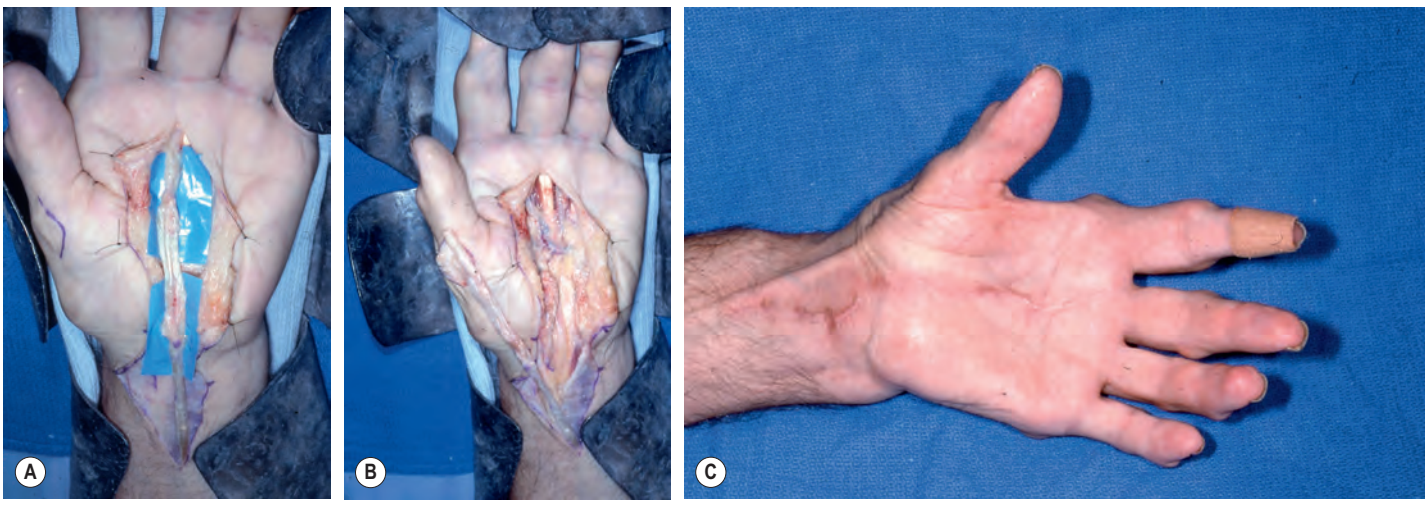

Fig. 34.16 **(A)** In this patient with severe left carpal tunnel syndrome and thenar atrophy, the palmaris longus tendon is extended with a rolled-up sheet of palmar fascia and **(B)** transferred subcutaneously to the insertion of the abductor pollicis brevis tendon on the radial aspect of the metacarpophalangeal joint of the thumb. **(C)** One year postoperatively, the patient demonstrates excellent palmar abduction of the thumb; but because the vector of transfer is not from the region of the pisiform, the Camitz transfer does not provide pronation of the thumb.

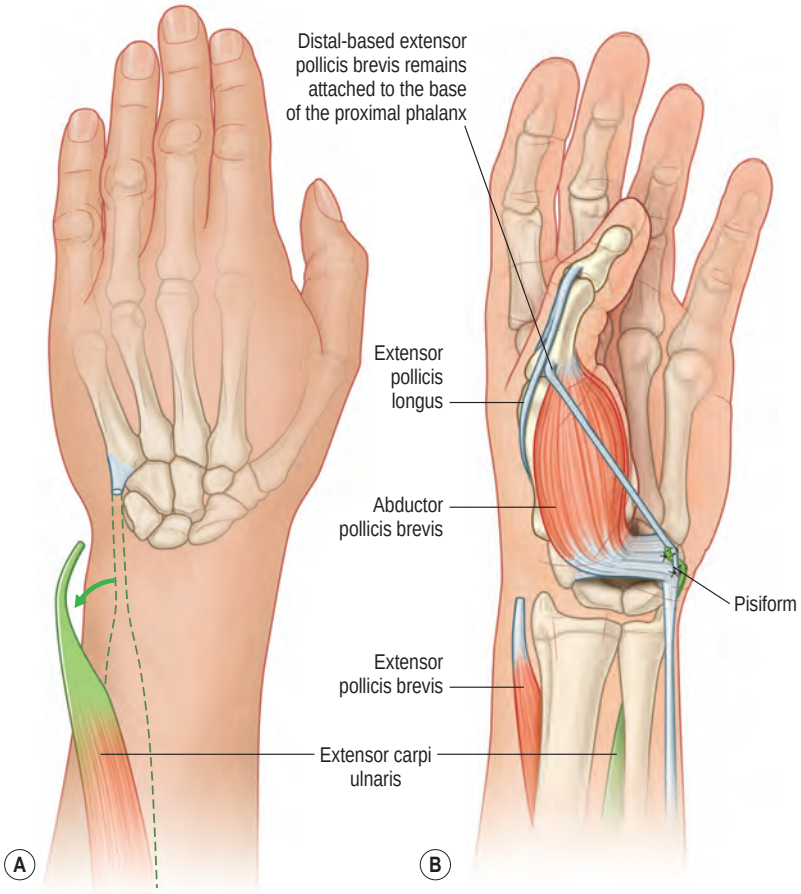

Fig. 34.17 (A) In the Phalen and Miller opposition tendon transfer, the ECU is detached from the base of the small finger metacarpal and transferred around the ulnar border of the forearm and sutured to the distal-based EPB tendon **(B)**.

the abductor pollicis brevis muscle at the MCP joint of the thumb. Hemostasis is achieved after releasing the tourniquet and the entire abductor digiti minimi muscle rotated 180° through the subcutaneous tunnel in the palm and sutured into the abductor pollicis brevis tendon. This transfer has been compared to turning the page of a book.[42] Cawrse and Sammut[44] described a modification of the Huber transfer in which the abductor digiti minimi is released both distally and proximally, so that the muscle is a complete island. This eliminates any compression of the ulnar nerve by the muscle transfer.

Phalen and Miller[35] advocate the use of the extensor pollicis brevis (EPB) tendon activated by extensor carpi ulnaris (ECU). The EPB is divided at its musculotendinous junction in the distal forearm and retrieved through an incision at the metacarpophalangeal joint of the thumb. This distally based tendon may then be passed through a subcutaneous tunnel obliquely across the palm to the area of the pisiform. The extensor carpi ulnaris tendon is transected at the base of the fifth metacarpal and routed subcutaneously around the ulnar border of the wrist to be interwoven with the extensor pollicis brevis tendon (Fig. 34.17).

Taylor described the use of the extensor digiti minimi (EDM) as an opposition tendon transfer.[45] This transfer, which was also described by Schneider, re-routes the EDM around the ulnar side of the hand to the thumb MCP joint.[46]

High median nerve palsy

Indications

The functional deficit following injury to the median nerve proximal to its innervation of the extrinsic forearm flexor muscles consists of inability to flex the index finger at the PIP and distal interphalangeal (DIP) joints and the thumb at the interphalangeal joint in addition to loss of opposition (Fig. 34.18). This is due to paralysis of all four flexor digitorum

Fig. 34.18 Typical posture of high median nerve palsy with inability to flex the interphalangeal joint of the thumb and inability to flex the proximal interphalangeal and distal interphalangeal joints of the index finger.

superficialis muscles, the flexor digitorum profundus tendons to the index and long fingers, and the flexor pollicis longus muscle. Patients are often still able to flex the long finger due to interconnections between the FDP tendons to the long, ring, and small fingers in the distal forearm. Therefore, the two functions that need to be restored in patients with a high median nerve palsy are flexion at the interphalangeal joint of the thumb and flexion of the PIP and DIP joints of the index and long fingers, together with a conventional opposition tendon transfer.

Operations

Flexion of the interphalangeal joint of the thumb may be restored by transfer of brachioradialis (BR) to flexor pollicis longus (FPL) and flexion of the DIP joint of the index and long fingers by side-to-side tenorrhaphy of the FDPs of index and long fingers to the FDPs of the ring and small fingers[16] (Fig. 34.19). The brachioradialis is divided at its insertion on the radial styloid and extensively mobilized from its investing fascia up into the proximal third of the forearm so that the freed muscle can develop approximately 30 mm of excursion. If reinnervation of the flexor pollicis longus muscle is not expected to occur following repair or grafting of the median nerve, the tendon can be divided at its musculotendinous junction and woven end-to-end into the brachioradialis tendon. However, if there is any possibility of reinnervation of FPL, the brachioradialis tendon should be woven end-to-side into the flexor pollicis longus tendon, which remains in continuity. Through the same volar forearm incision, the FDP tendons to the index and long fingers can be sutured side-to-side to the ulnar innervated FDP tendons to the ring and small fingers. The results of these two transfers are also relatively predictable (Fig. 34.20).

If power flexion of the index and long fingers is required, then formal transfer of the extensor carpi radialis longus tendon to the index and long finger FDP tendons may be performed. The ECRL is transected through a small transverse incision at the base of the index finger metacarpal and passed subcutaneously around the radial border of the distal forearm into the volar incision. The FDP tendons to the index and long fingers are woven into the ECRL tendon so that with the wrist in 30–45° of extension, the tips of the index and long fingers almost touch the palm. Similarly, with the wrist in full palmar flexion, the fingers will almost assume a fully extended position. Adjusting tension on this transfer using the tenodesis effect of the wrist is absolutely critical, because the donor ECRL tendon has only 30 mm of amplitude whereas the FDP tendons normally have 70 mm of excursion. If this transfer is sutured under too much tension, it will result in flexion contractures of these two fingers.

The timing of tendon transfers in a high median nerve palsy remains controversial.[6] If a good primary or delayed primary nerve repair can be performed, there is a reasonable chance of reinnervation of the extrinsic flexor muscles in a young patient. Consequently "early" brachioradialis to flexor

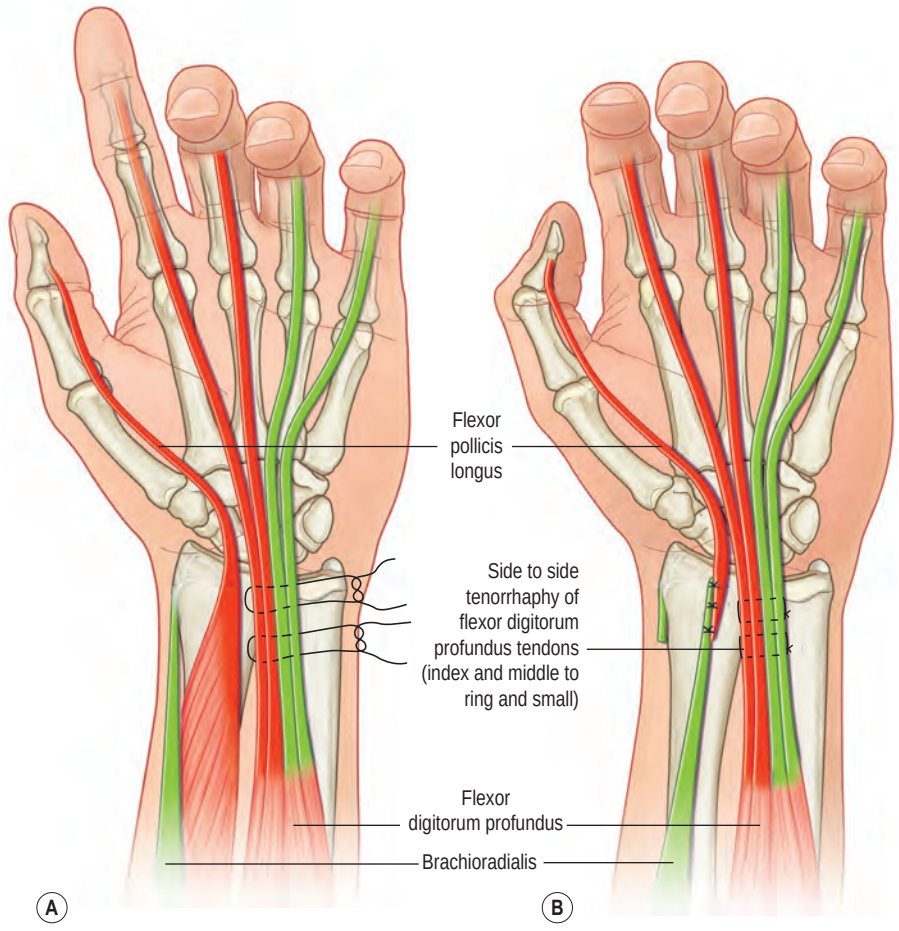

Fig. 34.19 **(A)** The flexor digitorum profundus (FDP) tendons of the index and long fingers are sutured to the FDP tendons of the ring and small fingers, which are still innervated by the ulnar nerve. **(B)** The flexor pollicis longus tendon is sutured to the brachioradialis tendon to restore flexion of the interphalangeal joint of the thumb.

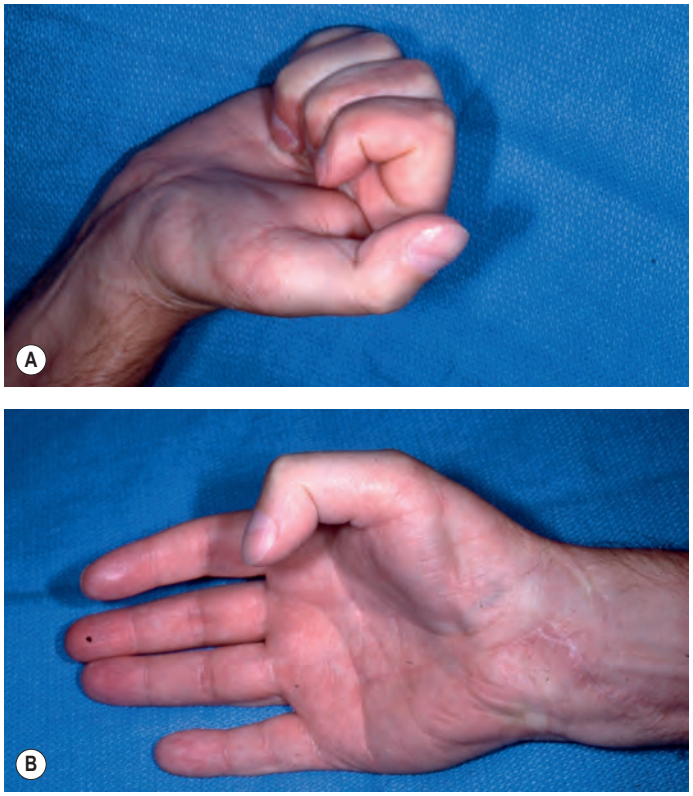

Fig. 34.20 (A) Postoperatively after side-to-side tenorrhaphy of the flexor digitorum profundus tendons, the patient has regained satisfactory flexion at the proximal interphalangeal and distal interphalangeal joints of the index finger. **(B)** After the brachioradialis to flexor pollicis longus transfer, the patient has satisfactory flexion of the interphalangeal joint of the thumb. The patient also underwent a Burkhalter opposition transfer using extensor indicis proprius and has excellent abduction of the thumb.

pollicis longus or side-to-side repair of the index and long finger FDP tendons to the ring and small finger FDP tendons is not necessary. However, if the patient is seen late and requires secondary nerve grafting of the median nerve, then tendon transfers for restoration of thumb flexion and index and long finger flexion should be performed simultaneously with the nerve graft.

Outcomes

There is no standard measurement of opposition in the literature. Some authors have developed functional scales to rate outcome, while others have reported subjective patient satisfaction.[47,48] An anatomic and biomechanical study by Cooney *et al*.[36] showed that the FDS of the ring finger and the ECU were the best transfers for replacing thenar muscle strength, abduction, and pronation. They calculated that the ECU and FDS transfers restored 60% and 40% respectively of required thenar muscle strength. The Camitz transfer provided good abduction, but weak flexion and opposition.

Excellent or good results were obtained in approximately 88% after EIP transfer in patients with nerve deficits secondary to leprosy.[49] Similar results have been reported by other authors, but little data exists documenting thumb range of motion or rigorous functional outcomes. Schwartz and MacDonald[50] performed a retrospective review of 156 opposition tendon transfers primarily using FDS. Objective parameters were rated as good or excellent in 89% and patient satisfaction was rated as good or fair in 93%. There are few publications containing objective data that discuss the long-term functional outcomes of the Bunnell FDS transfer. Brandsma *et al*.[51] reported 32% excellent and 51% good results. Some of the other patients in this study underwent FDS transfers for intrinsic function. Of the 158 donor fingers, swan neck deformities were seen in 15%, DIP joint flexion contractures in 29%, and PIP joint flexion contractures in 18%. Groves and Goldner[52] reported 75% success in 16 patients with high median nerve or brachial plexus lesions reconstructed with FDS opposition transfers.

While Phalen and Miller[35] reported good results with the ECU transfer, another study described the development of significant radial deviation in one-third of cases.[53] These authors cautioned that the FCU must have normal strength to maintain proper wrist balance after ECU transfer.

Braun[40] reported good results in 28 patients who underwent the Camitz transfer. Foucher *et al*.[41] reported 91% good long-term results in 73 Camitz transfers performed at the same time as carpal tunnel release. Terrono *et al*.[54] retrospectively reviewed their experience with 33 Camitz transfers for severe median nerve compression in patients with a mean age of 65 years. Ninety-four percent of the patients felt that their thumb dexterity and speed were improved by the operation; only two patients were unhappy with the results. No objective biomechanical data are available for this transfer.

Table 34.3 catalogs some of the clinical studies of opposition tendon transfers. Success is defined differently in each study and thus a cohesive evaluation and enlightened recommendation is difficult to make. Data on high median nerve palsy reconstruction are even more scarce.

Low ulnar nerve palsy

Indications

Injury to the ulnar nerve distal to the innervation of the ring and small finger FDP and FCU muscles produces a functional deficit consisting of paralysis of all seven interossei, the ulnar two lumbricals, the hypothenar and the adductor pollicis (AP), and part of the flexor pollicis brevis (FPB) muscles. This results in an imbalance of the flexor and extensor forces at the MCP, PIP, and DIP joints of the fingers. Since the interossei are the main flexors of the MCP joints, extension of the proximal phalanges at the MCP joints by the extrinsic extensor tendons is unopposed and MCP joint hyperextension occurs to the extent allowed by the volar plates. Because the extrinsic extensor tendons concentrate their extension at the MCP joints and the interossei are unable to actively extend at the PIP and DIP joints, the increased tension in the flexor tendons that occurs as the MCP joints begin to hyperextend will be unopposed at the PIP and DIP joints. This therefore results in the typical claw hand with hyperextension at the MCP joints and reciprocal flexion at the PIP and DIP joints (Duchenne's sign) (Fig. 34.21).

Imbalance between the extrinsic extensor and flexor tendons leads to asynchronous flexion of the fingers and weak grip strength. The MCP joints do not flex until after the interphalangeal joints have become completely flexed, resulting in curling of the tips of the fingers into the palm with loss of ability to

grasp large objects. In a low ulnar nerve palsy, the clawing and loss of integrated MCP and interphalangeal joint flexion are confined to the ring and small fingers and to a lesser extent the long finger, since the lumbricals to the index and long fingers remain innervated by the median nerve. However, in a combined median and ulnar nerve palsy, all four fingers are affected (Fig. 34.22). Fowler[55] has shown that the PIP joints can be extended by the extrinsic extensor tendons provided that the MCP joints are stabilized against hyperextension. Both the claw deformity and the asynchronous flexion may therefore be improved either by static procedures to prevent hyperextension at the MCP joints or by dynamic tendon transfers to produce either MCP joint flexion alone or to provide both MCP joint flexion and interphalangeal joint extension.

The other significant impairment in patients with low ulnar nerve palsy is weak thumb–index finger pinch, which may be only 20–25% of normal due to paralysis of the adductor pollicis, one half of the FPB, and the first dorsal interosseous muscles. However, in 58% of ulnar nerve injuries, there is dual innervation of the flexor pollicis brevis muscle, which can to some extent provide thumb MP joint flexion and key pinch to the index finger. Loss of key pinch is usually manifest by compensatory activation of the flexor pollicis longus producing excessive flexion at the interphalangeal joint (Froment's sign) (Fig. 34.23) and occasionally hyperextension at the MCP joint (Jeanne's sign) as the patient attempts forceful pinch. In such patients with weak pinch, tendon transfers will be required to restore adduction of the thumb and abduction of the index finger.

Patients may also develop an irritating ulnar deviation of the small finger in addition to clawing at the MCP joint of the small finger (Wartenberg's sign) caused by paralysis of the third palmar interosseous muscle and the unopposed action of the extensor digiti minimi tendon. Occasionally, a tendon transfer may be required to correct this ulnar deviation of the small finger.

Therefore, tendon transfers may be indicated in an ulnar nerve palsy[15,16] (Table 34.4) to correct:

1. Clawing and asynchronous flexion of the fingers
2. Weak thumb–index finger pinch
3. Ulnar deviation deformity of the small finger
4. Weak FDP flexion at the DIP joints of the ring and small fingers.

Fig. 34.21 Typical posture of the ulnar claw hand characterized by hyperextension at the metacarpophalangeal joints, usually the ring and small fingers and reciprocal flexion at the proximal interphalangeal and distal interphalangeal joints.

Fig. 34.22 A patient with a combined low median–low ulnar nerve palsy demonstrating asynchronous flexion of the fingers, with flexion at the proximal interphalangeal and distal interphalangeal joints occurring before flexion at the metacarpophalangeal joints. Because of severe thenar atrophy, there is also loss of opposition of the thumb.

Fig. 34.23 With absence of the adductor pollicis muscle in a low ulnar nerve palsy, flexor pollicis longus primarily flexes the interphalangeal joint of the thumb, which results in hyperflexion of the interphalangeal joint when the patient attempts to produce key pinch (Froment's sign) and occasionally hyperextension at the metacarpophalangeal joint (Jeanne's sign).

Timing

Timing of tendon transfers for ulnar nerve palsy is primarily dependent on two factors: the probability of motor recovery and the severity of the functional deficit. Primary microsurgical repair of the ulnar nerve at the wrist can be expected to yield useful results in about 75% of patients. Secondary nerve grafting has been reported to provide some functional motor recovery in approximately 40% to 75% of cases, with a somewhat worse prognosis for sensory recovery. As in other peripheral nerve injuries, younger patients, those with shorter nerve defects, and those without other significant associated injuries have a better chance of obtaining useful results from ulnar nerve repair.

"Early" tendon transfers should be considered for those with a debilitating claw deformity. While clawing should be treated proactively using a lumbrical block splint, some patients may benefit from early static transfers to prevent MCP hyperextension and clawing. Trevett *et al*.[56] studied the functional results following both high and low ulnar nerve repairs to better define the indications for tendon transfers. They demonstrated continued improvement in intrinsic muscle power, grip strength, and sensation for at least 2 years in high and 3 years in low ulnar nerve repairs. The significant conclusion from this study was that early tendon transfers should only be performed in manual laborers who complain of poor grip or key pinch.

Static procedures to correct clawing of the fingers

Static procedures to prevent hyperextension of the proximal phalanges at their MCP joints include A1 pulley release, fasciodermadesis at the MCP joint level, capsulodeses, and various tenodeses. Capsulodesis of the MCP joint, described by Zancolli,[57] is a very simple technique in which the A1 pulley is first released, the volar plate is incised longitudinally and detached from the metacarpal to create two distally based flaps, which are then advanced proximally and attached to the metacarpal neck to maintain the MCP joint in approximately 20° of flexion. Omer[58,59] described creating a distal-based flap of the volar plate by making two parallel incisions on the medial and lateral aspects of the volar plate and excising Burow's triangles distally to allow proximal advancement of the volar plate (Fig. 34.24). The volar plate is anchored to the metacarpal neck with wire sutures through drill holes or by using a bone anchor. Recurrence of clawing has been demonstrated in long-term follow-up studies.[60]

Parkes[61] has described an effective tenodesis both to prevent hyperextension at the MCP joints and to provide extension at the interphalangeal joints by using tendon grafts sutured to the transverse carpal ligament and passed volar to the deep transverse intermetacarpal (intervolar plate) ligaments to insert into the radial lateral band of each finger. Omer[58] modified the Parkes tenodesis by attaching one tendon graft to the ulnar lateral band of the ring finger, passing around the deep transverse intermetacarpal ligament and suturing it to the radial lateral band of the small finger, with a second tendon graft from the ulnar lateral band of the index finger around the deep transverse intermetacarpal ligament to the radial lateral band of the long finger. Fowler attached tendon grafts to the extensor retinaculum, routed them dorsally through the intermetacarpal spaces and then volar to the deep transverse intermetacarpal ligaments and attached the grafts to the radial

Table 34.4 **Tendon transfers for ulnar nerve palsy**

Function to be restored	Preferred tendon transfer
Clawing of the ring and small fingers	Two slips of ring finger or long finger FDS to the radial lateral bands or proximal phalanges or A2 or A1 and A2 pulleys of the ring and small fingers
Clawing of all four fingers	EF4T or PL4T transfers to the radial lateral bands of the long, ring and small fingers and the ulnar lateral band of the index finger; or to the combined interosseous tendon insertion
Thumb adduction	ECRB + tendon graft to adductor pollicis

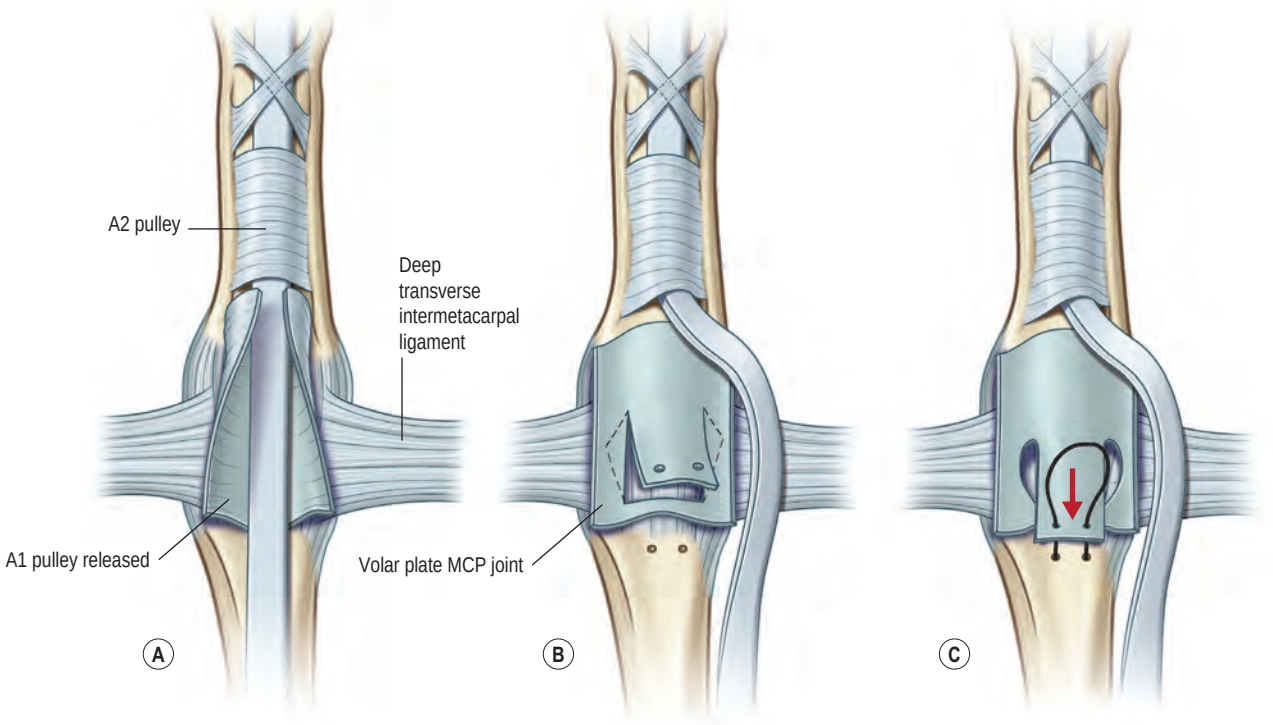

Fig. 34.24 Omer modification of the Zancolli capsulodesis: **(A)** The A1 pulley is released. **(B)** A distal-based flap of the volar plate is created and **(C)** advanced proximally and fixed to the metacarpal neck.

lateral bands of the fingers.[55] The Riordan tenodesis employs a similar dorsal route, utilizing two distally based strips of the ECRL and ECU tendons passed down the lumbrical canals, volar to the deep transverse intermetacarpal ligaments and attached to the radial lateral bands.[24]

The various dynamic tendon transfers that have been described to correct clawing differ primarily as to whether they provide only MCP joint flexion or whether they provide both MCP joint flexion and interphalangeal joint extension. The surgeon can determine which general type of transfer is most appropriate by preoperative testing of PIP and DIP joint extension with the MCP joints held passively flexed – the Bouvier maneuver. With the MCP joints flexed, if the extrinsic extensor tendons can produce full extension at the PIP and DIP joints (Fig. 34.25), the transfer may only need to produce strong MCP joint flexion by insertion of the transfer either into the A1 pulley (Zancolli[62]); the A2 pulley (Brooks–Jones[63]) (Fig. 34.26C); the A1 and proximal half of the A2 pulley Anderson[64]; or through a drill hole in the proximal phalanx (Burkhalter[65]) (see Fig. 34.26B). However, with longstanding flexion deformities of the PIP joints, the central slip of the extensor mechanism may become attenuated. Consequently, even with passive flexion of the MCP joints, the patient cannot actively extend the PIP joints using the extrinsic extensor tendons. In these circumstances, the transfer should be inserted into one of the lateral bands (see Fig. 34.26A); or into the dorsal base of the middle phalanx; or into the combined interosseous tendons (which Zancolli termed "direct interosseous

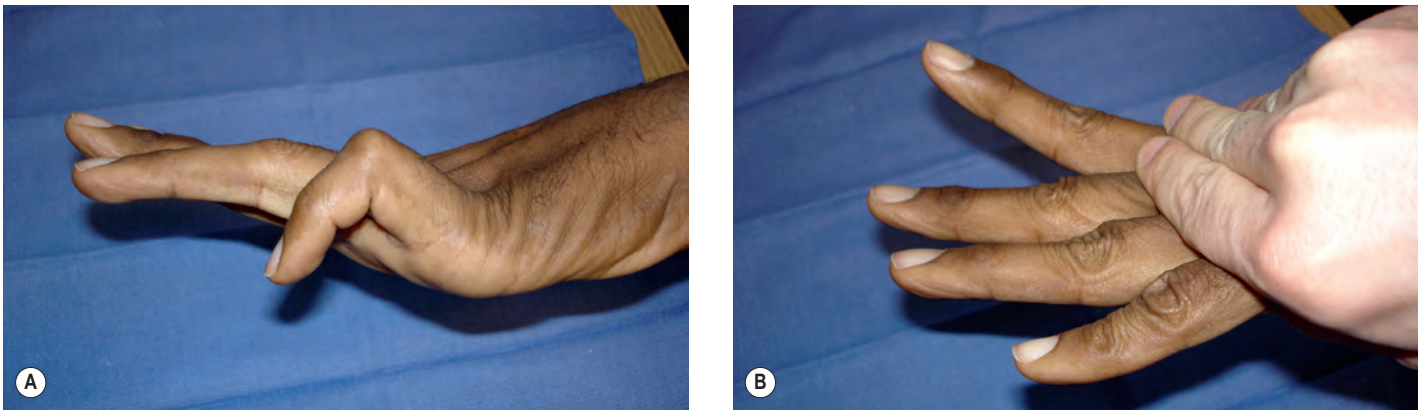

Fig. 34.25 The Bouvier maneuver: **(A)** Typical claw hand deformity of the small finger and to a lesser extent the ring finger with hyperextension at the metacarpophalangeal (MCP) joints and flexion at the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints. **(B)** In the Bouvier maneuver, the surgeon blocks hyperextension at the MCP joints and in this patient the extrinsic extensor tendons are able to produce full extension at the PIP and DIP joints.

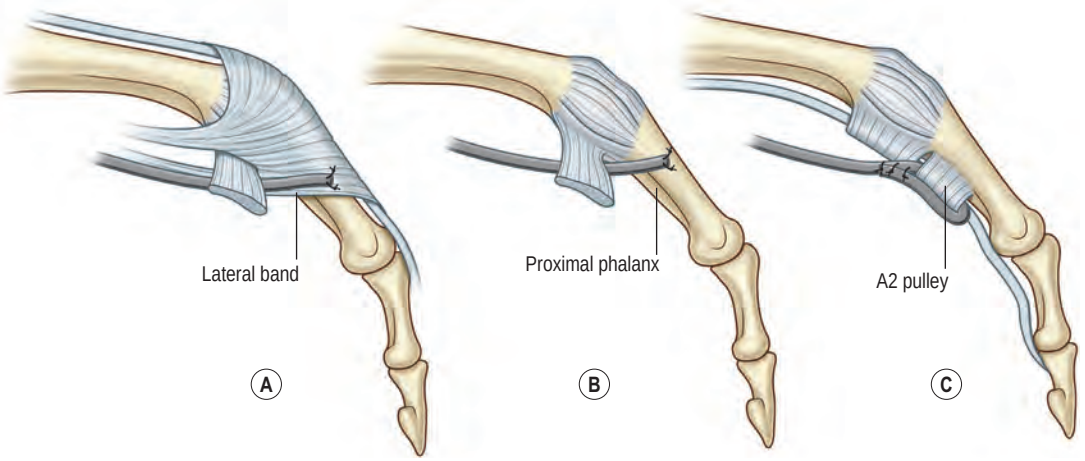

Fig. 34.26 Alternative insertions for tendon transfers to prevent clawing: **(A)** Into the lateral band. **(B)** Burkhalter insertion through a drill hole or bone anchor in the proximal phalanx. **(C)** "Lasso" insertion into either the A1 pulley (Zancolli); the A2 pulley (Brooks–Jones); or the A1 and proximal half of the A2 pulley (Anderson).

activation"[62,66]), so that both MCP joint flexion and PIP joint extension can potentially be restored.

If one of the FDS tendons is used as a donor tendon to produce either MCP joint flexion alone or both MCP joint flexion and interphalangeal joint extension, it does not produce any increase in power grip; whereas adding an extra muscle–tendon unit from outside the hand to activate these transfers, such as a wrist flexor (FCR) or extensor tendon (ECRL, ECRB), will potentially lead to increased grip strength.

Tendon transfers to correct clawing

All of the following have been described as the donor muscle–tendon unit in tendon transfers to correct asynchronous finger flexion and clawing in ulnar nerve palsy[67] (see Table 34.4):

1. Flexor digitorum superficialis
2. Extensor carpi radialis brevis
3. Extensor indicis proprius and extensor digiti minimi
4. Flexor carpi radialis
5. Extensor carpi radialis longus
6. Palmaris longus.

Stiles and Forrester-Brown[68] originally described transfer of one slip of each FDS tendon into the extensor mechanism and this was subsequently modified by both Bunnell[69] and Littler.[33] The Littler modification is referred to as the modified Stiles–Bunnell technique and involves transfer of the FDS of the ring finger or long finger or both fingers, splitting the tendon longitudinally into two slips, passing each slip of the FDS tendon down the lumbrical canals, and attaching them to the radial lateral bands of the fingers (Fig. 34.27).

If the Bouvier maneuver confirms that the extrinsic extensor tendons can produce full extension at the PIP and DIP joints with the MCP joints flexed, alternative insertions of the modified Stiles–Bunnell transfer into either the pulleys or the proximal phalanx can be considered in an attempt to prevent the risk of developing a secondary hyperextension deformity at the PIP joint. Zancolli originally described dividing the FDS tendons to the ring and small fingers distal to the A1 pulley between the A1 and A2 pulleys through a distal palmar crease incision. Each tendon is withdrawn from the flexor sheath between the A1 and A2 pulleys, looped around the A1 pulley, and sutured back to itself. This has been termed the "lasso" procedure.[62] In patients with a high ulnar palsy, the ring and small finger superficialis tendons cannot be used and therefore the long finger FDS tendon is divided into two slips and each slip is passed under the A1 pulleys of the ring and small fingers and sutured to itself (see Fig. 34.27). The FDS tendon slips are sutured with the wrist in neutral, the MCP joints in 60° of flexion and the wrist is then immobilized in 10° of flexion and the MCP joint is 90° of flexion for 3 weeks, but allowing motion at the PIP and DIP joints. Omer and Brooks–Jones[63] described looping the FDS tendon around the A2 pulley (see Fig. 34.26C) rather than the A1 pulley, and Anderson[64] has described an extended pulley insertion (EPI) by looping the FDS tendon around both the A1 and the proximal half of the A2 pulleys. Burkhalter[65] recommended insertion of the FDS tendon slips of a modified Stiles–Bunnell transfer into a radial–ulnar drill hole in the proximal phalanx (see Fig. 34.26B).

In a combined high median–ulnar nerve palsy, all the FDS tendons are paralyzed and consequently an "indirect lasso" procedure is required. After passing the FDS tendons around the A1 pulleys, the proximal ends of the FDS tendons are activated either by extensor carpi radialis longus or flexor carpi radialis. Brooks and Jones[63] have described a variant of this transfer in which the extensor carpi radialis longus or flexor carpi radialis are elongated with plantaris or toe extensor tendon grafts passed through the carpal tunnel and inserted more distally into the A2 pulley. Burkhalter and Strait[65] have also used the same donor tendons, the ring finger FDS and extensor carpi radialis longus but with insertion through a transverse drill hole in the middle third of the proximal phalanx. The ring finger FDS is divided at the level of the PIP joint withdrawn into the palm and divided into two slips. Each slip is then passed down the lumbrical canal into a transverse drill hole on the radial aspect of the middle third of the proximal phalanx of the ring and small fingers.

Modified Stiles–Bunnell transfer (see Fig. 34.27)

In the modified Stiles–Bunnell transfer[33] for patients with an isolated low ulnar nerve palsy, the ring finger FDS tendon is

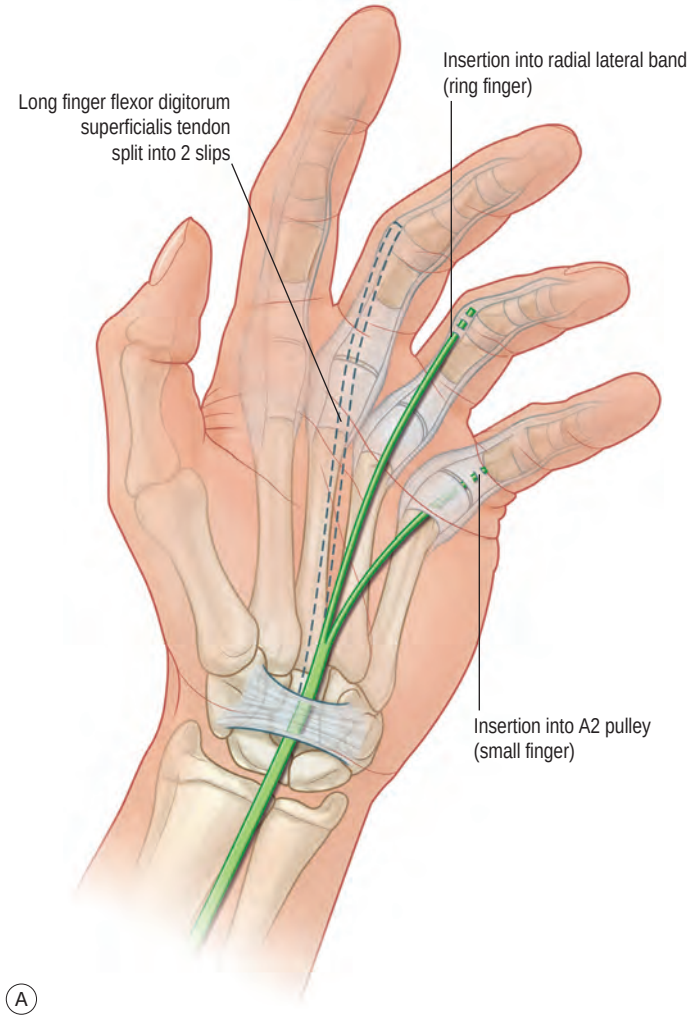

Fig. 34.27 **(A)** Modified Stiles–Bunnell transfer to prevent clawing. The flexor digitorum superficialis (FDS) tendon from the long finger is split into two slips and inserted into the radial lateral band (ring finger) or the A2 pulley (small finger). **(B)** Splitting of the FDS tendon from the long finger into two slips, which are passed down the lumbrical canals to the radial lateral bands of the ring and small fingers.

divided just proximal to the PIP joint, withdrawn through a transverse distal palmar crease incision, and split longitudinally into two slips. The radial lateral bands of the ring and small fingers are exposed through radial midaxial incisions and each slip of the FDS tendon is passed down the lumbrical canals of the ring and small fingers. With the wrist in neutral, each slip is sutured under adequate tension to the radial lateral bands with the MCP joints in 45–55° of flexion and the interphalangeal joints fully extended (see Fig. 34.27). Tension is assessed using the tenodesis effect of the wrist – with wrist extension, the fingers should assume the "intrinsic-plus" position. The hand is immobilized in a dorsal block splint with the wrist in slight flexion and the MCP joints flexed 70° for 3½ to 4 weeks. In a high ulnar nerve palsy, the ring finger FDS tendon is the only remaining extrinsic flexor tendon in the ring finger and therefore the long finger FDS tendon is used. Occasionally, the long or ring finger FDS tendon may be split into three slips, should the long, ring, and small fingers need correction. With a total intrinsic palsy, the FDS tendons to both the long and ring fingers are each divided into two slips and passed down the lumbrical canals to the radial lateral bands of the index, long, ring, and small fingers. Brand advocates insertion of the slip to the index finger into the ulnar lateral band to provide improved three-point pinch. However, this may result in scissoring of the index and long fingers. Zancolli[62] has described insertion of the FDS donor tendon into the combined interosseous tendons rather the radial lateral bands and termed this alternative technique of restoring MCP joint flexion and interphalangeal (IP) joint extension as "direct interosseous activation".

One of the disadvantages of the modified Stiles–Bunnell transfer is that the ring finger superficialis is not expendable in a high ulnar nerve palsy or in a combined high median–high ulnar nerve palsy. Secondly, the transfer may result in progressive overcorrection of the claw deformity eventually resulting in a "swan neck" hyperextension deformity at the PIP joints. A "swan neck" hyperextension deformity can be prevented by utilizing one of the distal slips of FDS as a tenodesis across the PIP joint. Thirdly, the donor long or ring finger may develop a flexion contracture at the PIP joint or loss of extension at the DIP joint. North and Littler[70] recommended harvesting the FDS tendon through a Bruner incision between the A1 and A2 pulleys rather than a midaxial incision at the level of the PIP joint. The modified Stiles–Bunnell transfer should therefore only be used in patients with mild PIP joint flexion contractures or stable fingers without passive hyperextension at the PIP joints.

Brand EE4T transfer (Fig. 34.28)

Due to his extensive experience of tendon transfers in leprosy patients, Brand[4,71] originally described transfer of the extensor carpi radialis brevis (ECRB), extended with four tendon grafts, passed from dorsal to palmar through the intermetacarpal spaces and then down the lumbrical canals to be attached to the radial lateral bands of the middle, ring, and small fingers, and to the ulnar lateral band of the index finger (EE4T: extensor tendon, extensor route, four-tailed graft). However, during wrist extension, the ECRB and tendon grafts relax, which is a relative disadvantage of this dorsal routing of the original Brand transfer. Burkhalter and Strait[65] modified the Brand EE4T transfer by using ECRL instead of ECRB and by only

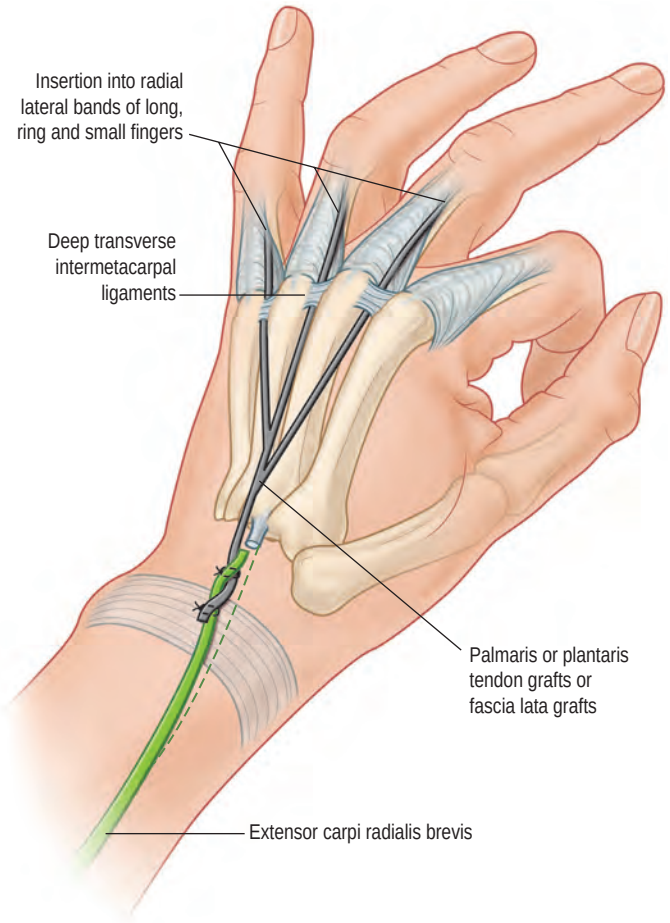

Fig. 34.28 Brand EE4T (extensor tendon, extensor route, four-tailed graft) transfer: Extensor carpi radialis brevis is extended by three tendon grafts which are passed volar to the intermetacarpal ligaments and inserted into the radial lateral bands of the long, ring, and small fingers.

correcting the ring and small fingers. The ECRL is lengthened with two tendon slips which are passed through the third and fourth intermetacarpal spaces, down the lumbrical canals, volar to the deep transverse intermetacarpal ligaments and inserted into a drill hole on the radial aspect of the middle third of the proximal phalanges. The wrist is immobilized in 40° of extension and the MCP joints in 70° of flexion for 4 weeks. This transfer will only produce MCP joint flexion, but is an alternative transfer for a combined high median–high ulnar nerve palsy when the modified Stiles–Bunnell flexor digitorum superficialis transfer is not available. Riordan[24] described a similar transfer using flexor carpi radialis (FCR) transferred dorsally around the radial border of the forearm and elongated with tendon grafts passed dorsal-to-palmar through the intermetacarpal spaces volar to the deep transverse intermetacarpal ligaments and inserted into the radial lateral bands. This transfer is mutually beneficial if there is an associated flexion contracture of the wrist.

The dorsal route also forms the basis for the Fowler transfer using both the EIP and extensor digiti minimi (EDM) tendons. The two tendons are divided just beyond the MCP joints of the index and small fingers and each tendon is split longitudinally into two slips. The four slips are tunneled subcutaneously to the radial lateral bands of the fingers.[55] The EIP tendon controls the index and long fingers and the EDM tendon controls the ring and small fingers. In a modification of this Fowler transfer, Riordan has described splitting only the EIP tendon into two slips and passing them from dorsal to palmar through the third and fourth intermetacarpal spaces to insert into the radial lateral bands to correct clawing of the ring and small fingers.[72] A relative disadvantage of the Fowler and Riordan transfers is that the EIP and EDM tendons are only just long enough to reach the radial lateral bands and these transfers are rarely used.

Brand EF4T transfer (Fig. 34.29)

Brand[71] modified his original dorsal transfer of ECRB by extending extensor carpi radialis longus (ECRL) with a four-tailed tendon graft or fascia lata graft through the carpal tunnel to the radial lateral bands of the long, ring, and small fingers and the ulnar lateral band of the ring finger (EF4T: extensor tendon, flexor route, four-tailed graft). In an isolated ulnar nerve palsy, this transfer is only attached to the radial

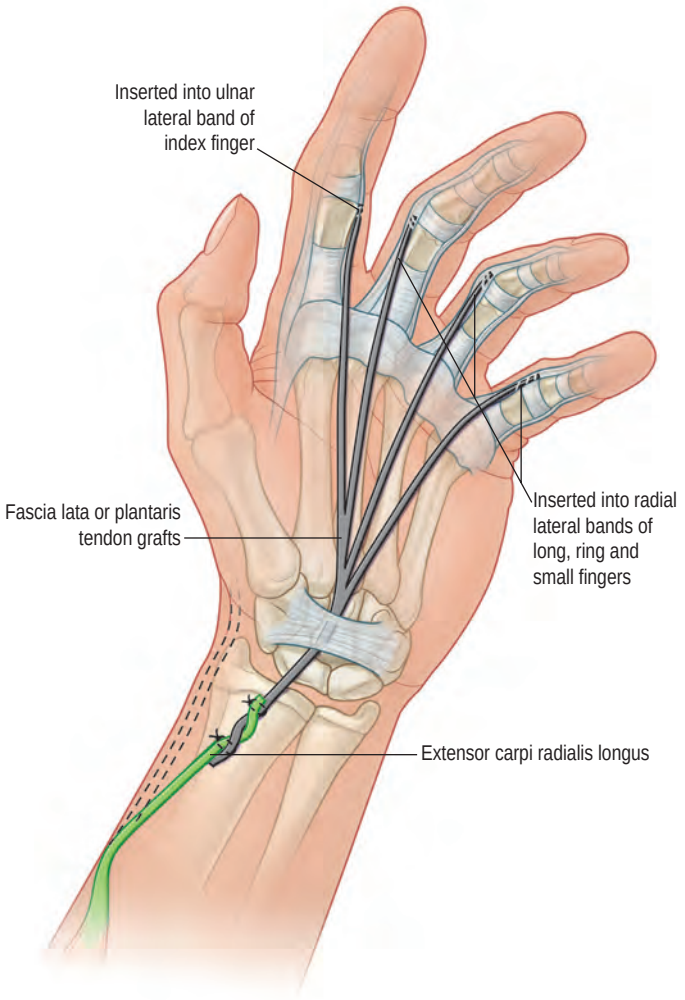

Fig. 34.29 Brand EF4T (extensor tendon, flexor route, four-tailed graft) transfer to correct clawing of all four fingers: Extensor carpi radialis longus is transferred around the radial border of the forearm, extended by four tendon grafts, which are passed through the carpal tunnel and inserted into the radial lateral bands of the long, ring, and small fingers and the ulnar lateral band of the index finger.

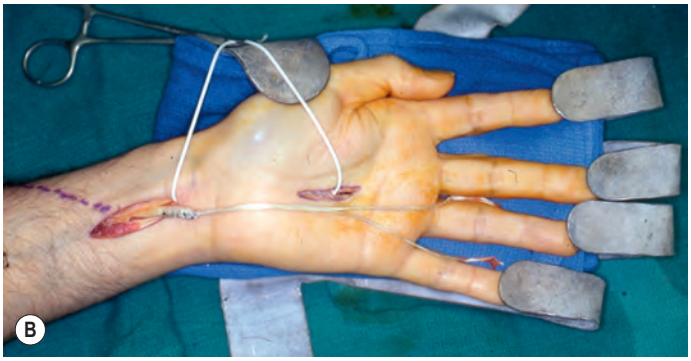

Fig. 34.30 Brand EF4T (extensor tendon, flexor route, four-tailed graft) transfer to correct clawing of the ring and small fingers in a low ulnar nerve palsy. **(A)** Extensor carpi radialis longus (ECRL) is detached from its insertion on the base of the index finger metacarpal. **(B)** A palmaris longus tendon graft has been sutured to ECRL and passed around the radial border of the forearm (or through the interosseous membrane). The palmaris longus tendon graft is passed through the carpal tunnel and split into two slips, which are passed down the lumbrical canals to be inserted into the radial lateral bands of the ring and small fingers. **(C)** Postoperative correction of the claw deformity of the ring and small fingers.

lateral bands of the ring and small fingers (Fig. 34.30). Two short transverse incisions are made, one over the second dorsal extensor tendon compartment to allow transection of the ECRL tendon, which is withdrawn into the second incision over the radial aspect of the mid-forearm. Either a folded fascia lata graft or a plantaris tendon graft is sutured to the distal end of the ECRL tendon projecting through the radial forearm incision. The elongated ECRL tendon is then passed around the radial border of the forearm into a transverse volar forearm incision just proximal to the wrist crease. Through a 3 cm-long incision on the ulnar side of the thenar crease, a tendon-tunneling forceps is introduced distal to the superficial palmar arch and passed along the floor of the carpal tunnel to exit on the radial side of the volar forearm incision and the tendon grafts or fascia lata graft are then pulled distally through the carpal tunnel into the palmar incision. The proximal tendon juncture therefore lies distal to the volar forearm incision, but proximal to the transverse carpal ligament. Each of the two plantaris slips are split longitudinally to produce four slips or the fascia lata graft is split into four slips. Through radial midaxial incisions over the proximal phalanges of the long, ring, and small fingers, the tunneling forceps is passed down each lumbrical canal volar to the deep transverse intermetacarpal ligaments into the palmar incision and the three tendon slips are brought out into each midaxial incision. The tendon slip to the index finger is tunneled to an ulnar midaxial incision and attached to the ulnar lateral band. This will produce supination of the index finger and may provide better three-point pinch. The hand is positioned on a frame with the wrist flexed 30°, the MCP joints flexed 70° and the interphalangeal joints fully extended. Proximal traction is applied to each lateral band to take up any slack in the extensor mechanism. After taking up the slack in all four plantaris tendon grafts, they are sutured to the lateral bands just proximal to the PIP joints under equal tension. Tension is adjusted in the index finger first, then the small finger, and finally the long and ring fingers. The hand is immobilized with the wrist in neutral, the MCP joints flexed 90°, and the IP joints straight for 3 weeks.

Fritschi PF4T transfer

Fritschi[73] has described the palmaris longus as an alternative motor for the Brand EF4T transfer. In the Lennox–Fritschi PL4T (palmaris four-tail) transfer, the palmaris longus tendon is lengthened with a tendon graft or fascia lata graft, which are then passed through the carpal tunnel to the lateral bands in a similar route to the Brand EF4T procedure. However, the palmaris longus is obviously a much weaker donor muscle than the ECRL.

Two alternative insertions have been described for the Brand EF4T and Lennox–Fritschi PL4T transfers, either the common interosseous tendon insertion or the A2 pulley. Zancolli[62] originally described looping the tendon graft or fascia lata grafts around the common interosseous tendon – a technique described as "direct interosseous activation". In addition to restoring MCP joint flexion, this insertion may potentially provide abduction of the fingers. Palande[66] has also reported using both the ECRL and palmaris longus tendons extended with tendon grafts, inserting them around the common interosseous tendons. ECRL or palmaris longus are elongated with tendon grafts or fascia lata grafts which are then tunneled through the carpal tunnel to emerge distal to the superficial palmar arch through an incision just to the ulnar side of the thenar crease. The first dorsal interosseous tendon, the palmar and dorsal interosseous tendons in the second, third, and fourth webspaces and the muscle–tendon junction of the hypothenar muscles are all identified through

a transverse incision along the distal palmar crease. The plantaris tendon grafts or fascia lata grafts are split into four or five slips. One slip is looped around the muscle–tendon junction of the first dorsal interosseous; one slip around the combined first palmar interosseous and second dorsal interosseous tendons in the index–long finger webspace; one slip around the combined third dorsal interosseous and second palmar interosseous tendons in the long–ring finger webspace; one slip around the combined fourth dorsal interosseous and third palmar interosseous tendons in the ring–small finger webspace; and if necessary the final fifth slip can be looped around the muscle–tendon junction of the hypothenar muscles. The hand is positioned with the MCP joints flexed 60° and the interphalangeal joints straight. After slack has been taken up, each of the four of five slips are sutured back onto themselves, starting on the radial side with the index finger, then the slip between the ring and small fingers and finally the slips between the index and long fingers and between the long and ring fingers. The correct tension is confirmed by performing a wrist tenodesis maneuver. The hand is immobilized for 3 weeks with the wrist neutral, the MCP joints in 90° of flexion, and the interphalangeal joints extended.

Brooks and Jones[63] described amalgamating the Brand EF4T transfer with the Zancolli lasso procedure in which the ECRL or FCR tendons are elongated with plantaris or toe extensor tendon grafts and passed through the carpal tunnel and looped around the A2 pulleys of each finger. This variant of the EF4T transfer will only produce MCP joint flexion.

Tendon transfer to correct ulnar deviation of the small finger

A variant of the Fowler transfer has been advocated by Blacker *et al*.[74] to correct the ulnar deviation deformity of the small finger (Wartenberg's sign). The ulnar half of extensor digiti minimi is detached, passed volar to the deep transverse intermetacarpal ligament and sutured into the insertion of the radial collateral ligament of the MCP joint at the base of the proximal phalanx, or if there is associated clawing of the small finger, it is looped under the A2 pulley and sutured back to itself (Brooks' insertion). Chung *et al*.[75] described transferring EIP to the distal radial aspect of the extensor hood of the small finger to correct the persistent abduction deformity of the small finger in an ulnar nerve palsy.

Tendon transfers to provide adduction of the thumb

The most successful tendon transfers to restore adduction of the thumb have a transverse direction of pull across the palm deep to the flexor tendons to insert into the tendon of adductor pollicis. Littler[33] has advocated transfer of the ring finger FDS tendon deep to the flexor tendons of the index and long fingers, parallel and superficial to the transverse fibers of adductor pollicis and inserted into a drill hole just distal to the adductor insertion, and has been able to document an increase in pinch strength to 71% of the opposite hand. Smith[76] described using extensor carpi radialis brevis extended by a free tendon graft passed through the second intermetacarpal space and tunneled deep to the flexor tendons but superficial to the adductor pollicis to an insertion into the adductor tendon (Fig. 34.31). Other tendon transfers to restore adduction of the thumb have included either the brachioradialis[77] or extensor carpi radialis longus[78] elongated with a tendon graft and passed through the third intermetacarpal space to the thumb MCP joint, and the extensor indicis proprius passed through the second intermetacarpal space.[79] Combined transfers to provide both thumb adduction and index finger abduction have been described by splitting the extensor indicis proprius or extensor digiti minimi tendons.[80]

If there is a severe collapse Z-deformity of the thumb with hyperextension at the MCP joint and flexion at the IP joint, or

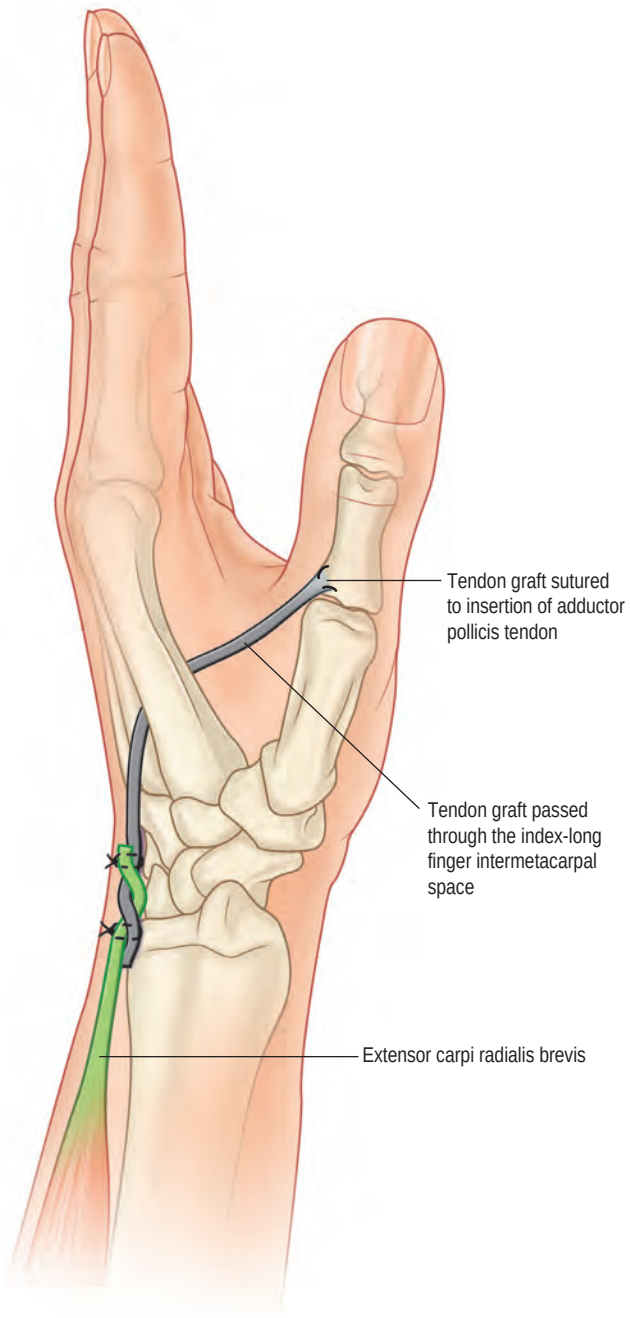

Fig. 34.31 Smith adduction transfer. A tendon graft is attached to the adductor tubercle on the ulnar base of the proximal phalanx of the thumb, passed through the second intermetacarpal space and sutured to extensor carpi radialis brevis.

an exaggerated Jeanne's sign when attempting to pinch, arthrodesis of the MCP joint may be necessary.[33,81] The thumb MCP joint is positioned in 15–20° of flexion and 15° pronation and arthrodesis achieved using a dorsal plate, interosseous wiring, or tension band wiring. Arthrodesis of the MCP joint may be combined with an adductor transfer or the transfer may be performed secondarily. Occasionally, if there is a severe fixed flexion deformity of the IP joint, arthrodesis of the IP joint is indicated[82] instead of the MCP joint, combined with an adductor transfer. IP joint arthrodesis is achieved with interosseous wiring, K-wires or a combination of each or headless compression screws.

For mild collapse deformities of the thumb without a fixed contracture, a split FPL to EPL transfer may be indicated.[83] Through a volar Bruner incision, the FPL is split longitudinally from its insertion proximally to the distal end of the A1 pulley. The radial half of FPL is transected at its insertion, retracted back proximal to the oblique pulley, and passed deep to the radial neurovascular bundle around the radial border of the proximal phalanx into a longitudinal incision on the dorsum of the proximal phalanx. The radial slip of FPL is sutured to the EPL tendon proximal to the IP joint with the MCP joint in 15° of flexion and the IP joint in full extension. The IP joint is fixed with a K-wire for 4 weeks.

Ring finger flexor digitorum superficialis adductor transfer

The ring finger FDS tendon is transected between the A1 and A2 pulleys through a short incision at the base of the ring finger.[33] The FDS tendon is then passed transversely across the palm deep to the index and long finger flexor tendons to the ulnar aspect of the thumb MCP joint, through a short incision just to the ulnar side of the thenar crease. The transfer is either sutured into the adductor pollicis tendon or passed through a drill hole in the proximal phalanx just distal to the adductor insertion and tied over a button. Tension is set with the wrist in neutral and the thumb adducted against the index finger with the FDS tendon at its resting length. Appropriate tension is confirmed by tenodesis of the wrist – with wrist flexion, the thumb should be able to be passively abducted. Edgerton and Brand[34] have described a variation of this transfer in which the ring finger FDS is brought through a window in the palmar fascia and then passed subcutaneously to the abductor insertion. The vertical septum of palmar fascia arising from the long finger metacarpal acts as a pulley. Obviously, the ring finger FDS cannot be used as an adductor transfer in patients with a high ulnar nerve palsy since this would deprive the ring finger of its only remaining flexor tendon.

Smith extensor carpi radialis brevis adductor transfer (see Fig. 34.31)

Extensor carpi radialis brevis is transected through a short transverse incision over the second dorsal extensor compartment just distal to the extensor retinaculum and withdrawn through a second transverse incision just proximal to the extensor retinaculum.[76] A small flap is then elevated over the ulnar aspect of the MCP joint of the thumb and a palmaris or plantaris tendon graft sutured to the adductor pollicis tendon. Through a short transverse incision overlying the proximal third of the second intermetacarpal space, a tendon passer is used to tunnel the tendon graft deep to the flexor tendons but superficial to the adductor pollicis, withdrawing it dorsally through the second intermetacarpal space. After passing the tendon graft subcutaneously to the most proximal incision, it is woven into the extensor carpi radialis brevis tendon with the wrist in neutral and the thumb adducted (see Figs. 34.31 & 34.33). Tension is then checked by tenodesis of the wrist – with wrist flexion, the thumb should become strongly adducted, whereas wrist extension should allow easy passive abduction of the thumb. Postoperatively the thumb is immobilized for 3 weeks midway between full abduction and full adduction with the wrist in 20–30° of extension.

Tendon transfers to provide index finger abduction

Restoration of strong abduction of the index finger is the second component required for powerful pinch. Bunnell[69] described the transfer of extensor indicis proprius (EIP) extended with a short tendon graft and inserted into the first dorsal interosseous tendon. Bruner[84] divided the extensor pollicis brevis (EPB) tendon over the dorsum of the MCP joint of the thumb and tunneled it subcutaneously beneath the extensor pollicis longus tendon into the first dorsal interosseous tendon. Hirayama[85] lengthened the palmaris longus tendon with a strip of palmar fascia (similar to the Camitz transfer) and tunneled it subcutaneously around the radial border of the forearm over the dorsum of the wrist and hand to insert into the first dorsal interosseous tendon. Graham and Riordan[86] transferred the FDS of the ring finger in a similar route around the radial border of the wrist over the dorsum of the hand to either the first dorsal interosseous tendon or into a drill hole on the radial aspect of the index finger. However, one of the accessory tendons of abductor pollicis longus (APL) extended with a free tendon graft or attached to the re-routed EDC tendon of the index finger may be the best choice to restore abduction of the index finger.[87]

Neviaser accessory abductor pollicis longus and free tendon graft (Fig. 34.32)

Neviaser *et al*.[87] described an accessory APL tendon elongated with a palmaris or plantaris tendon graft transferred to the insertion of the first dorsal interosseous tendon (see Figs. 34.32e and 34.33). A small flap is elevated over the radial aspect of the proximal phalanx of the index finger and a tendon graft sutured to the first dorsal interosseous tendon just distal to the MCP joint. The proximal end of the tendon graft is then passed subcutaneously to a transverse incision just distal to the first dorsal extensor compartment. After opening the compartment, one of the accessory APL tendons is transected and interwoven with the tendon graft with the wrist in neutral position and the index finger radially abducted.

High ulnar nerve palsy

Many surgeons fail to realize the significant functional deficit in a high ulnar nerve palsy associated with paralysis of the flexor carpi ulnaris and FDP tendons to the ring and small

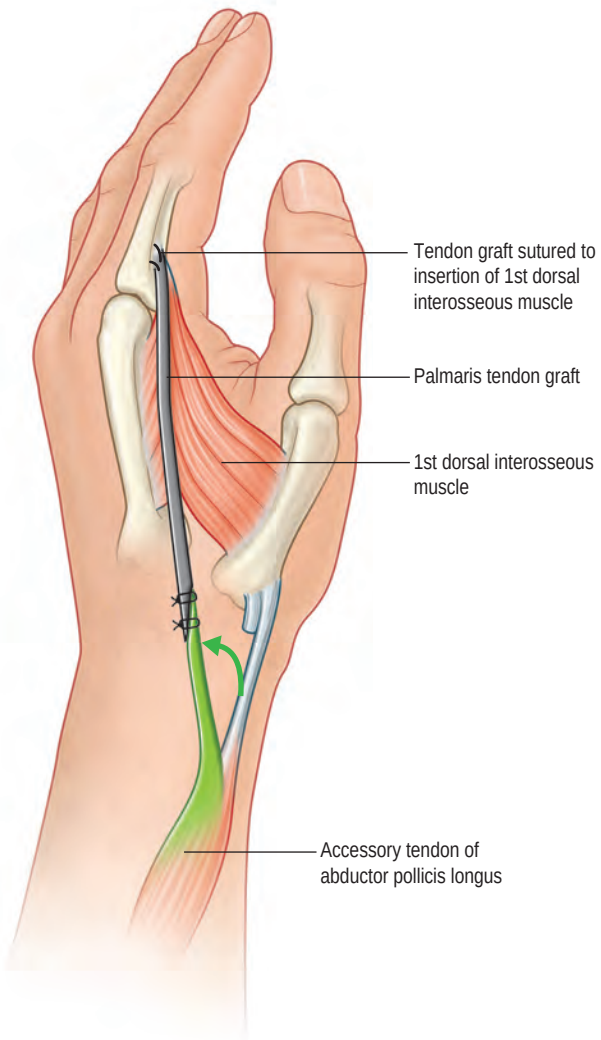

Fig. 34.32 Neviaser transfer to restore abduction of the index finger. A palmaris tendon graft is sutured to the insertion of the first dorsal interosseous muscle on the radial base of the proximal phalanx of the index finger and sutured to one of the accessory tendons of abductor pollicis longus.

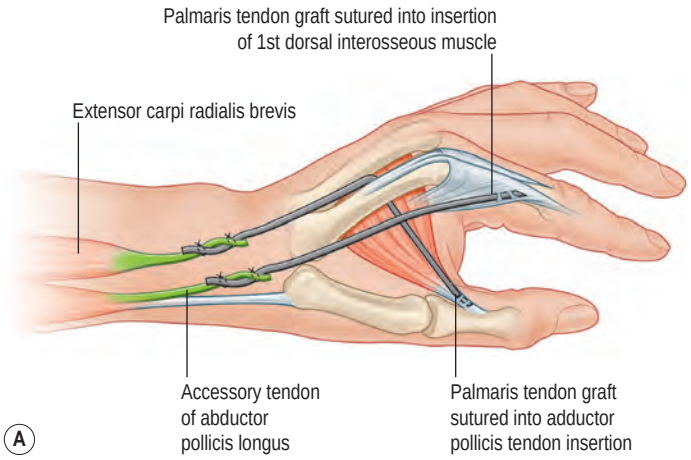
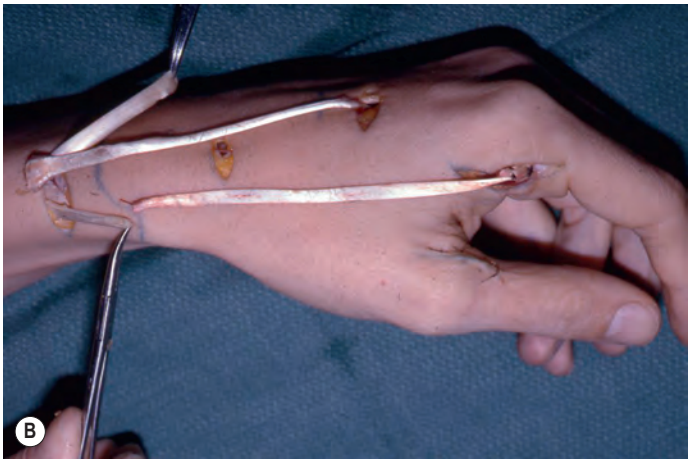
fingers. The only remaining tendons on the ulnar side of the hand are the FDS tendon to the ring finger and the usually diminutive FDS tendon to the small finger. However, paralysis of the FDP tendons to the ring and small fingers will often be masked by interconnections between these two tendons and the long finger FDP tendon at the wrist. If there is significant weakness of DIP joint flexion of the ring and small fingers (Pollock's sign), power grip can be restored by side-to-side tenorrhaphy of the ring and small finger FDP tendons to the median-innervated middle finger FDP tendon.[58] This should be performed before tendon transfers to correct clawing are performed, but patients should be warned that this will temporarily exaggerate their clawing and that they should use a lumbrical block splint. To restore independent flexion of the ring and small fingers, the FDS tendon of the long finger may be used as a donor tendon to activate the FDP tendons of the ring and small fingers. Patients requiring strong ulnar deviation and flexion of the wrist may occasionally need to be considered for transfer of the FCR tendon to FCU.[58]

Outcomes

There are very few reports to substantiate the relative effectiveness of the various transfers to restore synchronous MP flexion and IP extension of the fingers and thumb–index finger pinch. Hastings and Davidson[88] compared four techniques: Zancolli "lasso", Stiles–Bunnell, Brand, and Riordan and Fowler transfers to correct the claw deformity in 12 patients with high, 14 patients with low, and three patients with mixed high and low ulnar nerve palsy. Successful outcomes were seen in the majority of cases. Most failures occurred in the small finger and transfers utilizing the superficialis tendons were found to further weaken the hand. Only transfers using wrist flexors or extensors have been shown to increase grip strength. A later report examining the effectiveness of the FDS "lasso" procedure showed similar results, with correction of clawing in 19 of 23 digits but no significant improvement in grip strength.[89] The extended pulley insertion for a modified Stiles–Bunnell transfer produced good to excellent correction of clawing in 92% of fingers.[64] Brandsma *et al*.[51] reported good (57%) or excellent (21%) results using the FDS transfer to restore intrinsic function. The long or ring finger FDS transfer resulted in 95% good or excellent correction of clawing in leprosy patients at an average follow-up of 2 years.[64] The Brand EF4T transfer provided 79–86% good to excellent correction of clawing at a 10-year follow-up.[64] Eighty-five percent good to excellent results were obtained utilizing the common interosseous tendon insertion technique.[62] PIP hyperextension occurred in 6.25% when the common interosseous tendon insertion was utilized in an EF4T transfer, compared with a 13.75% incidence when the EF4T transfer was inserted into the lateral bands.[64] Therefore there is less chance of overcorrection producing a PIP joint hyperextension deformity by utilizing the common interosseous tendon insertion. An additional advantage of using ECRL as the motor is that the palmar arch is restored. Ozkan *et al*.[90] compared the results of three different tendon transfers to restore grip strength and correct the claw deformity in 44 patients with ulnar nerve palsy. Twenty-four patients were reconstructed with a modified Stiles–Bunnell four-tail procedure, 11 patients with the Brand EF4T transfer and nine patients with a Zancolli "lasso" procedure. With a recent paralysis, the Zancolli and Brand procedures were the most effective in restoring grip strength, but with long-standing paralysis, the Stiles–Bunnell four-tail procedure was the most successful in correcting the claw deformity.

Hastings and Davidson[88] showed an approximate doubling of pinch strength in hands treated with the ECRB adductorplasty transfer, although it is interesting to note that only 18 of the 34 patients in this study felt that pinch strength was compromised enough to warrant a tendon transfer. Robinson *et al*.[80] evaluated the combination of the ulnar slip of EDM to provide thumb adduction and EIP to restore index finger abduction in six patients and demonstrated an average improvement in pinch strength from 5% to 40–50% of the normal side. Fischer *et al*.[91] evaluated the results of tendon transfers to restore thumb adduction (ECRL was transferred to adductor pollicis) and index finger abduction (APL was transferred to the first dorsal interosseous) at an average of 6 years postoperatively. Key pinch averaged 73%, pulp-to-pulp pinch averaged 72%, grip strength was 73%, the force of thumb adduction was 63%,





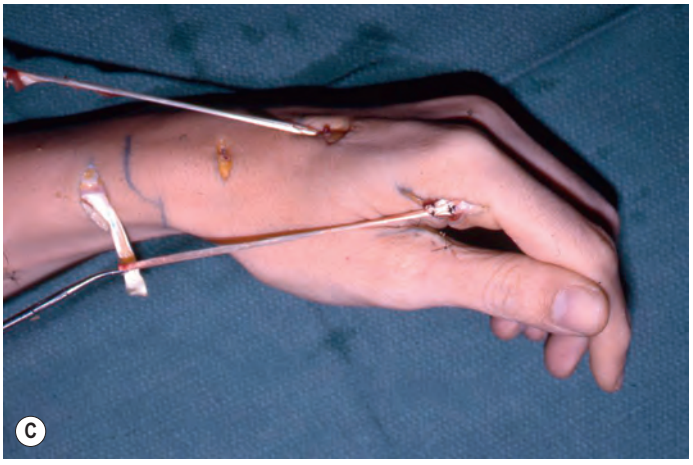


Fig. 34.33 **(A)** Smith transfer to restore adduction of the thumb and the Neviaser transfer to restore abduction of the index finger. **(B)** A tendon graft has been attached to the adductor pollicis insertion and passed deep to the flexor tendons and neurovascular bundles through the second intermetacarpal space from palmar to dorsal. A second tendon graft has been sutured to the tendon of insertion of the first dorsal interosseous muscle. **(C)** Traction on these two tendon grafts flexes and adducts the thumb and abducts the index finger at the metacarpophalangeal joint. **(D)** Postoperatively the patient has excellent abduction of the index finger for key pinch and **(E)** significant improvement in pinch strength.

and the force of index finger abduction was 58% of the normal hand.

Tendon transfers for combined nerve injuries

It is much more difficult to reconstruct the upper extremity affected by multiple nerve injuries. The majority of these patients require multiple reconstructive procedures and tendon transfers. The choice of tendon transfers and the timing of the surgery should be well planned, designed, and individualized to address the patient's specific functional needs. It is unwise to adopt a "cookbook" approach for reconstruction of the patient with combined nerve injuries. Basic principles of tendon transfers such as soft-tissue equilibrium, full passive range of motion of involved joints, selection of the appropriate donor muscle, and direction of transfer as outlined earlier should be carefully considered in preoperative planning.

Before any operation is performed, the patient should be educated about the goals and risks of the procedure and the

fact that the injured extremity will never be normal. As a general rule, the results of tendon transfers for combined nerve injuries are inferior to those for a single nerve injury.[92,93]

Adding to the complexity of these problems, the number of donor tendons is limited, more joints need to be mobilized, there is a more profound sensory loss, and the soft tissues may be more scarred in this patient population. Multiple nerve repairs or nerve grafting should be done as soon as clinically appropriate but return of motor function rarely extends beyond two major joints distal to the injury.[94] Reinnervated muscles, however, should not be used or only used with great caution as a donor for tendon transfers.

Dynamic tenodesis is an important concept in reconstruction of these combined nerve injuries. Wrist flexion or extension can be used to augment the excursion of any tendon transfer that crosses the wrist. For example, if a wrist flexor such as FCR is used to activate flexor digitorum profundus, flexion of the fingers will be enhanced if the patient extends their wrist using the ECRL or ECRB simultaneously with contraction of the FCR transfer. Therefore, if the excursion of a tendon transfer is less than optimal to produce a specific function, increased range of motion can be achieved through wrist tenodesis.[95]

Tendon transfers for low median–low ulnar nerve palsy

A low median and low ulnar nerve palsy is the most common combined nerve injury in the upper extremity and is usually the result of a "spaghetti-wrist" laceration.[92] This leads to complete loss of sensation on the palmar surface of the hand and a complete intrinsic motor paralysis that results in a claw hand deformity. A flat transverse metacarpal arch with hyperextension at the MCP joints and hyperflexion at the PIP joints (see Fig. 34.22) accompanied by an abducted small finger are the hallmark of this injury. It is especially important to prevent an adduction contracture of the thumb–index webspace.[95] The surgeon should repair or graft the median and ulnar nerves before any tendon transfers are performed in order to restore some protective sensibility to the hand. The goals of reconstruction in a low median–low ulnar nerve palsy are to restore thumb adduction, thumb abduction and opposition, abduction of the index finger, and improved extension of the PIP joints of the fingers.

Thumb adduction for key pinch can be restored by transfer of the extensor carpi radialis brevis extended by a tendon graft through the second intermetacarpal space and inserted into the adductor tubercle of the thumb metacarpal[76] or alternatively by transfer of the ring finger FDS tendon to the adductor insertion.[33] The best option for reconstruction of thumb opposition is the extensor indicis proprius transfer re-routed around the ulnar border of the hand and inserted into the abductor pollicis brevis tendon.[37,96] This transfer can be combined with arthrodesis of the MCP joint of the thumb to allow for maximum stability.[97] Index finger abduction for strong pinch can be restored by transfer of one of the accessory slips of the abductor pollicis longus tendon extended by a tendon graft to the first dorsal interosseous insertion.[87] Finally, clawing of the fingers can be corrected by using ECRL or palmaris longus[71,73] extended by four tendon grafts and inserted either into the radial lateral bands or the A2 pulleys as previously discussed. Alternatively, if the patient has developed a flexion contracture of the wrist, by involuntarily trying to prevent clawing by flexing their wrist, the FCR tendon may be used to motor the four tendon grafts.[25]

If the patient still has poor palmar sensibility despite nerve repair or nerve grafting, consideration should be given to transfer of a superficial radial nerve innervated flap to the thumb or nerve transfer of the superficial radial nerve to the distal median nerve.

Tendon transfers for high median–high ulnar nerve palsy

This is a very severe injury in which there is no active flexion of the fingers and thumb, and loss of thumb opposition and key pinch, in addition to the loss of palmar sensibility. Initially, the fingers may be fully extended even at the interphalangeal joints despite the intrinsic paralysis. However, once tendon transfers are completed to provide active finger flexion, the fingers gradually assume a claw posture. Tendon transfers for reconstruction of a high median–high ulnar nerve palsy have to be performed in two or three stages. The goals are to restore finger and thumb flexion, thumb–index finger pinch, abduction and opposition of the thumb, and correct the later development of clawing of the fingers.

Thumb adduction and key pinch can be achieved by transfer of extensor carpi radialis brevis with a free tendon graft through the second intermetacarpal space to the adductor pollicis insertion.[76,98] Finger flexion can be restored by transfer of extensor carpi radialis longus to the four FDP tendons.[58] This can be combined with tenodesis of the DIP joints of the three ulnar fingers.[92] Flexion of the thumb can be restored by transfer of the brachioradialis to flexor pollicis longus through the same palmar incision.[58] The brachioradialis muscle must be mobilized and elevated off the radius into the proximal third of the forearm. A Pulvertaft tendon weave is then performed between the brachioradialis and flexor pollicis longus in the distal third of the forearm.[78,92] As in a low median–low ulnar nerve palsy, the most reliable procedure for thumb opposition is transfer of the extensor indicis proprius to the abductor pollicis brevis insertion.[37] If the IP joint of the thumb tends to assume a flexed position, the EIP transfer should be inserted both into the APB insertion and then into the EPL tendon just proximal to the IP joint.[25] If thumb pinch remains unstable with MP extension and IP joint flexion, arthrodesis of the MP joint should be considered. A useful procedure that avoids the need to fuse the IP joint of the thumb involves longitudinal splitting of the FPL tendon, detaching the radial half from its insertion into the distal phalanx and transfer of this tendon slip dorsally where it is attached into the EPL tendon proximal to the IP joint of the thumb.[83] This results in a dynamic stabilization of the IP joint when the transfer pulls through the FPL.

If after finger flexion has been restored the fingers begin to adopt a claw position, there are no expendable wrist extensors (ECRL and ECRB) remaining to provide integration of MP flexion and IP joint extension, static tenodesis techniques may be necessary. Free tendon grafts can be placed from the deep transverse metacarpal ligaments to the lateral bands[61] or from the dorsal carpal ligament to the lateral bands.[25] Alternatively, hyperextension can be prevented by Zancolli capsulodeses or arthrodeses of the PIP joints. Finally, abduction of the index finger for pinch can be restored using an accessory abductor

pollicis longus tendon extended with a free tendon graft to the first dorsal interosseous[87] or alternatively by using extensor pollicis brevis.[84]

The importance of restoring sensibility to the radial side of the hand in a high median–high ulnar nerve palsy cannot be overstated, either by secondary nerve repair or nerve grafting. A sensate hand is the prerequisite for performing the tendon transfers mentioned above. If sensation cannot be restored, Omer has advocated a fillet flap of the index finger to resurface the thumb–long finger webspace with dorsal skin innervated by the superficial radial nerve.[92] Alternatively, a first dorsal metacarpal artery flap innervated by the superficial branch of the radial nerve can be transferred to the palmar surface of the thumb; or the superficial branch of the radial nerve itself can be transferred to the distal median nerve as a nerve transfer.

Tendon transfers for reconstruction after trauma

Tendon transfers are an excellent method of restoring active motion to the hand and wrist following traumatic injuries of the muscles and tendons of the forearm, wrist, and hand. If there has been segmental loss of tendon, a tendon graft is often used instead of a tendon transfer. With more severe trauma (industrial or motor vehicle accidents, blast, missile, and explosion injuries), associated damage to the soft tissues will leave a scarred bed which is unsuitable for tendon grafts, since a tendon graft is more likely to become adherent to the scarred surrounding tissue than a tendon transfer. If a forearm muscle itself has been badly damaged, a tendon graft will be unable to restore active motion and a tendon transfer will be necessary.

Time is another important consideration in reconstruction of the post-traumatic upper extremity. Myostatic contracture and atrophy are the unavoidable fate of injured muscle if there has been a long delay between the traumatic event and the reconstructive procedure, again making a tendon transfer a more suitable option for reconstruction.

Tendon transfers to restore thumb extension

Rupture of the EPL tendon occurs in approximately 1 in 200 distal radius fractures, classically at Lister's tubercle, and may happen at any time from several weeks to several months after the fracture. Ischemia of the tendon due to swelling and edema of the tenosynovium and attrition over the roughened dorsal radial cortex have been postulated as the etiology for this tendon rupture.[99–102] Patients present with weak or loss of extension at the interphalangeal joint (Fig. 34.34A) or paradoxically with incomplete extension at the MCP joint as well as inability to raise the thumb dorsal to the plane of the hand.

The optimal choice for restoration of thumb extension is the EIP to EPL transfer, which can be performed under local

Fig. 34.34 **(A)** This patient demonstrates inability to extend the interphalangeal joint of the thumb due to a rupture of the extensor pollicis longus (EPL) tendon caused by a minimally displaced Colles fracture of the distal radius. **(B)** The extensor indicis proprius tendon is transected at the metacarpophalangeal joint of the index finger and passed subcutaneously to be sutured to the ruptured end of the EPL tendon. **(C)** Postoperatively the patient demonstrates excellent extension and **(D)** flexion of the interphalangeal joint of the thumb.

anesthesia (see Fig. 34.34B). The EIP tendon is harvested through a short transverse incision just proximal to the index finger MCP joint and its distal stump is then sutured end-to-side to the EDC tendon of the index finger to prevent extensor lag of this finger. The EIP is retrieved through a second transverse incision just distal to the extensor retinaculum. A third incision is made over the distal third of the thumb metacarpal and the EIP is tunneled subcutaneously to this incision. The distal end of the EIP is sutured to the distal end of the EPL with the wrist held in neutral and the thumb fully extended and parallel or just volar to the plane of the palm.[103] The tension of the transfer can be checked by tenodesis of the wrist. With wrist flexion, the thumb should move dorsal to the plane of the palm and with wrist extension the thumb should be able to be placed in full passive abduction and opposition. The patient is even able to use the EIP transfer immediately and extend the thumb on the operating table if the surgery is performed under local anesthesia as "wide-awake" surgery.[104] Postoperatively, the wrist is immobilized in 40° of extension with the thumb in abduction and extension for 3–4 weeks. A removable splint is used for an additional 3–4 weeks and there is usually no need for retraining (see Fig. 34.34C,D).

Tendon transfers to restore finger extension

Restoration of finger extension after trauma can be accomplished by tendon transfers similar to those used for radial nerve palsy. Those transfers were discussed in detail earlier in this chapter and include transfer of either of the wrist flexors FCU or FCR to the EDC or the Boyes transfer of the FDS of the long and ring fingers to the EDC.

Tendon transfers to restore thumb flexion

Acute lacerations or ruptures of the flexor pollicis longus tendon can be treated by primary or delayed primary repair or tendon grafting. However, with a missed diagnosis, the muscle fibers undergo significant shortening, atrophy, and fibrosis within 6 months to a year from injury. In these situations it is preferable to restore thumb flexion using a tendon

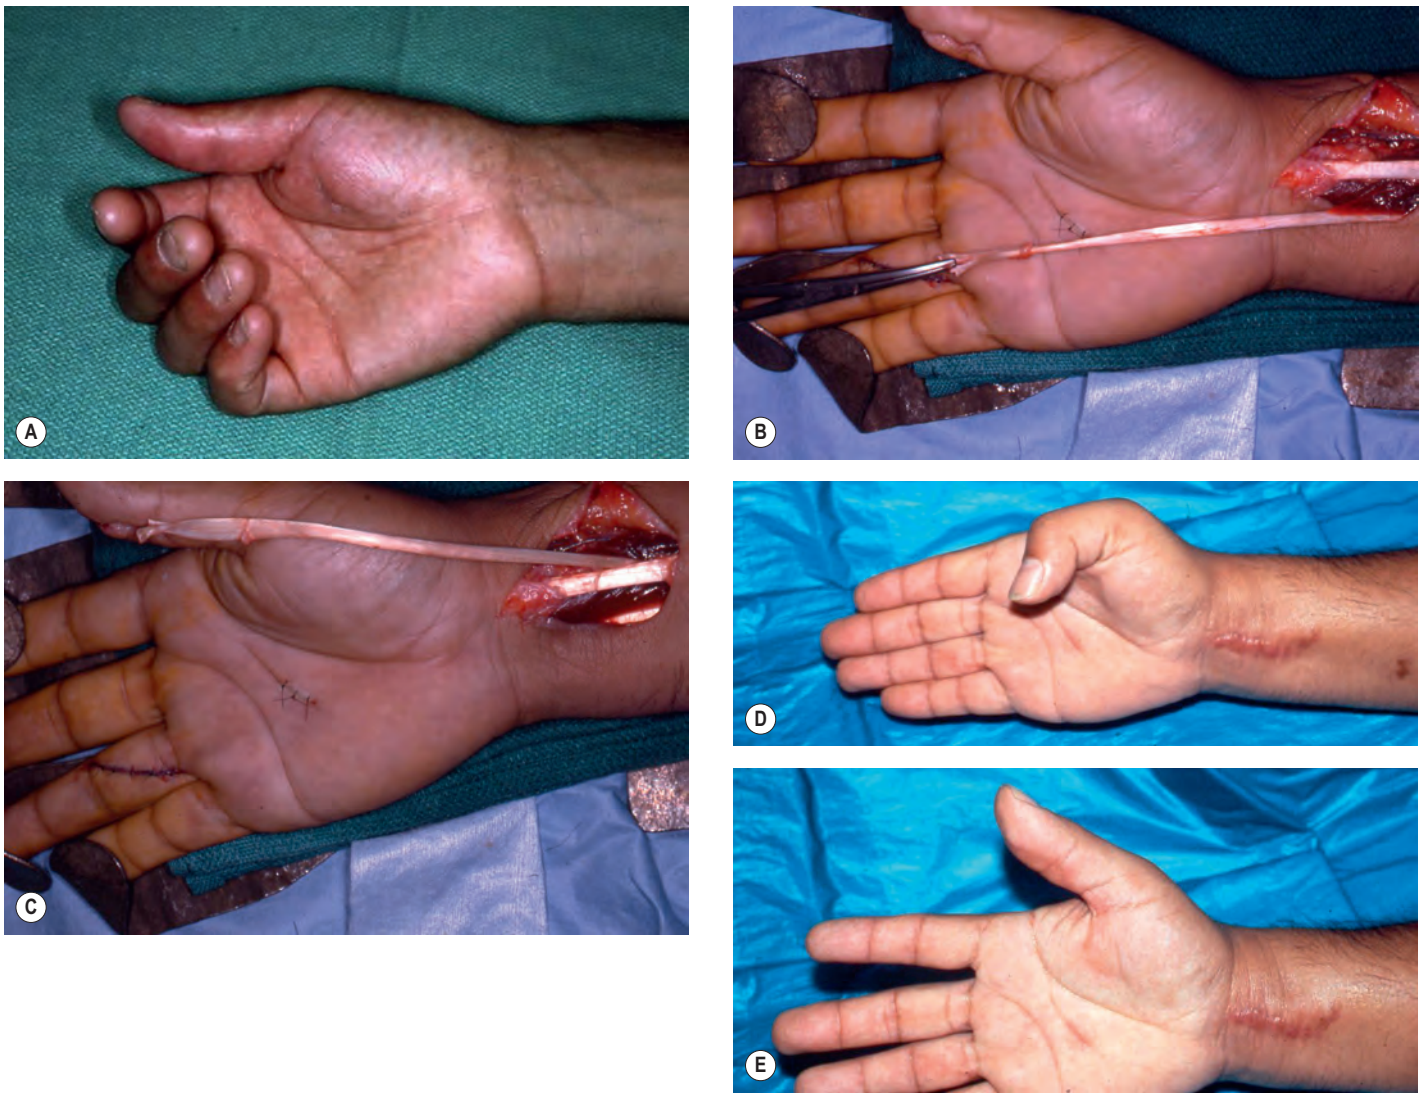

Fig. 34.35 **(A)** Loss of flexion at the interphalangeal joint of the thumb due to a missed laceration of the flexor pollicis longus (FPL) tendon. **(B)** The flexor digitorum superficialis of the ring finger is harvested and **(C)** transferred through the tendon sheath of FPL. **(D)** Postoperatively the patient demonstrates excellent flexion of the interphalangeal joint and **(E)** satisfactory extension.

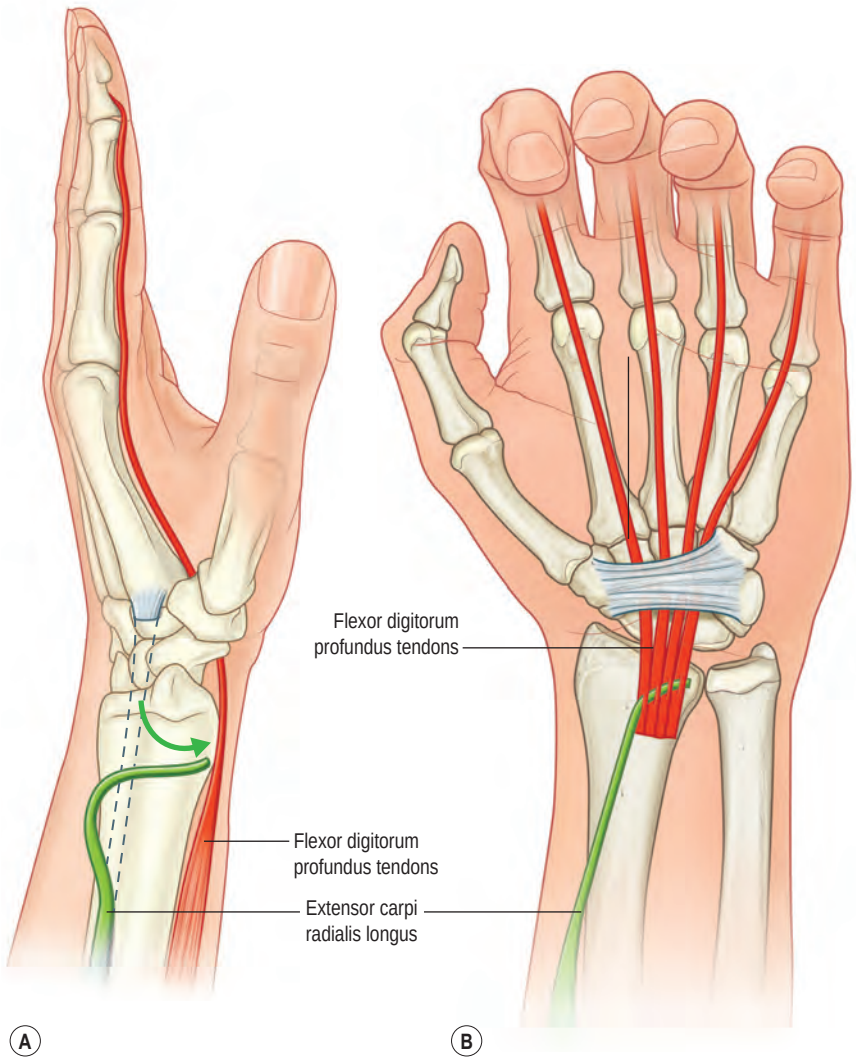

Fig. 34.36 Tendon transfers to restore finger flexion. **(A)** The extensor carpi radialis longus (ECRL) tendon is transected from the base of the index finger metacarpal and transferred subcutaneously around the radial border of the distal forearm. **(B)** The ECRL tendon is sutured to the flexor digitorum profundus (FDP) tendons of the index, long, ring, and small fingers proximal to the carpal tunnel. Correct tensioning of this transfer is absolutely crucial, because ECRL only has 30 mm of amplitude whereas the FDP tendons require 70 mm of excursion for full finger flexion.

transfer, usually the FDS of the ring finger[105] (Fig. 34.35). The ring finger FDS is harvested through a transverse incision at the base of the proximal phalanx and retrieved through a second incision in the proximal palm. It is then passed through the flexor pollicis longus sheath to the base of the distal phalanx through an open incision or attached to a fine rubber catheter or feeding tube and withdrawn distally through the sheath. The ring finger FDS to FPL tendon transfer can be performed in one stage or in two stages if the bed is scarred with initial placement of a Silastic tendon rod.[105] If necessary, a pulley can be reconstructed using the old FPL tendon remnant or with a palmaris longus graft.[95] The tendon is sutured to the distal phalanx of the thumb using a pullout suture fixed over a button. The tension of the transfer can be checked by wrist tenodesis. With the wrist in full flexion, the thumb should extend completely and with wrist extension the thumb tip should overly the ring finger MCP joint.

Tendon transfers to restore finger flexion

Occasionally patients may present with severe crushing or avulsion injuries involving the forearm flexor muscles. The options for secondary reconstruction of finger flexion are either a tendon transfer of the ECRL to all four FDP tendons (Fig. 34.36) or a functioning free gracilis muscle transfer. The ECRL is transected at the base of the index finger metacarpal and mobilized through a longitudinal incision on the dorsum of the forearm (Fig. 34.37). It is then tunneled subcutaneously around the radial border of the forearm to a palmar incision over the distal forearm. Great care has to be exercised in adjusting the tension when suturing the ECRL to all four FDP tendons, since the ECRL only has 30 mm amplitude and the FDP tendons require 70 mm of excursion for full finger flexion. Inserting the transfer too tightly will prevent full finger extension. The wrist tenodesis effect is vitally important in this transfer – wrist extension should cause the fingers to flex down to the palm, whereas wrist flexion should allow the fingers to come out to full extension. If the flexor pollicis longus is also non-functioning, thumb flexion can be restored by transferring brachioradialis to FPL through the same palmar incision (see Fig. 34.19B).

Summary

Tendon transfers, if carefully selected and performed meticulously, will provide a gratifying functional improvement to the hand affected by radial, median, ulnar or combined nerve

Fig. 34.37 **(A)** This boy sustained segmental loss of all the forearm flexor muscles as well as the median nerve and is unable to flex any of his fingers or thumb. **(B)** The extensor carpi radialis longus (ECRL) tendon is transected and mobilized more proximally. The extensor indicis proprius tendon has been harvested for a simultaneous opposition transfer for the thumb. Brachioradialis was also transferred to flexor pollicis longus to restore flexion of the thumb. **(C)** Postoperatively, satisfactory finger flexion has been restored by transfer of the ECRL to the flexor digitorum profundus tendons of all four fingers.

palsies, as well as severe trauma affecting the extrinsic flexor and extensor muscles and tendons. Quantitative outcome data is lacking for many of the tendon transfers described, but surgeons and patients can attest to the significant benefits derived from them.

Future directions

Comparative outcome studies must be designed in the future to document the effectiveness of the various tendon transfers and their ultimate impact on hand function and return to work. It has also been suggested that nerve transfers will usurp the role of tendon transfers in the future and prospective outcome studies will need to be designed to compare the relative outcomes of nerve transfers and tendon transfers.[106]

Free-functioning muscle transfer in the upper extremity

Pundrique Sharma, Isaac Harvey, and Gregory H. Borschel

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Free-functioning muscle transfer involves the transfer of a muscle from a distant location to replace a lost function.
- It is a complex procedure that requires a highly motivated patient.
- The procedure involves microvascular anastomoses and neural coaptation.
- Meticulous attention must be paid to proper positioning and tensioning of the transferred muscle.
- Postoperatively, a highly structured rehabilitation program is required for a prolonged period, often up to 2 years.
- In the appropriate patient, reliably good results can be achieved for patients with otherwise devastating injuries.

Introduction

Key points

- This is a complex procedure for use where no simpler alternative is available.
- Meticulous attention to microsurgical technique is required; thrombosis leads to muscle loss.
- Attention to muscle placement and tensioning is also critical.
- This technique is applicable to restoration of finger, thumb, and wrist flexion and extension, elbow flexion and extension, and shoulder flexion.

Free-functioning muscle transfer involves the microneurovascular transfer of a functioning muscle from its donor site to a recipient site in the upper limb. The aim of the procedure is to restore functionality that has been lost as a result of trauma or other acquired pathology such as sarcoma, or which was never present as in the case of congenital anomalies such as arthrogryposis.[1,2] It is a complex procedure that was developed for situations where no simpler alternative is available. Most muscles in the body have been assessed for their usefulness for tissue transfer, and many have been identified as expendable and suitable for microvascular transfer. Most of these muscles have a long pedicle of suitably large caliber. The viability of the muscle is maintained by microvascular anastomosis between the muscle's artery and vein and a suitable artery and vein in the recipient area. Neural coaptation of the transferred muscle's motor nerve to a suitable nerve in the recipient area provides the ability of the muscle to contract, giving functionality to the transfer. This functionality is dependent on viability of the muscle and neural regeneration as well as correct technical placement, positioning, and rehabilitative programs. The common indications for free functional muscle transfer include direct trauma with muscle loss, Volkmann's ischemic contracture, nerve injury such as brachial plexus injuries, and oncologic resection.

Free muscle transfers to the upper limb have been used to reconstruct functional deficits in finger flexion, finger extension, thumb abduction, elbow flexion and extension, and shoulder flexion. Key planning issues include: the choice of appropriate muscle for a given function, the choice of an appropriate local nerve to motor the transferred muscle, and/or creation of such a nerve via nerve grafts.

Although function may be restored, patients must be counseled to be realistic about their expectations of outcome from this type of surgery.

Basic science/disease process

The basic functional purpose of a muscle is to provide both static tension and functional shortening. To understand its functioning, one must understand the structure of a muscle

Historical perspective

After multiple attempts by numerous authors, Thompson[3] was able to demonstrate that non-vascularized muscular transfer was possible. The first functioning muscle transfer was reported in 1970 by Tamai *et al.*,[4] who transplanted the rectus femoris muscle in dogs. He was able to provide electrophysiological and biomechanical evidence of muscular contraction of the transferred muscle. Since this time, multiple authors have pursued functional muscle transfers throughout the body to replace lost function. Functional muscle transfers have been reported in both the upper and lower limb and also for facial reanimation. In 1973 at the Sixth People's Hospital in Shanghai, microsurgeons successfully transplanted the lateral portion of pectoralis major into the forearm of a patient with Volkmann's ischemic contracture.[5] This was the first clinical application of free functional muscle transplantation in the upper limb. A good range of finger motion and substantial grip force were reported. In 1976, Ikuta *et al.*[6] performed experimental work demonstrating the efficacy of free functional muscle transfer. They were also able to demonstrate almost normal histological condition of the transplanted muscle. In the same year, Harii *et al.*[7] showed that it was possible to transfer muscle to the face for treatment of facial paralysis.

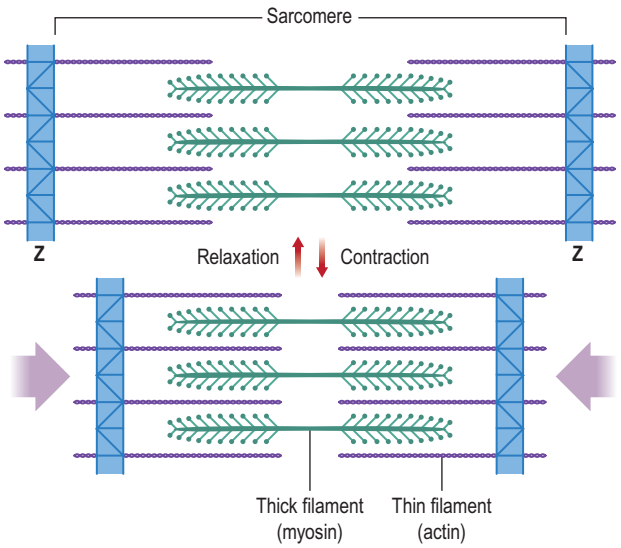

Fig. 35.1 Structure of striated muscle.

(Fig. 35.1). A skeletal muscle is composed of parallel muscle cells called myofibers. Each muscle cell is composed of smaller parallel myofibrils. These myofibrils are further subdivided into thin and thick filaments containing actin and myosin.[8] Within each muscle cell the myofibrils are arranged within functional compartments known as sarcomeres. These sarcomeres are made up of interdigitating fibers of actin and myosin that interact at a subcellular level (Fig. 35.2). When a muscle is stimulated to contract, the actin and myosin fibers move over one another by the flexing action of myosin cross-bridges.[9]

The amount of overlap of the actin and myosin fibers determines the number of side chains that are in contact and therefore able to contribute to force generation. When a muscle is overstretched there are fewer side chains in contact. When a muscle is overcontracted the myosin chains crumple and cannot contract further.[10]

This relationship leads to a length–tension relationship that provides for maximal force generation when the muscle is at its native physiological length (Fig. 35.3). The total force exerted by a muscle is the sum of the passive force provided by the elastic properties of the muscle fibers and surrounding tissues and the active force produced by the contraction of actin and myosin filaments.[8] The relationship of length to contractile force generation is described by a bell curve with decreasing ability of force generation further from the physiological resting state corresponding with less overlap of the actin and myosin fibers. For this reason, determination of the resting length of the donor muscle is critical prior to transfer, such that this length can be reconstituted after transfer at inset of the muscle and maximal contractile force can be generated.[10]

There are many morphological types of muscle in the body. They can be divided into two major types, strap muscles and pennate muscles, or a combination of the two (Fig. 35.4). In a strap muscle, the muscle fibers are arranged in parallel to the long axis of the muscle. This is important from a functional

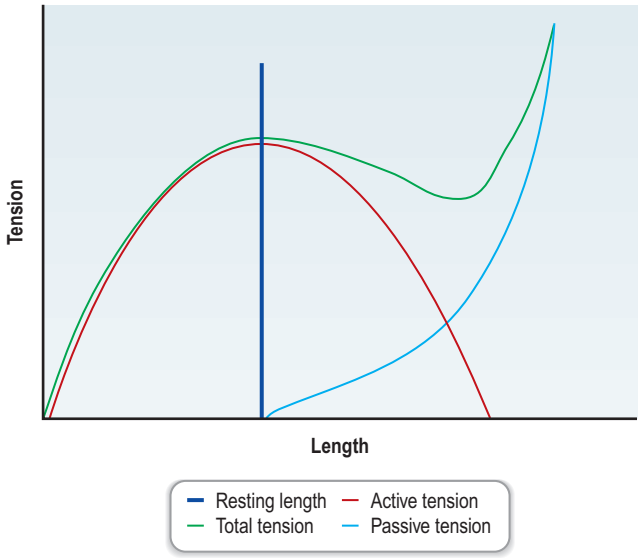

Fig. 35.3 The length–tension relationship.

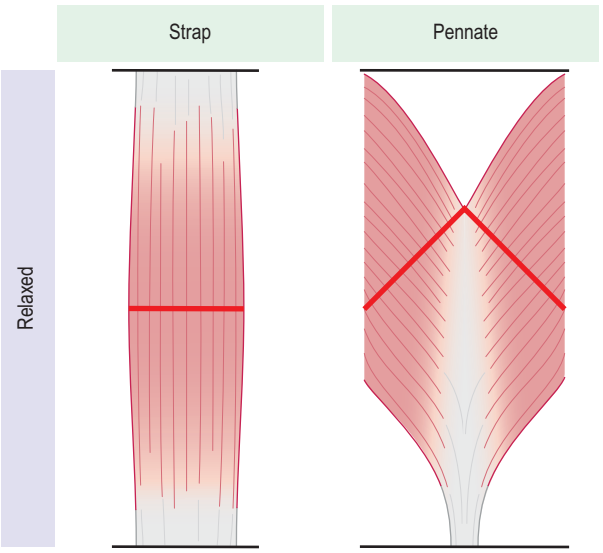

Fig. 35.5 In pennate muscle, the muscle fibers are arranged at an angle to a central tendon.

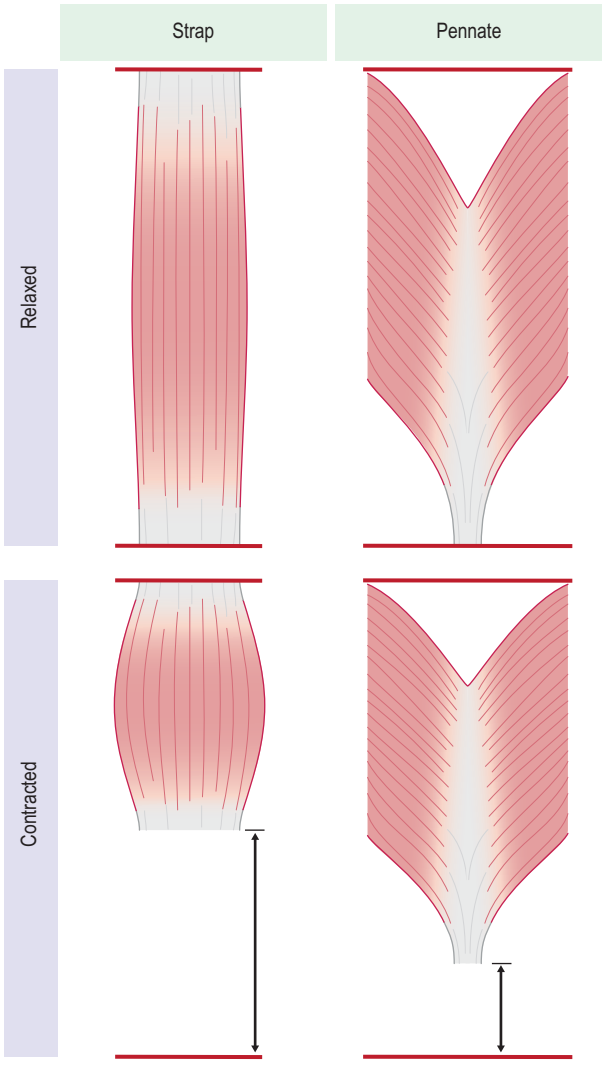

Fig. 35.4 Strap and pennate muscles.

standpoint, as the excursion of a strap muscle is directly proportional to its length. It has been demonstrated that at maximal contraction a strap muscle can contract up to 65% of its resting length.[8] In a pennate muscle, the muscle fibers are arranged at an angle to a central tendon (Fig. 35.5). As a result, the individual fibers in a pennate muscle usually do not run the entire length of the muscle. The excursion achieved by a pennate muscle is proportional to the length of the muscle fibers, not the length of the entire muscle. As such, a pennate muscle will usually yield lesser excursion than a strap muscle.[10]

The pennation angle, or angle of pull of the muscle in relation to the tendon, affects both force generation and excursion. Muscles with a lesser pennation angle (a straighter angle between the fibers and the tendon) produce a greater excursion with contraction but less power than those with a greater pennation angle.

The force generated by a muscle is proportional to its total cross-sectional area. Whether this is due to a greater number of muscle fibers or hypertrophy of a smaller number of fibers, the maximal force generation has been calculated in mammals to be approximately 4 kg/cm^2.[8] The cross-sectional area is calculated perpendicular to the direction of the muscle fibers. In a strap muscle this is perpendicular to the muscle as a whole and perpendicular to the tendon. In a pennate muscle this is perpendicular to the fibers and oblique to the tendon and muscle as a whole, resulting in a greater cross-sectional area and thus a greater potential for force generation.

The contraction of an individual muscle fiber is an all-or-none phenomenon: when a weak contraction is required, only a few fibers within the muscle are stimulated to contract.[9] When a forceful contraction is required, a greater number of muscle fibers are stimulated to contract. Each muscle is innervated by a motor nerve. The motor nerve joins the muscle via its motor endplates at the neuromuscular junction. A given nerve fiber within the nerve will have a defined number of motor endplates, each of these innervating specific fibers within the muscle. A muscle is thus composed of functional motor units, multiple muscle fibers innervated by the same

Table 35.1 **Principles of tendon transfer applicable to free-functioning muscle transfer**

- An elective tendon/muscle transfer should never be performed in the presence of unhealed wounds
- Full passive joint motion must be restored before tendon/muscle transfer
- The transfer should not pass through areas of scar tissue or under skin grafts. Furthermore, surgical incisions should not be placed directly over the transfer
- Whenever possible, cutaneous sensibility should be restored before tendon/muscle transfer
- The normal function of the transferred muscle must be expendable
- Synergism between the muscle's original and new actions facilitates rehabilitation (in the case of free muscle transfer this principle could be applied to the function of the donor motor nerve)
- The transferred muscle must have sufficient amplitude and power to perform its new function; thus, reinnervated muscles should be used only in exceptional circumstances

(Adapted from Anastakis D, Manktelow R. Free functioning muscle transfers. In: *Green's Operative Hand Surgery*, 5th edn. Philadelphia, PA: Elsevier, 2005.)

nerve fiber. Depending on the muscle, this may be as few as five muscle fibers, such as in the extraocular muscles, or as many as several hundred, as is the case with most major skeletal muscles. This relationship is important in relation to reinnervation and the number of axons provided by a given donor motor nerve. A muscle with smaller muscle units may provide finer control but less power for a given number of axons, and *vice versa* – a muscle with larger motor units requires fewer axons for greater force generation.

Individual muscles considered for transfer have been assessed with regard to their internal architecture, vascular anatomy, motor innervation, and characteristics relevant to desired function. Ideally, the transferred muscle should have a single dominant vascular pedicle (Mathes and Nahai type 1)[11] of sufficient length to allow easy anastomosis after transfer without the need for vein grafts. The muscle should possess a single motor nerve of sufficient length and in the correct orientation to allow for primary coaptation of the nerve to the donor motor nerve. The muscle and the limb into which it is to be transferred should possess the appropriate characteristics to allow the muscle to perform its desired function (Table 35.1). These characteristics have been well described for tendon transfers in the upper limb, but apply equally to free functional muscle transfer.

Diagnosis/patient presentation

Free functional muscle transfer is applicable to patients who have sustained a major loss of skeletal muscle in the upper limb resulting in a significant functional disability. Free functional muscle transfer is indicated to replace lost function where no easier local option is available. This may be seen following direct trauma, in the setting of Volkmann's ischemic contracture (Fig. 35.6), following tumor ablation such as sarcoma resection, and in longstanding nerve injury such as brachial plexus lesions. Other rarer indications include

Fig. 35.6 Appearance of arm with Volkmann's ischemic contracture.

electrical burns and post gas gangrene and post-replant patients.[12] Each of these indications presents its own special set of considerations.

Of particular note, in the setting of brachial plexus reconstruction, local donor nerves to power the muscle transfer may be limited or completely unavailable. In this case, careful consideration must be given to the choice of donor motor nerve. In some cases, it is necessary to perform nerve grafts as a preliminary procedure to bring viable motor axons into the denervated limb.[13,14] A similar picture can be found in the setting of Volkmann's ischemic contracture; however, here the anterior interosseous nerve of the forearm is often spared and can be available as a motor donor nerve.[15] This will be discussed further later in the chapter in the section on choice of donor motor nerve.

Patient selection

Probably the most important decision to be made is whether to proceed with free muscle transfer at all. This is a highly involved surgical procedure that requires a motivated patient who is aware of the potential of the procedure and who is fully equipped and prepared to undertake the oftentimes intensive pre- and postoperative rehabilitation that is required for a successful outcome. The patient must understand that the maximal outcome of the procedure will not be realized inside 1–2 years.[16] The importance of having a cooperative patient cannot be overemphasized. The ideal patient is stable, intelligent, and motivated to regain function and return to work, with no medical comorbidities. Inappropriate candidates are unfortunately common among patients with injuries who might otherwise benefit from this procedure. Head injuries may often accompany brachial plexus injuries in motor vehicle and motorcycle accidents.

Multiple physical factors must be taken into account prior to muscle transfer. The patient must have stable skeletal structure, including functional joints. He or she must have normal or near normal range of motion in the hand, wrist, and elbow. There must be adequate soft-tissue cover over the planned tendon-gliding site. If there is insufficient unscarred soft tissue to cover the planned site, soft-tissue reconstruction in the form of tissue expansion or local flaps may need to be performed prior to muscle transfer. Sensation in the hand should be normal to achieve optimal results, though this is not an absolute requirement.[12] There must be sufficient evidence that there are suitable recipient artery and veins in the arm to vascularize the transferred muscle. Preoperative Doppler ultrasound or angiography can be very helpful in this regard.[10] Also, a suitable donor nerve must be available

Table 35.2 Requirements for free functional muscle transfer

- Available, undamaged motor nerve, artery, and vein at the site of muscle transplantation
- Adequate skin coverage for the distal half of the muscle
- Supple joints and gliding tendons
- Good hand sensibility and intrinsic function
- Adequate antagonist muscle function
- Good patient motivation
- No simpler solution for the patient's problem

(Adapted from Anastakis D, Manktelow R. Free functioning muscle transfers. In: *Green's Operative Hand Surgery*, 5th edn. Philadelphia, PA: Elsevier, 2005.)

to power the transferred muscle. There should be adequate antagonist function in the arm to allow the transfer to be of use, for example in performing a transfer to replace long finger flexor function and restore grip, there must be adequate finger extensor function to oppose the new action of the transferred muscle and to release the grip (Table 35.2).

Multiple muscles have been used for free transfer in the upper limb. The gracilis muscle (see Fig. 35.6) has been the most widely used as it fulfills many of the criteria for the "ideal" muscle transfer.[17,18] Other transfers have included latissimus dorsi,[19,20] rectus femoris,[21,22] serratus anterior,[23–34] gastrocnemius,[26] hemisoleus,[27] flexor hallucis longus,[28] flexor carpi ulnaris,[29] pectoralis major,[30,31] pectoralis minor,[24] and tensor fasciae latae.[25] As the reconstructive community's comfort with microsurgical transfer has increased over the years, more complex reconstructions have also been successfully attempted. Of particular note, the use of double-free flaps for dual functional reconstruction (such as elbow flexion and extension) has come into more common use. For example, Doi *et al.*[35] in 1995 described the use of a staged double free muscle transfer in children following brachial plexus palsy. Simultaneous transfer and neurotization of the adductor longus and gracilis on the same vascular axis has also been described.[36,37]

The principles governing the choice of muscle for free functional transfer are similar to those that have been well described for tendon transfer. Additionally, the muscle ideally will have a singular dominant vascular pedicle and a single dominant motor nerve available for transfer.

Treatment/surgical technique

Selecting the appropriate muscle for transplantation is key to the success of the procedure. The ideal muscle to transfer will vary depending on which function it is intended to replace. Important considerations are the length, excursion, and power that are required for the given deficit, e.g., finger flexors normally have an excursion of ~7 cm and finger extensors ~5 cm. A transplanted muscle must be able to generate a sufficient force over the appropriate range of motion to be of functional value. The muscle must be expendable from its donor site with minimal functional deficit from its harvest. The muscle ideally should be easy to harvest, and should have a singular dominant vascular pedicle for ease and reliability of microvascular transfer. Ideally, the muscle should have a single easily identifiable motor nerve. Additionally a strong tendon allows for ease of inset with reduced chance of dehiscence of the muscle insertion. Muscle fibers of uniform length make the procedure technically much easier.

Multiple muscles have been used as functional transfers in the upper limb. For most applications in the upper limb, the gracilis muscle comes closest to satisfying the above criteria.[10,12] It is a fusiform muscle with longitudinally arranged fibers in the proximal portion. It has a single vascular pedicle easily accessible in the upper thigh with a single motor branch from the obturator nerve. Its functional range of motion can be up to 12–16 cm. The donor scar from the gracilis harvest on the inner thigh often widens but is placed in a relatively inconspicuous location for most patients. An additional advantage of the gracilis muscle is that the nerve is often arranged in 2–3 motor fascicles,[10,12] which stimulate discrete portions of the muscle. As such, it is possible to use the muscle split into two components for dual functionality with separate motor innervations.[32,33] A notable disadvantage of the gracilis muscle is the relatively short vascular and neural pedicles.

The gracilis muscle is a long slender strap-like muscle in the adductor compartment of the thigh (Fig. 35.7). It is the most superficial of the adductor muscles. It is thickest in its proximal portions and narrows to a tendon in its distal quarter. The gracilis originates from the body and inferior ramus of the pubis. Distally it narrows into a tendon, which passes behind the femoral condyle and inserts on the medial aspect of the tibia adjacent to the tibial tuberosity. McKee *et al.*[33] studied the muscle fiber anatomy of the gracilis in fresh and preserved cadavers. They described the muscle as fusiform with fibers of varying length. The shorter posterior fibers were found to insert more proximally into the gracilis tendon, whereas the longer more anterior fibers insert more distally. They also found that the fibers were parallel in the proximal three-fifths, whereas distally the fibers converge on to the tendon. The average fiber length within the gracilis muscle is 24 cm. The action of the gracilis is as a weak adductor of the leg and weak flexor of the knee joint. It also produces slight medial rotation of the tibia on the femur. Several authors have reported on harvest of the gracilis, finding that it does not result in a significant functional deficit.

The gracilis muscle may be harvested by a second team concurrent with preparation of the arm. The two-team approach significantly reduces operative time. For gracilis harvest, the markings are made along a line from the posterior aspect of the medial femoral condyle to the pubic tubercle. This line approximates the position of the adductor longus muscle. The gracilis muscle is found 2–4 cm posterior to the palpable margin of the adductor longus. An incision is planned in the upper thigh 2 cm behind the previously marked line. The patient is draped with the entire leg exposed and free-draped in the abducted and externally rotated position (Fig. 35.8). This allows movement of the limb intraoperatively.

An incision 8–10 cm long is made in the junction of the upper and middle third of the thigh. The gracilis muscle is identified beneath the deep fascia (Video 35.1 ▶). For the inexperienced operator, it can be useful to extend the knee to aid with identification of the gracilis muscle. The gracilis becomes taut on knee extension; the tension of the other adductors is unaffected. The fascia overlying the gracilis muscle is split longitudinally. This layer is preserved for later repair to prevent muscular herniation, a not uncommon problem if this layer is not repaired. The muscle is dissected proximally

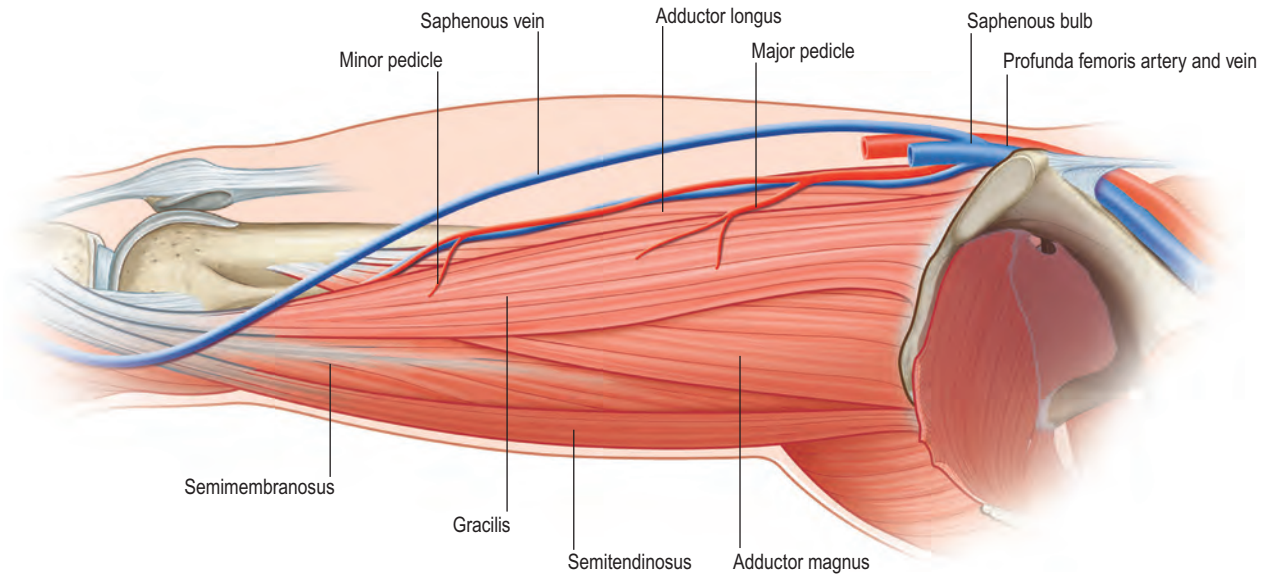

Fig. 35.7 The gracilis muscle.

and distally. The vascular pedicle is found approximately 10–12 cm inferior to the pubis in adults and proportionately the same distance in children (approximately 25% of the length of the thigh), usually entering the muscle from the posterior medial surface. The pedicle courses deep to the adductor longus muscle, which can be retracted to expose the pedicle. Muscular branches are given off to each of the adductors, which need to be divided. The origin of the pedicle is usually from the profunda femoris artery and it can be traced to here with relative ease in most cases. This usually yields a pedicle length of 6–8 cm. The nerve supply to the gracilis is from a branch of the anterior division of the obturator nerve (L2–3). This can be located taking an oblique course in the plane between adductor longus and magnus and entering the posterior medial surface of the muscle 1–3 cm above the vascular pedicle. This is traced superiorly as far as required to obtain sufficient length for transfer. This may be as much as 10 cm.[16] It is preferable to perform the nerve coaptation as close to the transferred muscle as possible, so a shorter nerve is preferable. A tension-free nerve coaptation is necessary; a single nerve coaptation is always preferable over a nerve graft, so harvest of a longer motor nerve is performed where required. It is necessary to mark the length of the muscle with the leg in full abduction prior to release of either the origin or insertion. 5-0 silk sutures placed at 5-cm intervals will ensure that a correct muscle length–tension relationship is re-established (Fig. 35.9).

If required, it is possible to perform intraneural dissection to identify discrete motor fascicles within the motor nerve that innervate separate portions of the muscle. In 90% of cases it is possible to identify a single fascicle that innervates the anterior 20–50% of the muscle.[10,31,34] Once these functional muscle subunits have been identified, it is possible to separate and inset them individually to the flexor pollicis longus and flexor digitorum profundus (FDP) tendons to recreate independent function of finger and thumb function.[17]

The gracilis is usually harvested as a muscle-only transfer. If it is to be used with a cutaneous paddle, care must be taken in orientation of the skin paddle over the proximal two-thirds of the muscle as the skin paddle becomes unreliable more distally. The operating surgeon must avoid injury to the musculocutaneous perforators, which are almost always

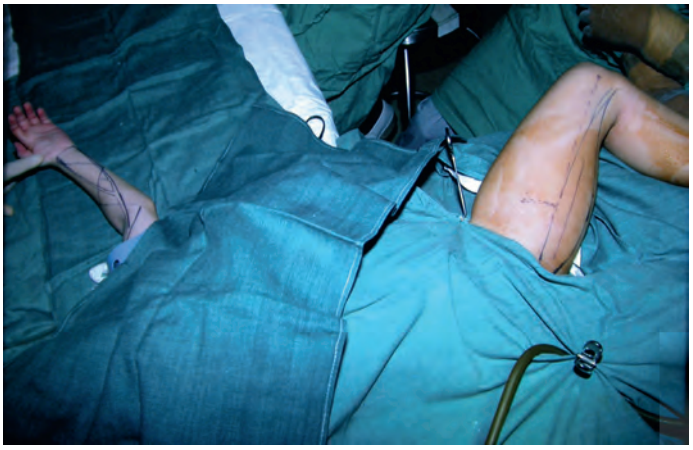

Fig. 35.8 Patient draped for simultaneous gracilis harvest and forearm dissection.

Fig. 35.9 Marking the length of the gracilis muscle with sutures placed 5 cm apart.

located directly over the dominant muscular pedicle. It is useful once the skin paddle has been incised to suture the skin edge to the gracilis fascia to prevent shearing of the musculocutaneous pedicle.

Preparation of the arm is an integral part of the procedure. Prior to embarking on a muscle transfer the surgeon should be satisfied that there is available a suitable vascular pedicle with which to vascularize the transferred muscle. Assessment of the vascularity of the limb should be performed clinically prior to any operation. In equivocal cases, imaging of the vascular system can be of assistance. A preoperative Doppler ultrasound examination or angiogram can be used.[17] However, the final decision to proceed with muscle transfer should be made intraoperatively once a suitable vascular pedicle and donor motor nerve have been identified. The choice of motor nerve is discussed further in the section on choice of donor motor nerve, below.

Incisions should be planned such that they do not cross the path of gliding tendons (Fig. 35.10). Wound closure can often be a problem. In adding the bulk of a transferred muscle and with intraoperative swelling, it is often not possible to close the arm completely. In this case, skin grafts are required to cover the remaining skin defect (Fig. 35.11). This should be planned for with the incisions, so that any areas that require skin grafting are over the more proximal portions of the transferred muscle that undergo less excursion with contraction.

Choice of donor motor nerve

A nerve must be selected that provides motor axons for reinnervation of the transferred muscle. For replacement of long finger flexor musculature, the preferred motor nerves are the anterior interosseous nerve, branches of the median nerve that previously supplied the flexor digitorum superficialis, or branches of the ulnar nerve previously supplying the FDP. For reconstruction of the finger and wrist extensors, branches of the radial nerve are used. For biceps reconstruction, branches of the musculocutaneous nerve are used; for the triceps, branches of the proximal radial nerve are used; and finally, for the deltoid, motor branches of the axillary nerve are selected.

Fig. 35.10 Incisions planned to avoid the gliding path of tendons.

Fig. 35.11 Transferred muscle skin grafted where insufficient coverage is available from local tissue (graft ideally would not be required for distal portions of the muscle).

Hints and tips

The anterior interosseous nerve may be found arising from the median nerve 3–6 cm distal to the elbow in adults. It courses through the pronator teres and then passes dorsally toward the interosseous membrane, lying next to the flexor digitorum profundus and flexor pollicis longus.

It is important to ensure that an undamaged motor nerve is available for use. This is usually apparent by clinical examination. When uncertainty exists, a preliminary exploration and biopsy of the nerve ends may be used. The biopsy specimen is sent for neurohistology to confirm the presence of motor axons in the resected nerve end. Once the presence of suitable motor nerve is confirmed, the surgeon may proceed with confidence. In the absence of a suitable motor nerve in the upper limb, e.g., in total brachial plexus avulsions, it is possible to perform nerve grafts as a preliminary procedure to introduce a donor source of motor axons into the upper limb. Once a sufficient period of time has elapsed to allow ingrowth of motor axons and there is evidence of regeneration along the nerve, such as a Tinel's sign at the distal end, the surgeon may then proceed with functional muscle transfer.

Muscle transfer to the flexor aspect of the forearm

Muscle transfers to replace long finger flexion are the most common indication for free muscle transfer in the upper limb. It is commonly required following trauma resulting in direct damage to the muscle or from ischemic necrosis following compartment syndrome. Where the extensor compartment remains undamaged, it may be more appropriate to perform a tendon transfer such as extensor carpi radialis longus (ECRL), as this is a less involved procedure with a faster recovery. However, evidence suggests that a free gracilis transfer is able to provide greater excursion and range of movement compared with an ECRL transfer.[10,12,31]

The forearm must satisfy all the previously mentioned requirements for transfer. If these are satisfied and suitable vessels and nerve are available, transfer may proceed. The gracilis has proven the most useful muscle for this location. The known location of the neurovascular hilum in the donor muscle is matched to the available recipients in the forearm. The length and orientation of the muscle are planned. Incisions are planned to provide good exposure of neurovascular structures and to provide cover of the musculotendinous junction in the distal forearm. As such, it is important that primary skin coverage is provided for the distal half of the muscle transfer. It is possible to harvest the gracilis muscle with a cutaneous pedicle to provide extra skin coverage in the forearm. In the majority of patients, this cutaneous paddle is too thick, resulting in suboptimal cosmetic appearance. Many patients later request revision of this skin paddle. Alternatively, the muscle can be transferred as a muscle-only flap and the proximal half can be skin-grafted. This solves the problem of the bulky skin paddle. The skin graft in the proximal half does not interfere with gliding and excursion of the transfer. If it will not be possible to provide coverage of the distal muscle and musculotendinous junction, it will be necessary to perform preliminary procedures to provide this. These procedures may include tissue expansion, or local and distant flaps such as groin or abdominal flaps. Once incisions are planned, dissection begins usually from proximal unscarred tissue to distal injured tissue. In dissecting the neurovascular structures, it is important that meticulous technique is used to avoid inadvertent damage to important structures (Fig. 35.12). The medial epicondyle is exposed in anticipation of suturing the proximal end of the transferred muscle. The FDP tendons are explored and checked for their gliding ability.

Fig. 35.12 The dissected forearm.

Hints and tips

Placing a small bean bag or gel roll under the ipsilateral hip permits greater exposure. A headlight is valuable for visualization. The incision must be carried quite proximally in order to visualize the neurovascular bundle adequately. There are usually two veins surrounding a single artery. A small set of perforating vessels may be seen entering the skin at the same level as the vascular pedicle deep to the muscle. A malleable retractor placed deep (posterior) to the pedicle assists in its dissection.

Once the forearm is dissected the muscle may be transferred. The neurovascular structures are aligned and the nerve positioned to allow nerve coaptation as close to the muscle as possible (Fig. 35.13). While the proximal portion is held to the medial condyle, the distal portion of the muscle is stretched to simulate finger flexion and extension. The neurovascular pedicle is observed during this movement to ensure that no tension will be placed on the repair during finger movement. Tacking sutures are then placed in the muscle to hold it to the forearm and prevent contraction during neurovascular repair. Microvascular repair is then performed under the operating microscope. Once vascular flow is re-established, the muscle is observed for bleeding from cut ends and the re-establishment of a "pink color". The distal portions of the muscle will typically take some minutes to regain their color. Any area that fails to appear adequately revascularized can be excised. This does not present a problem as the tendon of the gracilis extends intramuscularly for some way and the cut ends of resected muscle fibers can be rejoined to the intramuscular portion of the tendon without affecting function. The neural repair is performed as a fascicular repair using 10-0 or 11-0 suture, as the nerve to gracilis contains approximately 60% fatty connective tissue. This ensures proper alignment of the fascicles.

When a single muscle is to be used to provide flexion to all of the fingers, they should be positioned such that they flex together, giving simultaneous contact with the object being gripped. A side-to-side tenodesis of the FDP tendons is performed distally in this position with each finger slightly more flexed than the previous. This provides a balanced mass flexion effect of all the fingers together (Fig. 35.14). Where FDP is to be included with a single muscle function, it should be positioned such that the thumb closes slightly later than the fingers. This results in a useful pinch grip for the patient. Alternatively, the muscle may be separated into its functional components to provide separate finger and thumb flexion.

Fig. 35.13 Neurovascular structures aligned.

Fig. 35.14 Flexor tendons sutured to provide mass flexion effect.

Hints and tips

Most side-to-side tenodeses between adjacent distal tendons can be readily performed with mattressed 3-0 or 4-0 polyester sutures. A tendon weaver is not generally needed.

The muscle is inserted into the FDP tendons in such a way as to recreate its optimal functional length and excursion. Prior to transfer, the gracilis is placed on maximal physiological stretch by placing the thigh in maximal abduction. Sutures are then placed in the muscle every 5 cm. Once the muscle is transferred, the origin is fixed to the common flexor origin from the medial epicondyle. The wrist and fingers are then placed in maximal extension. The gracilis is then stretched distally to recreate the 5-cm distance between marking sutures (Fig. 35.15). The intersection of the FDP and gracilis muscle and tendons is then marked. The hand is then relaxed and a tendon weave is performed under no tension at the premarked site. This technique ensures that, once the procedure is completed, the transfer will allow a full range of finger and wrist extension and will allow finger flexion within the maximal force-generating range of the muscle. The principles of this technique are applicable to muscle transfers in all locations.

The limb is rested with the wrist and fingers slightly flexed so as to relieve any tension on the musculotendinous junction. Postoperatively at the 3-week mark, a program of passive mobilization and stretching is instituted. This helps prevent any myoclonic contracture and promotes gliding at the musculotendinous junction. Once the muscle regains innervation it is very important to institute an active mobilization program. Once a functional range of motion is regained, a graduated weight-training program can be instituted to improve strength. This should be pursued for at least 1 year following regaining a useful range of motion. This should be incorporated into the patient's work and activities of daily living to maintain patient interest and participation.

In the correct patient, good flexion (Fig. 35.16) can be expected including, where planned, independent finger and thumb flexion (Fig. 35.17).

Muscle transfer for finger extension

Muscle transfer for finger extension follows the same basic pattern as for finger flexion, although a marginally lesser degree of excursion is required. The gracilis muscle has also been used most widely for this application. The choice of motor nerve for reinnervation is crucial. The posterior interosseous nerve has been used most commonly. The most appropriate site for identification and use of the nerve is as it emerges from supinator. At this point, it is possible to identify the branches innervating finger, thumb, and wrist extensors. The ideal branches to use are those to the finger extensors; wrist extensor branches are less ideal. Identification of the nerve at this level is particularly useful if there are remnants of extensor motor function. In this case the nerve branches can be individually stimulated to select the appropriate branch or branches. The arterial anastomosis may be to any available artery. The posterior interosseous artery has been used, although this may be scarred or insufficient. In this case, the radial artery has been used in an end-to-side fashion, or the radial recurrent artery may be used. Similar attention as with the flexor reconstruction must be paid to achieving an appropriate physiological length. The distal extensors are joined together with a side-to-side tenodesis with the fingers in a

Fig. 35.15 Muscle *in situ* with recreation of original resting tension.

normal cascade. After proximal fixation of the muscle and establishment of vascularity, the wrist and fingers are maximally flexed. The muscle is stretched to recreate the 5-cm distance between marking sutures. The distal insertion is marked after attachment of the muscle has been performed. This allows fixation of the muscle at its maximal physiological length. Postoperatively, the wrist is splinted in neutral with the digits in the safe position. This relieves tension on the muscle during the initial healing period. A mobilization program similar to that used with flexor reconstructions is initiated.

Muscle transfers for elbow flexion (biceps reconstruction)

The loss of elbow flexion can be a devastating injury. Fortunately both the biceps and brachialis can accomplish this function in the absence of the other. Loss of both these muscles is rare. Loss of innervation of these muscles is, however, much more common in the setting of brachial plexus injuries. Many authors have reported on the use of free functional muscle for reconstruction of elbow flexion in this setting.[16,18] The principles are the same as for the previously described transfers. The acromion and bicipital aponeurosis are exposed for attachment of the transferred muscle. End-to-side vascular anastomosis to the brachial artery is performed and, if available, the musculocutaneous nerve is used for neural coaptation. The choice of nerve in brachial plexus cases may be more difficult and is based on preoperative examination and intraoperative findings. In this case, donor nerves can be intercostal nerves (ideally three nerves), motor fascicles of the ulnar or median nerves, or occasionally the spinal accessory or thoracodorsal nerve. Similar attention to length and tension of inset must be paid as previously described.

Transfers have been described for elbow extension, shoulder flexion, and thumb opposition, in which similar principles are applied.

Complications

Complications can be divided into early or late. As the procedure is long and complicated, care must be taken during the

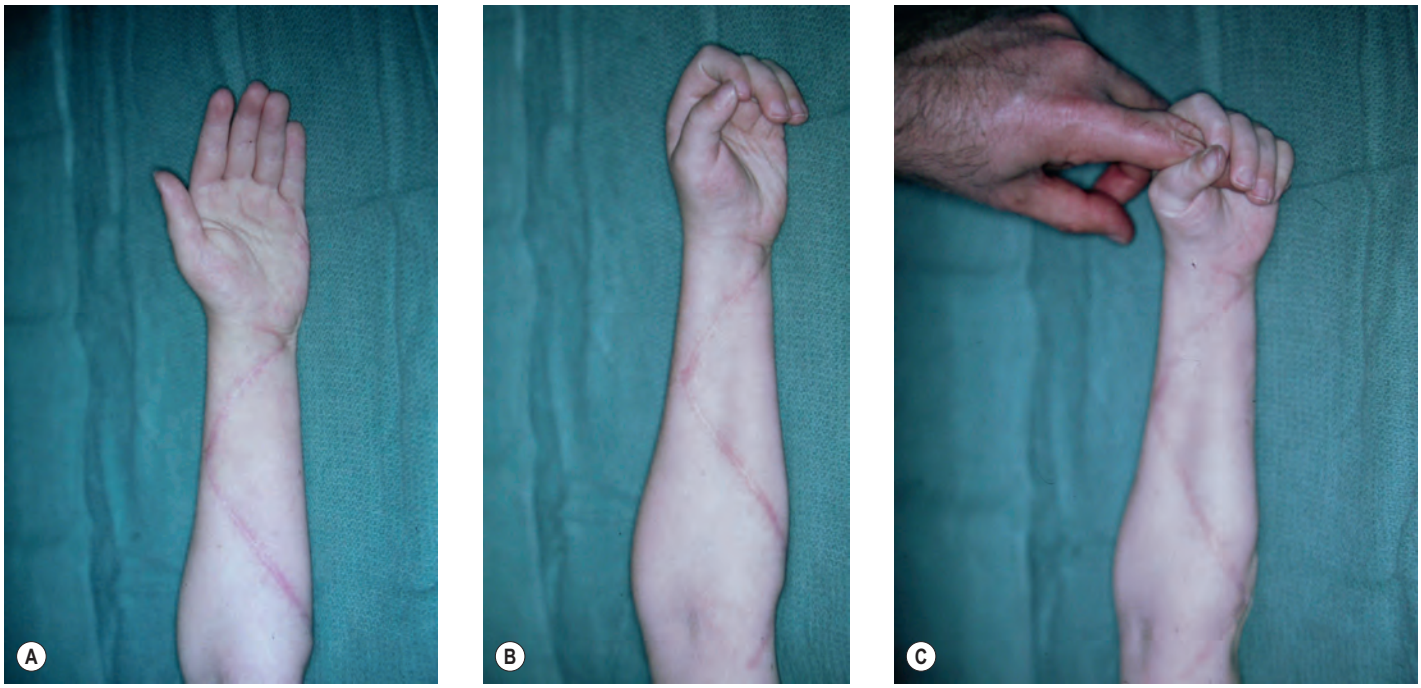

Fig. 35.16 (A–C) Postoperative patient demonstrating good finger flexion.

Fig. 35.17 (A–D) Postoperative patient demonstrating independent finger and thumb flexion after separation of gracilis into independent functional units.

intraoperative period to protect the patient with particular attention to care of pressure areas and appropriate use of thromboprophylaxis. The most feared early complication is vascular insufficiency of the transferred muscle. After a period of 4–5 h sufficient ischemic damage is sustained by the muscle as to make salvage impossible. In this circumstance, a new free muscle transfer is required. Though not a common complication, this is unfortunately more common than detecting the vascular compromise in time to salvage the muscle. Vascular insufficiency may be due to thrombosis or technical problems with the anastomosis such as kinking or external pressure. Infection is also a risk, as the procedure is often performed through a heavily scarred bed and involves open wounds for a prolonged period. The routine use of pre- and intraoperative antibiotics is necessary. Delayed wound healing is a not uncommon complication but should not delay a rehabilitative program.

Late complications include inadequate power and adhesions. Insufficient power can be due to insufficient motor reinnervation either from an insufficient nerve or problems with the neural coaptation. In the setting of adhesions, a tenolysis may be required to allow improved function. If this is to be done, it is wise to wait for complete reinnervation of the muscle so that an aggressive postoperative mobilization program can be instituted. Wrist flexion contractures have been noted as a late complication after transfers for finger flexion. As the transferred muscle regains power, it may overpower the extensors, resulting in a flexion deformity. This can be overcome by early splinting programs but, even with appropriate treatment, further serial casting or surgical procedures may be required.

Secondary procedures

Unfortunately, some patients will not regain function following transfer. This can be due to technical problems, loss of the muscle due to ischemia, failure to reinnervate the muscle, tendinous adhesions, or co-contraction of antagonist muscles. In each case, a reason must be sought individually to explain the poor outcome. In the case of tendinous adhesions, a simple tenolysis may be sufficient. Inadequate or excessive tension on the muscle may result in a functioning muscle with incomplete or weak range of motion. In these cases, it may be possible to reposition the musculotendinous junction, or to perform repositioning of the muscular origin from the common flexor origin. These are both difficult procedures and are best addressed by attaining the correct tension at the primary procedure. In the case of muscle loss or failure of reinnervation, where a reason for the failure can be addressed, it is reasonable to perform a second free-functioning transfer with the expectation of a good functional result.

Future directions

Future developments in free muscle transfer are likely to involve techniques to improve neural regeneration, as it is known that the number of motor nerve units that grow across a nerve repair site affect the functional outcome.[38] Potentially exciting new avenues to improve neural regeneration include nerve cross-bridging,[39,40] in which nerve grafts from a healthy nerve are coapted to a regenerating nerve and the use of a 1-h period of electrical stimulation at the time of neurorraphy.[41]

Brachial plexus injuries: Adult and pediatric

David Chwei-Chin Chuang

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Complexity of brachial plexus injury (BPI): BPI is characterized by many complex problems and remains a dilemma to many reconstructive microsurgeons. These complexities include: (1) diverse injury patterns; (2) disrupted anatomy; (3) unpredictable nerve degeneration and regeneration; (4) difficult physical examination and diagnosis; (5) challenging nerve surgery; (6) long rehabilitation; (7) different palliative surgeries for sequelae deformity; (8) no consensus of outcome evaluation; and (9) difficult pain management. Many reconstructive microsurgeons show great interest but are greatly frustrated by this field.
- BPI can occur in adults and children. Although the anatomy is the same, there are many differences. Therefore, these two different entities will be discussed separately.

Introduction

Clinical tips

There are significant differences between adult brachial plexus injury and obstetric brachial plexus palsy (or neonatal brachial plexus palsy). The diagnosis and treatment of these different entities should be considered separately.

BPI can occur in adults and children. Although the anatomy is the same, there are many differences, including mechanism of injury, type and degree of injury, preoperative evaluation and diagnosis, surgical options, postoperative management and rehabilitation, palliative surgery for sequelae deformities, outcomes evaluation and pain management (Table 36.1).

Over 1900 adult and 500 pediatric brachial plexus palsy patients have been treated by the author since 1985. The following text will deal with the author's experience regarding adult and pediatric BPI.

Adult brachial plexus injury

Introduction

Clinical tips

For adult brachial plexus injury, there is debate between early (within 1 month) and delayed early (within 3–5 months after injury) nerve exploration. The latter is becoming more popular. Clinical evaluation is the most essential step for preoperative and postoperative judgment. Imaging studies can help the diagnosis, especially for level I (root) injury. Predicting the level of the lesion can help avoid unnecessarily long incision and dissection.

Adult brachial plexus injury (BPI) is characterized by many complex problems, and remains a dilemma to many reconstructive microsurgeons. These complexities include: (1) complexity of anatomy; (2) level of BPI; (3) diverse injury patterns; (3) unpredictable nerve degeneration and regeneration; (4) difficult physical examination and diagnosis; (5) challenging nerve surgery; (6) long rehabilitation and follow-up; (7) different palliative surgeries for sequelae deformity; (8) no consensus of outcome evaluation; and (9) difficult pain management. Many reconstructive microsurgeons show great interest but are greatly frustrated by this field.

Anatomy

Gross anatomy

The brachial plexus is a large plexus, which has the most complex structures in the peripheral nerve system. It is located superficially between two highly mobile structures, the neck and arm, causing its susceptibility to sustain injury, especially traction injury.

Table 36.1 **Differences between adult and pediatric brachial plexus injury**

	Adult brachial plexus injury	Obstetric brachial plexus palsy
Popular terminology	BPI	Two types: (1) infantile OBPP (I-OBPP; also called neonatal brachial plexus palsy, NBPP) and (2) child OBPP with deformity
Etiology (mechanism)	Trauma, more closed injuries than open Majority caused by traction injury, mostly by motorcycle accident	All are closed and traction injuries following delivery
Demography	All ages	All are infants and children
Incidence	Increasing	Reducing (improvement in obstetric care)
Physical examination	Complex	Simple
Horner's syndrome	Reliable and persistent	Not reliable, not persistent
Spontaneous recovery	Less	Many
Classification of Injury	Four levels of injury: Level I: inside the bone Level II: inside the muscle Level III: pre- and retroclavicular Level IV: infraclavicular	All are level I–III injuries, very rare in level IV Five types of injury: Type 1: upper plexus palsy (Erb's palsy) Type 2: extended Erb's palsy Type 3: entire plexus without Horner's syndrome Type 4: entire plexus with Horner's syndrome Type 5: lower plexus palsy, Klumpke palsy
Intraoperative findings		
Patterns	More in root injury (level I)	Upper plexus tend to be rupture injury; lower plexus tends to be avulsion injury In operated cases, type 3 or 4 more common; in non-operated cases, type I or 2 more common
Dissection 3 months after injury	Difficult, more hazardous to dissect and expose the lower plexus	Highly possible to expose the whole spinal nerves
Vessel injury	Segmental occlusion of the subclavian artery in level I, and axillary artery in level IV are common	Rarely associated with vascular damage
Degree of nerve injury	In rupture injury, the gap is always more than 5 cm	The gap is short (2–4 cm); high incidence of aberrant reinnervation with co-contraction following nerve repair or spontaneous regeneration
Platysma muscle	Varies in thickness	Very thin or scarce
Surgical techniques		
Priority	Elbow flexion, shoulder abduction and rotation, hand sensation and finger flexion, then elbow and finger extension	Hand and shoulder function, elbow flexion
Nerve reconstruction	Nerve transfers more than nerve grafts	Nerve grafts more than nerve transfers
Phrenic nerve transfer	A strong neurotizer, often utilized	Rarely applied, risk for severe respiratory distress
Distal nerve transfers	Often	Less required
Contralateral C7 transfer	Often applied in total root avulsion	Rare
Postoperative		
Postoperative immobilization	3 weeks	4 weeks
Rehabilitation	Good and cooperative	Poor cooperation
Prognosis		
Recovery after repair	More expected, e.g., nerve grafts in level II rupture injury, time to achieve elbow flexion >M3, usually takes 1 year	Slow and unpredictable, e.g., nerve grafts in rupture injury, time to achieve elbow flexion usually takes 2 years
Intercostal nerve transfer	Fair result	Better result
C8 and T1 root injury	Recovery, all or none	Usually incomplete, (some T1 function is spared)
Intrinsic recovery following repair	Never	May happen
Backup (second) procedure to improve results	Less frequent (less than 10%)	More often (>50%)
Pain management	Big issue	Little problem

The brachial plexus is formed by the anterior primary rami of the lower cervical (C5–8) and the first thoracic (T1) spinal nerves, which give motor innervation to muscles of the shoulder, including all anterior and posterior chest muscles related to glenohumeral joint movement, muscles of the entire upper limb, and sensory innervation of the entire upper limb except the skin on some part of the medial aspect of the upper arm (T2 zone). Not infrequently, the C4 and T2 spinal nerve also contribute nerve fibers to it. Whenever the C4 contribution is large and the T1 contribution is small, the brachial plexus is called the "prefixed brachial plexus". When the C5 contribution is small and T2 contribution is large, it is termed the "postfixed brachial plexus". Clinically, the prefixed type is more common than the postfixed. But postfixed plexus in adult BPI has been rarely seen, probably because the injuries are either so extensive that further dissection of C8–T1 is hazardous and unnecessary, or the injuries are diagnosed not to involve C8–T1, so that further identification is also unnecessary. Each spinal nerve is formed by the joining of the ventral root (motor fibers) and the dorsal root (sensory fibers). Each root is formed by a number of rootlets, which exit from each spinal cord. These separate rootlets can be defined on magnetic resonance imaging (MRI) with three or four bands in the upper cervical roots (C5–7) and two bands of rootlets in the lower roots (C8–T1). The dorsal roots carry sensory information to the central nervous system, while the ventral roots convey motor fibers to the muscles. The cell bodies (neurons) of the motor fibers are located in the anterior horn of the spinal cord, while the cell bodies of the sensory fibers reside in the dorsal root ganglion located within the intervertebral foramen, immediately outside the dura mater of the spinal cord. The ventral and dorsal roots carry with them an extension of the arachnoid and dura, which forms the root sleeve, where the root sleeve attaches to the ventral root and ganglion to form the sheath of the spinal nerve so that the cerebrospinal fluid space does not extend beyond the intervertebral foramen.

The dorsal and ventral roots unite a few millimeters distal from the ganglion to form a spinal nerve, a mixed nerve, which goes through the interscalene space between the scalene anterior and middle muscles. Nerves arising from the anterior primary ramus include branch to scalene muscles (C5–8), branch to longus colli muscle (C5–8), the long thoracic nerve (C5–7), a portion of phrenic nerve (C5), and a portion of the dorsal scapular nerve (C5).

Just out of the scalene muscles, the five postganglionic spinal nerves make a first union to form the three trunks: upper (formed by C5 and C6), middle (C7 itself), and lower trunk (formed by C8 and T1 spinal nerves). Two branches are given off from the upper trunk: the nerve to the subclavius muscle and the suprascapular nerve. Each trunk divides into anterior and posterior divisions just proximal to or directly under the clavicle, i.e., retroclavicular. Lateral pectoral nerve is formed from anterior divisions of the upper and middle trunk to innervate the clavicular part of pectoralis major muscle; medial pectoral nerve is formed from the anterior division of the lower trunk to innervate the sternal part of the pectoralis major muscle.

Infraclavicularly, the nerves exchange fibers and form the second union, just distal to the clavicle, and are termed "cords". The lateral cord is formed by the fusion of the two anterior divisions of the upper and middle trunks, containing fibers derives from the C5 through C7. The posterior cord is a joining of all three posterior divisions, containing fibers derived from the C5 through C8. The medial cord is simply continuation of the anterior division of the lower trunk, containing fibers from the C8 and T1. Subclavian artery becomes axillary artery at lateral border of the first rib. Names for cord relationship are based on the axillary artery. Lateral and medial cords pass anterior, and the posterior cord passes posterior to the axillary artery. The cords run anterior to the subscapularis muscle, just distally behind the pectoralis minor muscle. Each cord has two or more terminal branches to the periphery. The medial and lateral cords, giving one or two terminal branches, join in a Y-shape to form the median nerve. Other main terminal branches of the cords contain the musculocutaneous nerve from the lateral cord, the ulnar nerve from the medial cord, the axillary and radial nerve from the posterior cord.

Numerous anatomical variations of the brachial plexus do exist[1–3] and should be always kept in mind. For example, the musculocutaneous nerve may sometimes arise from the median nerve and not from the lateral cord. In some rare cases of C5–6 root avulsion, the musculocutaneous nerve is still found to be functional because part of the musculocutaneous nerve derives from the median nerve with its origins from C7.

Microanatomy

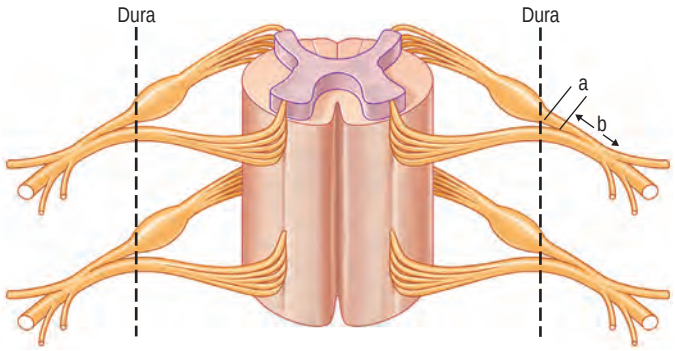
The microanatomy or internal topography of the brachial plexus has been extensively studied and described.[2,3] The monofascicular pattern is usually found in regions of: (1) the spinal nerves; (2) anterior and posterior divisions of the upper trunk; and (3) the origin of the suprascapular and musculocutaneous nerve. Marked changes in fascicular topography occur every 10 mm. It is especially true at the level of the upper trunk where interfascicular crossovers are so extensive that direct repair or repair with short nerve grafts will frequently lead to co-contractions due to aberrant regeneration of a group of muscles. This aberrant regeneration is mainly found in obstetric brachial plexus palsy (OBPP) patients but rarely in adult BPI. In addition, plexus connective tissue is more abundant than neural tissue. All these factors are reasons why the results of brachial plexus nerve surgery are so unpredictable. Knowledge of the internal topography of the plexus can be helpful in connecting corresponding nerve fibers with bridging nerve grafts. However, localization within the spinal nerve to define specific axonal groups to supply specific muscles or specific branches is difficult and not practical.

Level of brachial plexus injury

Various classifications of the level of BPI have been proposed[1, 4–12] (Table 36.2), e.g., two levels as supraclavicular and infraclavicular[4]; three levels as supra-, retro-, and infraclavicular,[5,6] four levels as preganglionic root, postganglionic root, trunk and division, cord and terminal branches.[7–8] These numerous classifications have made the understanding of the anatomy of the brachial plexus complex and confusing. The most confusing aspect is the so-called postganglionic root (Fig. 36.1). In fact, after the dorsal root ganglion, both ventral and dorsal roots continue for only a few millimeters (<5 mm) in distance and unite to become a mixed nerve where it is no longer a root. Sunderland[13] has stated that "the term nerve

Table 36.2 **Classifications for level of brachial plexus injury**

Authors	Levels	Area of injury
Leffert[1]	2 levels	Supraclavicular injury (supraganglionic, infraganglionic, and sub- or retroclavicular) and infraclavicular injury
Krakauer and Wood[4]	2 levels	Supraclavicular (roots, trunks and divisions), infraclavicular (cords and branches)
Terzis *et al.*[5]	3 levels	Root, supraclavicular postganglionic, infraclavicular
Ferrante[6]	3 levels	Supra-, retro-, and infraclavicular
Millesi[7]	4 levels	Supraganglionic root, infraganglionic root, trunk, and cord
Alnot[8]	4 levels	Preganglionic root, postganglionic root, supra- and retroclavicular, and infraclavicular
Chuang[9]	4 levels	Preganglionic root, postganglionic spinal nerve, pre- and retroclavicular, and infraclavicular
Narakas[10]	5 levels	Supraganglionic root, infraganglionic spinal nerve, infraganglionic trunk, retroclavicular and terminal branches
Mackinnon and Dellon[11]	6 levels	Root avulsion (preganglionic and postganglionic), trunk injury, lateral cord, posterior cord, medial cord, terminal cord branches injury
Boome[12]	8 levels	C5–6; C5–6–7; C5–6–7 posterior divisions; C5; C6; lateral and medial cords; posterior cord



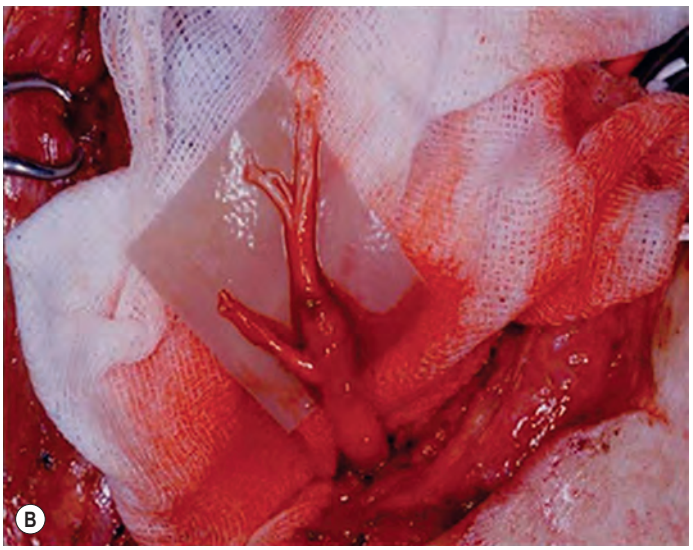


Fig. 36.1 **(A)** The illustration shows that the postganglionic root is part "a"; postganglionic spinal nerve is part "b" from the anatomical point of view; **(B)** an avulsion C7 (distal stump) during dissection.

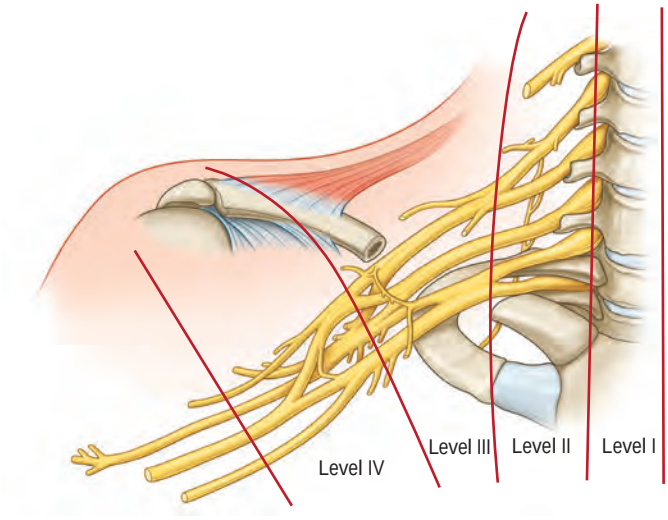
root should be reserved for the paired anterior and posterior nerve roots in the spinal canal," and that "the part of the plexus extending from the union of nerve roots to the formation of the trunks of the plexus should be referred to as a spinal nerve." The author agrees with this statement. Therefore, the components of the brachial plexus are roots, spinal nerves, trunks, divisions, cords, and terminal branches.

To avoid anatomical confusion, we have described brachial plexus lesions with "numbers", levels I–IV, instead of word descriptions[14] (Fig. 36.2), e.g., two levels 4, three levels 5, 6; four levels 7–9; five levels 10; six levels 11 and even eight levels 12. A total of 819 cases of adult BPI were included (1986–2003) in this new classification and the incidence at different levels was determined:



Level I Preganglionic root injury
Level II Postganglionic spinal nerve injury
Level III Pre- and retroclavicular injury (trunks and divisions injury)
Level IV Infraclavicular injury (cords and terminal branches injury)

Fig. 36.2 Anatomy and numbered level of brachial plexus injury (see text).

- Level I injury: inside the (vertebral) bone; this is a preganglionic root injury including spinal cord, rootlet, and root injury; 70% of BPI patients are unfortunately injured at this level.
- Level II injury: inside the (scalene) muscle; this is a postganglionic spinal nerve injury, located at the interscalene space proximal to the suprascapular nerve; pure level II injuries account for around 8%.
- Level III injury: pre- and retroclavicular; this includes trunks and divisions; pure level III injuries account for about 5%.
- Level IV injury: infraclavicular; including cords and terminal branches injury proximal to the axillary fossa; the second largest population of BPI patients, at about 17%.

There are some relationships among the levels of injury:

1. An extended-level injury on the same nerve is frequently observed: for instance, C7 injury from the root level down to the interscalene space (level I and II injury).
2. A combined-level injury on different nerves is common: for instance, C5 and C6 spinal nerve rupture injury (level II) accompanied with C7–T1 root avulsion (level I).
3. A skip-level injury is rare: for instance, a longitudinal skip-level injury in which C5 and C7 are injured (avulsion or rupture) but C6 is intact; a horizontal skip-level injury in which level I and level III are injured, but level II is grossly intact.
4. Level IV injuries are usually isolated, and rarely show upward extension.

The term "supraclavicular BPI" will cover a large zone of injury, including level I, II, or III lesions.

Preoperative differential diagnosis of supra- (level I–III) and infraclavicular (level IV) injury is important to avoid large incisions, unnecessary dissection and tissue damage, prolonged operative time, increased postoperative morbidity and resulting scars. With help of imaging studies and preoperative clinical evaluation, it is not difficult to diagnose a level I lesion. However, when the injuries are incomplete, differential diagnosis becomes difficult[15] (Table 36.3).

Patterns of brachial plexus injury

There are two types of characteristic lesions seen in BPI: avulsion and rupture. Both are traction injuries but with different characteristics. Avulsion refers to the nerve being torn from its attachment (proximal avulsion occurs at the spinal cord, distal avulsion at the muscle or bone edge). Rupture is a nerve injury involving a traction force on an incompletely divided nerve, causing a complete division with irregular proximal and distal ends. In avulsion injury, only one disrupted end with a coiled spring-like appearance can be seen in the operative field in the acute stage (Figs. 36.3A & 36.4A), or a fusiform pattern (glioma) in the chronic stage (see Figs. 36.3B & 36.4B). If a surgeon attempts to locate the other avulsed end, a second operative wound is usually required. However, in rupture injury the two nerve ends can be visualized in the same operative wound in the acute stage (see Fig. 36.3C), or within a big neuroma noted in the chronic stage.

Table 36.3 Differentiation diagnosis (DD) between supra- and infraclavicular BPI with incomplete paralysis of shoulder and elbow

Condition	Supraclavicular BPI	Infraclavicular BPI	Differential diagnosis
Isolated axillary nerve injury	Impossible	Yes	No need to DD
Isolated musculocutaneous nerve injury	Impossible	Yes	No need to DD
Shoulder dislocation		Yes	No need to DD
Infraclavicular Tinel's sign (+)	+ (due to nerve regeneration)	+	**Need to DD**
Muscle strength examination			
(A) When supraspinatus (M0), serratus anterior (M0)	Yes	Impossible	No need to DD
(B) When supraspinatus (M>3), serratus anterior (M>3)	Impossible	Yes	No need to DD
(C) When supraspinatus (M<2), serratus anterior (M<2)	?	?	**Need to DD**
(C-1) When C-PM (M>3), teres major (M>3), LD (M>3)	Impossible	Yes	**No need to DD**
(C-2) When C-PM (M<2), teres major (M>3), LD (M>3)	High possible level III		
(C-3) When C-PM(M<2), TM (M<2), LD (M<2)	High possible level II–III		
Condition

C-PM, Clavicular part of pectoralis major muscle; EMG, electromyography; LD, latissimus dorsi; NCV, nerve conduction velocity.

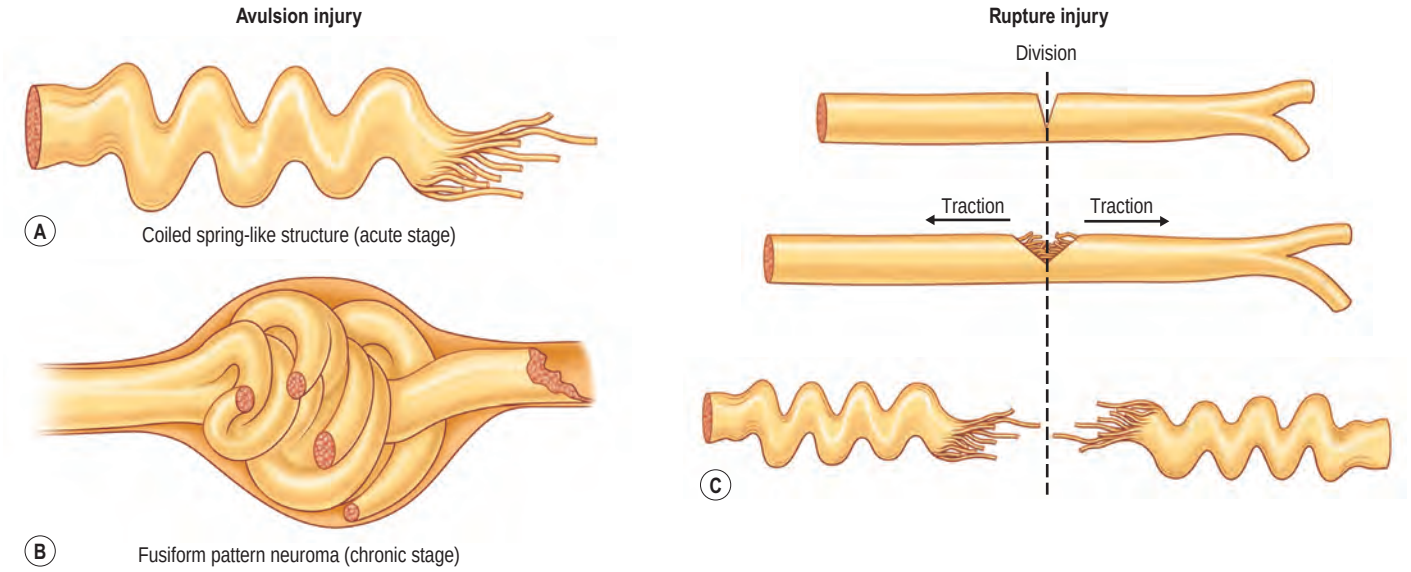

Fig. 36.3 The drawing shows the mechanism of avulsion injury **(A,B)** vs. rupture injury **(C)**.

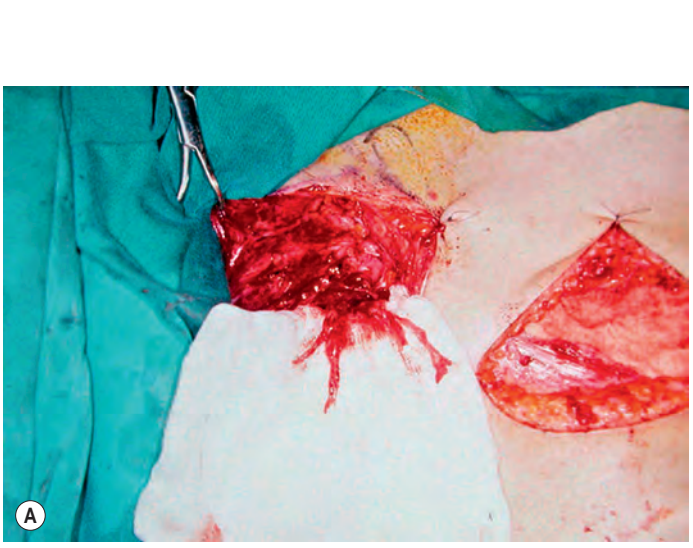
Root avulsion is very common in BPI due to its weak supporting structures consisting of dura and dentate ligaments. A novel approach to performing spinal cord implantation with or without nerve graft[16,17] showed unsatisfactory clinical results. This implies that in avulsion injury only one end (distal end) is available, while the other end (proximal) is absent or unsuitable for repair. "Root injury" is an obscure term that may mean avulsion from the cord (true avulsion) or rupture or stretch at rootlets or roots. Root avulsion in BPI is usually accompanied by dural tearing and a cerebrospinal fluid leak with cyst formation, called pseudomeningocele. However, in some cases, the root can be avulsed at its origin with an intact dura cone (called "avulsion *in situ*"). The nerve root may remain inside the spinal canal or at the dural orifice, giving a grossly normal appearance or loosening with curvature of the spinal nerve at the time of surgical intervention despite established paralysis. Most often, however, the entire avulsed root, including ventral and dorsal roots, and ganglia, retracts and migrates downward to the interscalene or preclavicular region (see Fig. 36.2B).

Pathophysiology and degree of nerve injury

Timing of nerve exploration is dependent upon the degree of nerve injury. The degree of peripheral nerve injury can be classified into neuropraxia, axonotmesis, and neurotmesis (Seddon classification[18]) or grade 1–5 injury (Sunderland classification[19]). Seddon's axonotmesis or Sunderland's second-degree injury starts to have Wallerian degeneration at proximal and distal stumps. Seddon's neurotmesis or Sunderland's third- to fifth-degree injury has the potential for aberrant reinnervation after nerve regeneration. In Sunderland's fourth- or fifth-degree injuries, only nerve repair can succeed in restoring continuity, but in first-, second-, or third-degree



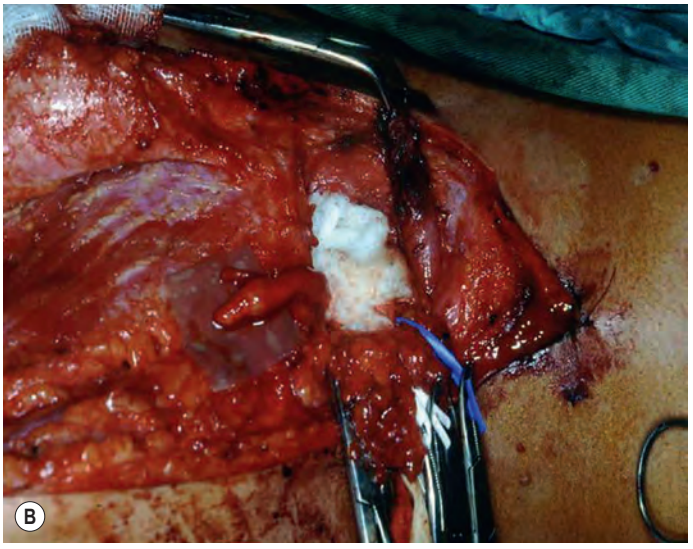


Fig. 36.4 **(A)** Coiled spring-like structure with irregularity of stumps of C5 and C6 avulsion (acute stage); **(B)** fusiform pattern neuroma (or glioma) of the distal C7 stump (chronic stage) during dissection.

injuries, spontaneous recovery, complete and incomplete, may occur.

Timing of brachial plexus exploration

There are five times for brachial plexus exploration and repair:

- Immediate repair or repair within days
- Early repair within a month
- Delayed early repair within 3–5 months
- Late repair at more than 6 months
- Chronic repair at more than 1 year.

There is rarely an argument against immediate exploration after penetrating injury by sharp objects for direct nerve repair. Some surgeons also advocate exploration of the BPI as early as possible[20,21] for adult closed BPI for its advantages, including easy diagnosis of root avulsion and avoidance of difficult dissection through scarring. However, such early exploration is not recommended by most brachial plexus surgeons.[7–9,22] In cases of closed BPI, the degree and extent of injury are difficult to judge soon after injury and are often underestimated. The benefits of waiting usually outweigh the advantages of early surgery.[14]

Clinical evaluation

Etiology of adult brachial plexus injury

BPI may be caused by trauma (open or closed type), compression, tumor, infection, inflammation, toxins, and other etiologies.

Patient history

Patient history should include mechanism of injury, level of consciousness at the time of trauma, associated injury (such as head injury, fracture, open wound, chest injury, vascular injury), kinds of previous surgical intervention (such as chest intubation, cervical spine surgery), and characteristics of pain. This information helps to determine the degree and extent of injury and the need for surgical intervention. Mechanism of injury (e.g., upward or downward traction and with or without rotation) is not easily detected due to the patient's loss of consciousness or amnesia for the accident. A history of shoulder dislocation or glenoid fracture may have a high incidence of level IV injury, whereas a history of cervical spine injury or fracture may cause a level I root injury. Artery rupture and repair imply the site of nerve injury. For instance, arm traction by rolling machine or conveyor belt often causes an open wound in the axilla, extensive ecchymosis around the shoulder and chest (due to rupture of axillary vessels), and level IV BPI. Segmental thrombosis of the subclavian artery is usually associated with C8–T1 root injury. History of rib fracture and chest intubation may preclude intercostal nerve transfer because of a higher failure rate.[23] Extreme causalgia with or without a phantom limb is often seen in cases of root avulsion in lower-root (C8–T1) avulsion as they contain the richest sympathetic fibers. The pain character, like electric shooting pains, continues for a short duration (seconds), followed by spontaneous relief and recurrence. Extreme causalgia is also a major factor for poor outcome due to poor rehabilitation. Sometimes a partial Brown–Sequard syndrome (hemitransection of the spinal cord with ipsilateral upper motor neuron lesion below the level of lesion, and contralateral abnormal sensation to pain and temperature, which may not be at the same level) is also noted in the level I injury.[24]

Preoperative evaluation and diagnosis

Most adult BPIs are closed injuries. Accurate assessment of the extent and severity of the injury in closed BPI is difficult. Clinical evaluation is still essential and is the most important step in establishing the diagnosis of site and degree of injury, and determining the treatment and prognosis. A brachial plexus chart (left and right formats, Fig. 36.5A,B) outlining the possible injury should be completed before definitive brachial plexus surgery. This chart is filled at the initial examination, and usually performed at 2 months after injury. The chart is also useful for follow-up evaluations, allowing comparison of clinical pictures.

Motor examination

Muscle-by-muscle examination should be completed in a distal-to-proximal fashion and recorded using the British Medical Research Council (MRC) scale (M0–5).[25] We have modified the motor evaluation system, adding more detailed differentiation: M5, strength against four-finger (examiner) resistance; M4, against one finger, resistance for longer than 30 s; and M3, against gravity (Table 36.4). M4 is recognized as useful muscle strength. The action of each muscle should be examined separately in relation to the movement of a single joint. Although there is no single muscle innervated by a single spinal nerve, some muscle palsy can give specific information related to the level of the injury. For instance:

1. Diaphragm palsy implies C4 and very proximal C5 (level I) injury.
2. The levator scapulae muscle lies anterior to the trapezius muscle in the neck, and can be more easily detected than the rhomboid muscles, which are covered by the trapezius muscle. Both levator scapulae and rhomboid muscles are innervated by the same nerve (dorsal scapular nerve, or C4 and C5). Preservation of its function in upper plexus or total plexus injury may imply C5 is a rupture injury (level II) with an available proximal stump.
3. Serratus anterior muscle: The long thoracic nerve has two portions: the upper portion originating from C5 and C6, and the lower portion from C7. The upper portion is responsible for scapular protraction, and the lower portion is important for scapular stabilization.[26] Positive anterior traction of the scapula (shoulder protraction test) shows that at least C5 is ruptured after branching to the long thoracic nerve, so the proximal C5 is available for transfer. Scapular winging is observed only when the lower portion is denervated, but isolated C7 root avulsion is rarely seen in adult BPI. In pure C5–6 level I injury, the lower part of the muscle is still functional. The result of spinal accessory nerve transfer to the suprascapular nerve is much superior in the reconstruction of total root avulsion.
4. Clavicular and sternal portions of the pectoralis major muscle: The major pectoral muscle can be separated into two parts: clavicular and sternal parts. The clavicular

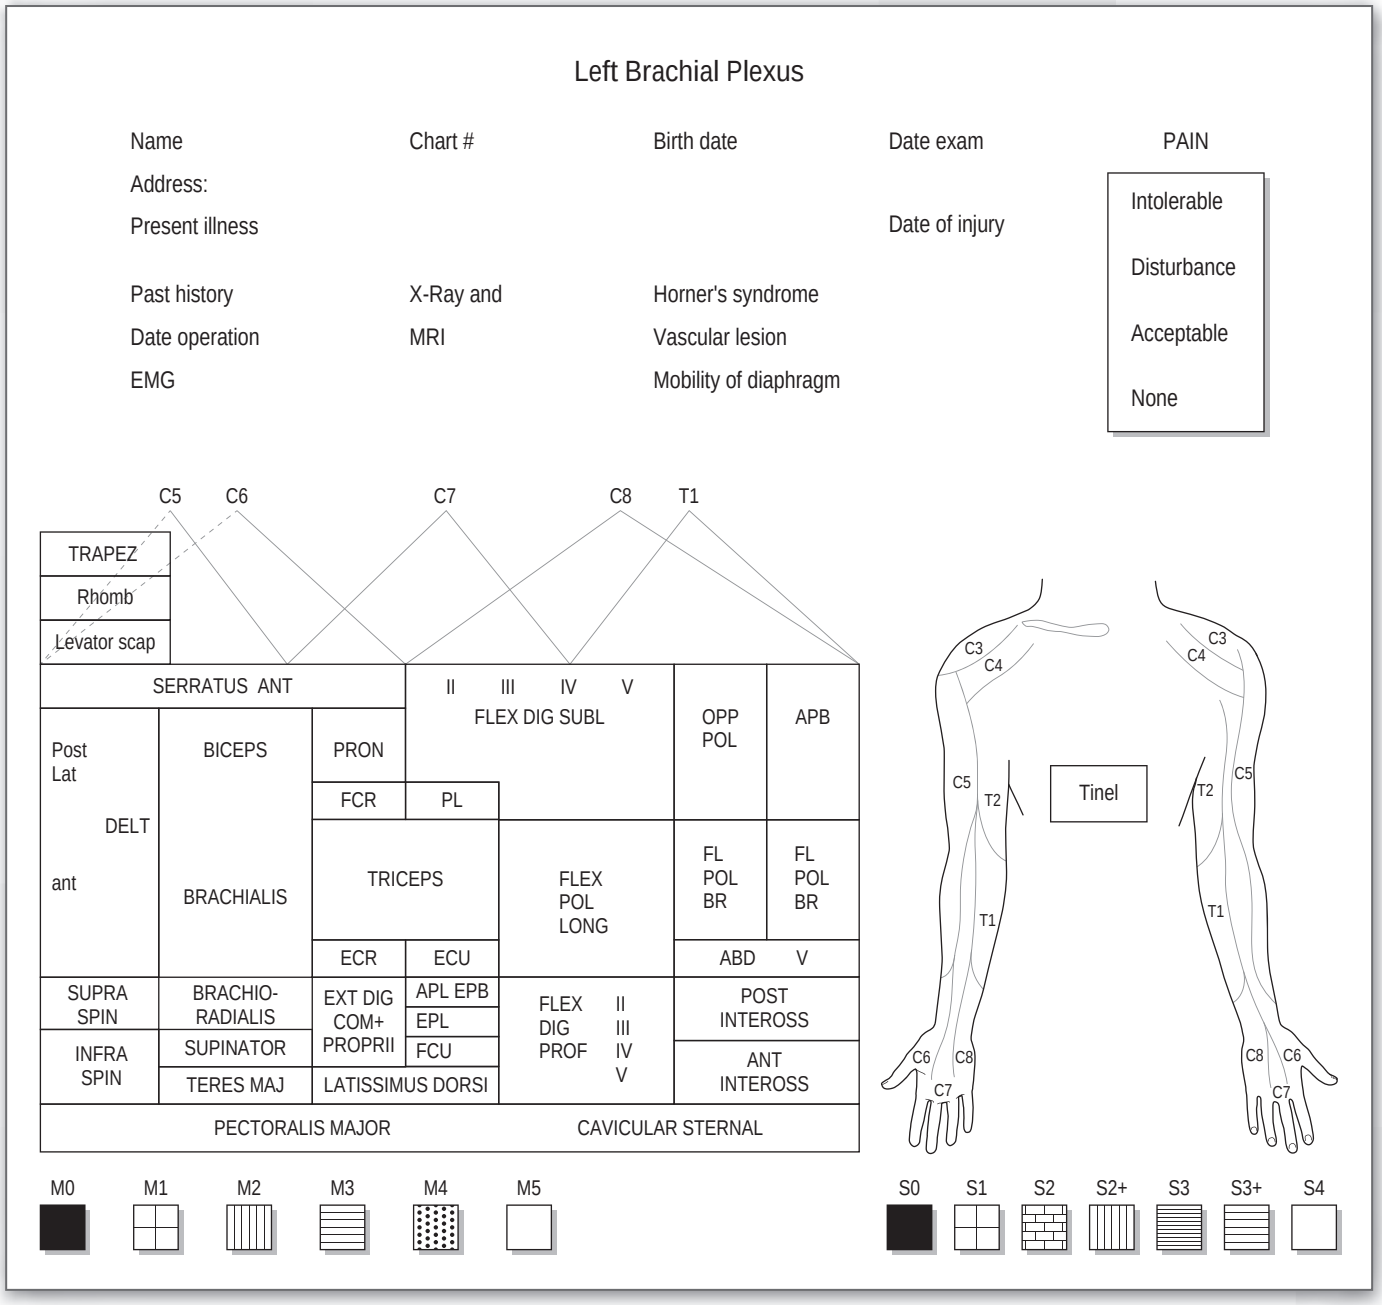
Continued



B

Fig. 36.5, cont'd

part is innervated by upper and middle trunks or its divisions (lateral pectoral nerve), while the sternal part is innervated by the lower trunk (medial pectoral nerve). An incomplete and complete paralysis of the clavicular part of the pectoralis major muscle may imply at least level III or more proximal lesion.[15]

Sensory examination

Sensory evaluation should include sensory tests and elicitation of a Tinel's sign. Sensibility tests include pain and temperature appreciation, static and moving two-point discrimination, constant touch, and vibration. However, performing complete sensory tests in BPI is both unnecessary and illogical because we are examining the dermatomal distribution from spinal nerves, not the cutaneous distribution. Pinprick test from areas of normal to abnormal sensation to map out the area of sensory disturbance is sufficient for most brachial plexus-injured patients. Sensory grading is based on the British MRC scale (S0–4),[25] modified by adding a grade for sensory over-reaction (S2+) (see Table 36.4). Such sensory evaluations can give some clues about the level and degree of BPI.

The Hoffman–Tinel's sign is an important clinical sign to determine the location of a neuroma or to track the

regeneration of the injured nerves. Palpation or percussion at the neck, at the supraclavicular Erb's point (clavicular insertion of the sternocleidomastoid muscle), at the infraclavicular coracoid process of the scapula, or at the route of different nerves along their course may induce an electric current sensation (like pins and needles) running down to the shoulder or the hand (positive Tinel's sign). If the Tinel's sign remains at a fixed point, which means retardation of its progression, surgical exploration is warranted. If the Tinel's sign advances from supraclavicular to infraclavicular and distally to the arm or forearm at successive examinations, observation is recommended, as this may indicate a Sunderland third-degree lesion. A weak or absent Tinel's sign in the neck region usually indicates total root avulsion.

Horner's syndrome (miosis, ptosis, enophthalmos, and anhidrosis) is a sign of sympathetic nervous system disturbance. It indirectly implies avulsion of the T1 and C8 roots because the sympathetic fibers from the T1–2 sympathetic ganglia are quite close to the preganglionic fibers of T1 and C8. This syndrome may regress with time. It is a more reliable sign in adult BPI, but less accurate in obstetric traction injury.

Plain X-ray and imaging studies

Clinical tips

- Direct multiplanar imaging capabilities and superior soft-tissue contrast have turned MRI into the primary imaging tool for BPI evaluation.
- The MRI protocol for brachial plexus includes MRI myelogram (two-dimensional), FIESTA (three-dimensional), Cor (coronal) T1, Cor STIR, Sag (sagittal) T1, Sag STIR, Ax (Axial) T1 and Ax STIR, and DWI (diffusion-weighted imaging) techniques for determination of the BPI level.

Plain X-rays of the chest and cervical spine are required. The chest X-ray should include inspiration and expiration views to exclude diaphragmatic palsy. Cervical spine X-rays are evaluated for any fracture of the transverse process, spinous process, or vertebrae body.

Cervical myelography and computed tomography (CT) myelography can provide valuable information related to the level I injury of the brachial plexus.[27,28] However, in recent years these studies have been gradually replaced by non-invasive MRI.[29,30] The most useful MRI technique for the evaluation of a possible level I lesion is the three-dimensional (3D) fast imaging employing steady-state acquisition (FIESTA). These 3D source data are reconstructed along the planes of ventral and dorsal rootlets using a curve planar reformat technique to demonstrate the respective rootlets in a better perspective. Other MR techniques help in the imaging of the whole brachial plexus, notably of level II (Fig. 36.6A–F).

Electrodiagnostic studies

Clinical tips

- Electrodiagnostic studies (EDX) are useful for differential diagnosis between demyelinating conduction block (Sunderland 1 injury) and axon loss lesions (Sunderland 2–5 lesions).
- Before Wallerian degeneration occurs, the distal stump remains capable of conduction of action potentials (within 2 weeks); the EDX during this period is useless.
- Most adult BPI are due to axon loss without accompanying focal demyelination; however, less frequently, concomitant demyelination is present (especially in shoulder dislocation reduced within 2 h).
- EDX essentially includes three components: sensory nerve conduction velocity (SNCV), motor nerve conduction velocity (MNCV), and needle electromyography (EMG).
- The amplitude of compound muscle action potentials (CMAP) (in MNCV) is the most useful component for quantifying the amount of axon loss. The amplitude in SNCV and fibrillation in EMG tend to overestimate, and the amplitude of MNCV (CMAP) tends to underestimate the severity of axon loss.

Electrodiagnostic studies, mainly consisting of nerve conduction studies (NCS) and needle EMG, are used to localize the lesion and to assess its severity. For the NCS, only amplitudes of the sensory nerve action potentials (SNAP) and CMAP are of value. Both SNAP and CMAP amplitudes provide a good indication of the degree of axon loss, or in contrast, the number of survival axons capable of conducting impulses.[31,32] Sensory NCSs assess the function of the postganglionic portion of the sensory pathway. Therefore, abnormally low SNAP amplitudes indicate a ganglionic or postganglionic lesion. Conversely, the SNAP amplitude remains normal in a complete paralysis of limb implies pure level I lesion (root avulsion). A combination of unelicitable CMAPs with abnormal low or absent SNAP amplitudes suggests a combined preganglionic and postganglionic lesion. To assess the major elements of the brachial plexus, NCSs of multiple nerves are usually required. These include sensory NCS of the median, ulnar, radial, musculocutaneous, and axillary nerves, as well as motor NCS of the median, ulnar, radial, musculocutaneous, and axillary nerves. The presence of fibrillation potentials on needle EMG may suggest that the lesion is at least axonotmesis. The reduction of amplitude of compound muscle action potentials during motor NCS is more reliable than the presence of fibrillation potentials to indicate axonal loss rather than a neurapraxia lesion.

Needle EMG can detect a minimal amount of motor axon loss. For a comprehensive evaluation of the brachial plexus, adequate EMG sampling of muscles is critical. In addition to muscles innervated by major terminal nerves, examination of those supplied from or proximal to the brachial plexus can help to localize the lesion. These include the rhomboid major, serratus anterior, pectoralis major (both the clavicular and sternocostal parts), latissimus dorsi, teres major, and cervical paraspinous muscles. Needle EMG can also reveal evidence of early reinnervation and chronicity of the lesion. Presence of denervation potentials (i.e., fibrillation potentials and positive sharp waves) is the most sensitive indicator of motor axon loss. However, they require about 3 weeks to develop after axon injury.[27]

Percutaneous somatosensory evoked potentials (SEPs) provide far less information than comprehensive NCSs and needle EMG studies in most patients with BPI. Thus SEPs are not routinely performed. Intraoperative SEPs may be useful to determine the continuity of individual segments of the brachial plexus and roots.

Vascular injury

Absence or weakness of pulsation of the radial artery at the wrist indicates a possible vascular injury of the axillary or subclavian artery. It may further indicate the extent and severity of the trauma. Subclavian artery occlusion may indicate a

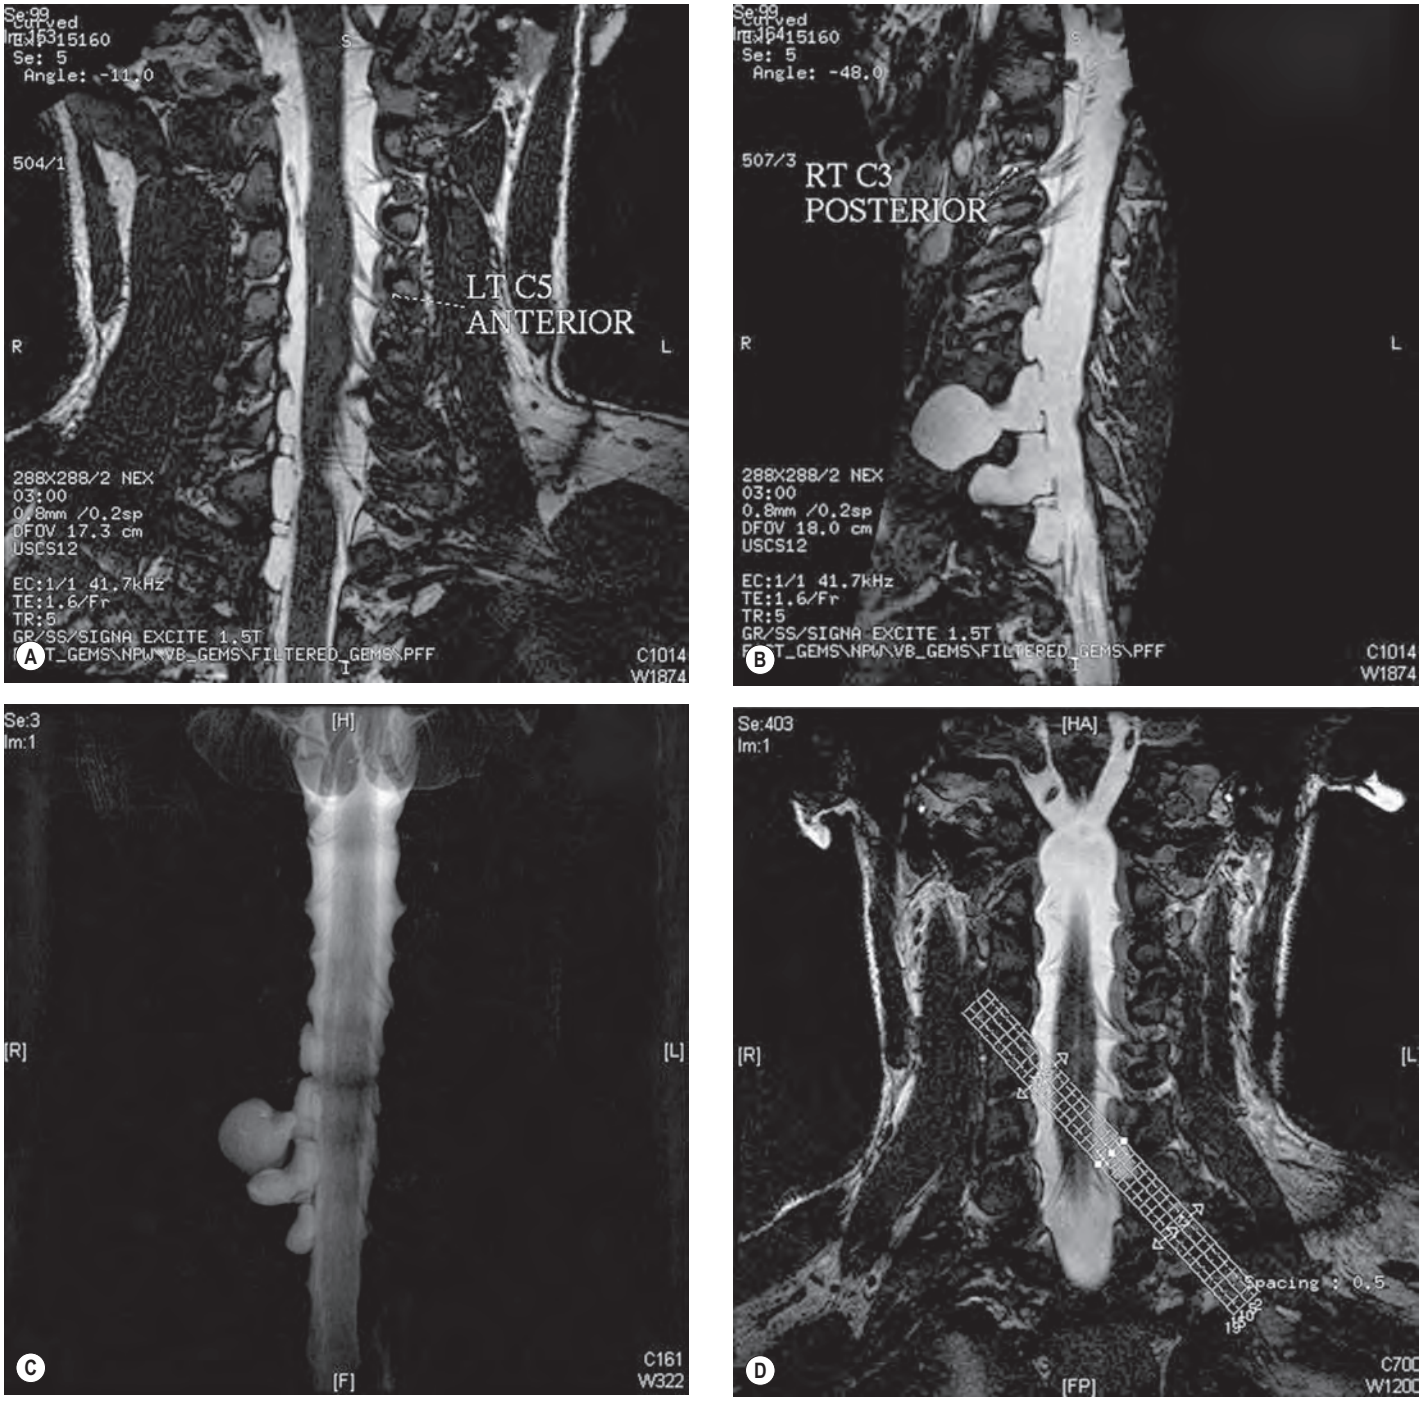


Fig. 36.6 The patient with right C5-T1 total root avulsion: **(A)** coronary view of MR(magnetic resonance) FIESTA (fast imaging emplying stead-state acquisition) neurogram, **(B)** oblique view of FIESTA neurogram, and **(C)** MR myelogram all show right C5-T1 avulsion cysts; The other patient with left C7 root avulsion: **(D)** using MRI curve planar reformat techniques, **(E)** axial view, and **(F)** Short-Tau Inversion Recovery (STIR) neurogram show the C7 avulsed cyst, and all other spinal nerves are still in continuity in Level II and III.

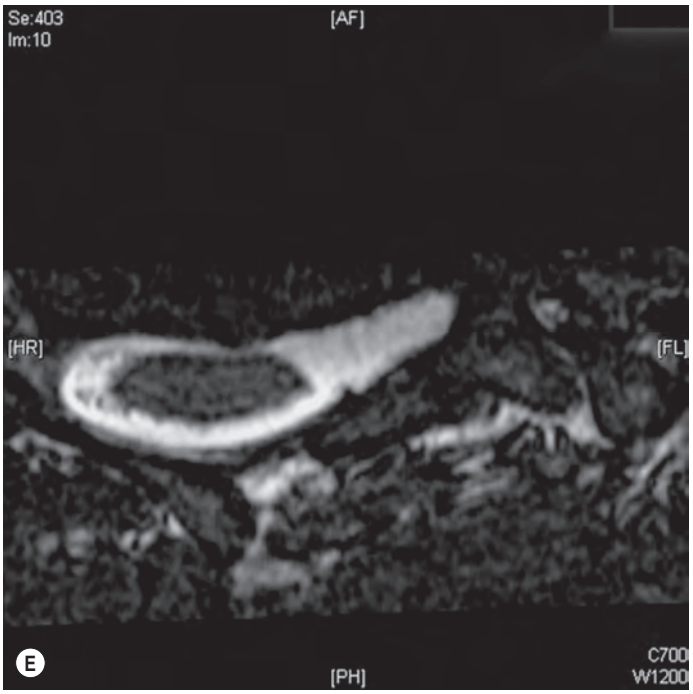

Fig. 36.6, cont'd

level I injury, while axillary artery occlusion may be associated with a level IV lesion. Vascular injury should be taken into account when considering the use of a vascularized ulnar nerve grafts for reconstruction because the ulnar artery is transferred with the ulnar nerve.

Surgical treatment and techniques

Clinical tips

- There are different incision lines for different purposes (Fig. 36.7).
- There are many important landmarks and key points for brachial plexus exploration for supraclavicular and infraclavicular brachial plexus exploration with safety and efficiency (Fig. 36.8).
- Surgical methods depend on the level of BPI. (Table 36.5).
- Debate between proximal nerve transfers and distal nerve transfers for incomplete BPI exists. The former is a traditional strategy; the latter is a new strategy and is becoming more popular (Table 36.6).
- Debate of reconstruction strategy between primary nerve reconstruction (multiple nerve transfers) and functioning muscle transplantation for total root avulsion of BPI exists. The former is proximal-to-distal, the latter is distal-to-proximal in reconstruction priority (Table 36.7).
- Postoperative management and follow-up should be longer: at least 2 years for upper plexus, and 4 years for lower plexus reconstruction.
- Induction exercise is an essential rehabilitation when any type of nerve transfer is utilized, including functioning free muscle transplantation.

Different incision lines for different approaches

Different incision lines for brachial plexus surgery are determined by preoperative diagnosis of level of BPI and management strategy (see Fig. 36.7). For the supraclavicular approach, a linear incision from the midpoint between the mastoid process of the temporal bone and the jugular notch, going along the posterior border of the sternocleidomastoid muscle, and curving laterally parallel to and above the clavicle (a C-curved incision) is a popular incision (see Fig. 36.7, mark 1). For the infraclavicular approach, the incision is just along

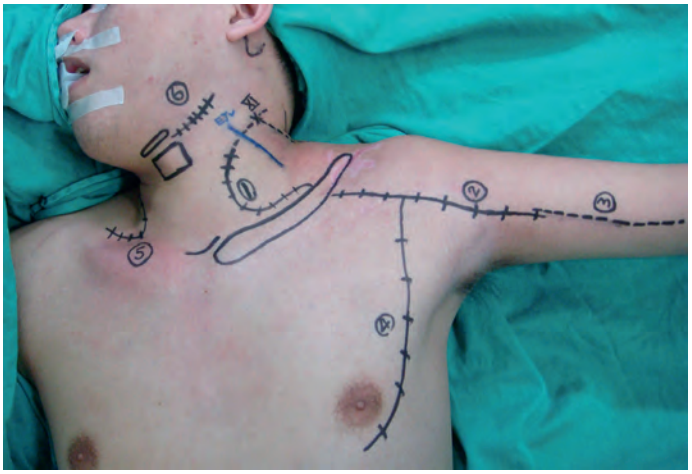

Fig. 36.7 Multiple incision lines for different purposes: 1, for supraclavicular brachial plexus exploration; 2, for infraclavicular brachial plexus exploration; 3, for Oberlin or Mackinnon method of nerve transfer; 4, for intercostals nerve dissection; 5, for contralateral C7 dissection; 6, for hypoglossal nerve dissection; and extended 1 incision for spinal accessory nerve dissection.

Table 36.5 Reconstructive strategies for different level of root avulsion

Condition	Nerve reconstruction	Late reconstruction
Five-root (C5–T1) level 1 injury	Ph → distal C5 for shoulder elevation IC → musculocutaneous nerve for elbow flexion contralateral C7 → median nerve for hand	Wrist and thumb fusion, FFMT for EDC and elbow (XI)
Four-root injury (C5 level 2, C6–T1 level 1)	C5 → median nerve for hand IC → musculocutaneous nerve for elbow flexion Ph → distal C5 for shoulder elevation	Wrist and thumb fusion, FFMT for EDC and elbow (XI)
Three-root injury		
1. C5, C6 level 2, C7–T1 level 1	C5 → SS + PD of UT for shoulder C6 → C8 or median nerve for hand IC → musculocutaneous nerve for elbow flexion	Variable
2. C5–7 level 1, C8–T1 intact	Ph + XI → distal C5 for shoulder elevation Part ulnar → biceps br Part median → brachialis br for elbow	Variable
Two-root injury		
1. C5–6 level 1, C7–T1 intact	Ph + XI → distal C5 for shoulder elevation Part ulnar → biceps br Part median → brachialis br for elbow	Variable
2. C6–7 level 1, C5 level 2, C8–T1 intact	Ph + XI → distal C5 for shoulder elevation C5 → AD of UT for elbow	Variable
3. C8–T1 level 1, C5–7 level 2 injury	C5 nerve grafts for shoulder C6 → median nerve for hand C7 nerve grafts to C7	Variable
4. C8–T1 level 1 injury, others intact	No nerve reconstruction	ECRL → EDC for finger extension FCR → FDP for finger flexion Br for opponensplasty Thumb IP fusion
Single-root injury		
1. C5 level 1 injury	Ph + XI + CMB → distal C5	
2. C6 level 1, usually C5 level 2 injury	C5 → C6 or AD of UT for elbow Ph + XI + CMB → distal C5	
3. C7 level 1, C5–6 level 2 injury	C5, C6 nerve grafts itself	

Ph, Phrenic nerve; IC, intercostal; XI, spinal accessory nerve; CMB, cervical motor branches; FFMT, functioning free muscle transplantation; EDC, extensor digitorum communis; SS, suprascapular nerve; PD, AD, UT, posterior division, anterior division of the upper trunk; br, branch; ECRL, extensor carpi radialis longus; FCR, flexor carpi radialis; FDP, flexor digitorum profundus; IP, interphalangeal joint.

Table 36.6 Proximal nerve transfer versus distal nerve transfer in adult BPI

	Proximal nerve transfer	Distal nerve transfer
Philosophy	Traditional and physiological	New strategy
Donor nerve	Supraclavicular, far from the target muscle	The nearby nerve close to the target muscle
Advantages	For diagnostic and treatment Proximal nerve(s), powerful Nerve cut stump often unhealthy, fewer functional deficits	A treatment procedure, but not diagnostic Direct repair; no need of nerve graft No scars, easy dissection, shorter operation time Nerve cut stump healthy Short rehabilitation, faster recovery
Disadvantages	More scars, difficult dissection Nerve cut stump unpredictable, often unhealthy All need nerve grafts, moreover long nerve grafts (>8 cm) Longer operation time Longer rehabilitation period	Nerve cut, risk of causing deficits Risk of iatrogenic injury May need multiple incisions
Indication	All kinds of avulsion/rupture injury of brachial plexus injury	Not global BPI Intrinsic palsy of the hand

Table 36.7 Comparison of multiple nerve transfers vs. functioning muscle transplantation for total root avulsion of BPI

	Multiple nerve transfers first	FFMT first
Authors prefer	Chuang[40]	Doi[39]
Philosophy	Traditional strategy Proximal-to-distal in reconstruction priority Shoulder, elbow first, then finger sensation and flexion, then finger extension	New strategy Distal-to-proximal in reconstruction priority Finger extension and flexion, then elbow flexion; then shoulder
Reconstructive strategy	Multiple nerve transfers are essential FFMT is an adjuvant procedure to backup the results	Two FFMTs are essential Nerve transfers are adjuvant
Brachial plexus exploration	Yes	Maybe not
Nerve reconstruction: For shoulder For elbow For finger	 Yes (by NT) Yes (by NT) Yes (by NT)	 May or may not be needed Need FFMT Need FFMT
Stage requirement for full reconstruction	Can be one stage	Always multiple stages
Rehabilitation period	At least 4 years	2 years
Patient selection	Should be a highly motivated and intelligent patient	Can be a less intelligent and impatient patient
Predict outcomes: Shoulder elevation Elbow flexion Finger flexion Finger extension (EDC)	 Better (≥60°) Usually better (M4) M2–4 M0	 Shoulder fusion (10–30°) M3–4 M2–4 M2–3

NT, Nerve transfer; FFMT, functioning free muscle transplantation; EDC, extensor digitorum communis.

Fig. 36.8 Chuang angle, and "white line" between clavicular and sternal part of pectoralis major muscle (see text). C-PM, Cervical part of pectoralis major; S-PM, sternal part of pectoralis major.

the deltopectoral groove and extends upward to meet the supraclavicular incision, or downward to the medial sulcus of the biceps (see Fig. 36.7, mark 2). Other additional incisions may be required: extended neck incision for accessing the spinal accessory nerve (upward extending incision of the mark 1 incision); chest semicircular incision for the intercostal nerve (see Fig. 36.7, mark 4); inframental incision for the hypoglossal nerve (see Fig. 36.7, mark 6); medial arm incision for the biceps nerve and brachialis nerves (see Fig. 36.7, mark 3); and a contralateral neck C-curved incision for contralateral C7 spinal nerve dissection and transfer (see Fig. 36.7, mark 5). The different incision lines are used to avoid: a large incision wound, unnecessary dissection, prolonged operative time, increased postoperative morbidity (pain and numbness), and long ugly scars.

Landmarks and key points for supraclavicular dissection

1. A platysma musculocutaneous flap is elevated with the C-curved incision.
2. Dissection beneath the sternocleidomastoid muscle to the internal jugular vein is made but should never go beyond the internal jugular vein, the most medial landmark of the brachial plexus exploration. In addition, the suprascapular sensory nerves are the uppermost landmark, and one should never go above them.
3. The omohyoid muscle just behind the sternocleidomastoid muscle is identified and spared if

possible as it is an important landmark for possible secondary exploration.

4. Below the omohyoid muscle, there is an abundance of adipofascial tissue containing rich lymphatic ducts, lymph nodes, and the transverse cervical vessels. A similar C-shaped incision along the internal jugular vein medially and subclavian vein inferiorly is made and a superiorly based adipofascial flap is elevated. All the lymph tissues, including the ducts coming from the deep plane of the internal jugular vein, should be coagulated or ligated before division to avoid postoperative lymph leakage. The phrenic nerve and anterior scalene muscle are identified following adipofascial flap elevation.
5. The transverse cervical artery and vein in the inferior plane of the adipofascial tissue are preserved if possible as they are potentially required as the recipient vessels for a vascularized ulnar nerve graft. Sometimes the transverse cervical artery is abnormally beneath the brachial plexus. The subclavian artery just beneath the scalene anterior muscle is carefully protected.
6. The fibrotic scalene anterior muscle can be segmentally or totally excised depending on the necessity to expose the more proximal spinal nerve in level II injury for intraoperative diagnosis and nerve manipulation.
7. The vertebra C5 has a more prominent anterior tubercle of the transverse process than vertebra C6 or C4. While detaching the scalene anterior muscle and fascia, the nerve comes out above the tubercle is C5, and below is C6 spinal nerve.
8. Other anatomic landmarks are also helpful for localization:
   a. The nerve beneath the transverse cervical artery is usually C5 or the upper trunk.
   b. The nerve beneath the subclavian artery is C8 or the lower trunk.
   c. The first branch from the upper trunk is the suprascapular nerve, exiting from the plexus and traveling backward. The division beside the suprascapular nerve is the posterior division of the upper trunk, which travels in a posterior plane, while the anterior division of the upper trunk travels in an anterior plane.
   d. The spinal accessory (XI) nerve can be found through two ways: (1) dissection between the adipofascial tissue and platysma skin flap down to the trapezius muscle where the XI nerve lies in front of the trapezius muscle; or (2) extending the incision upward across the supraclavicular (sensory) nerves to locate the great auricular nerve, when the XI nerve will be seen within about one finger-breadth above the great auricular nerve, and beneath the sternocleidomastoid muscle. This can be confirmed by a nerve stimulator.

Landmarks and key points for infraclavicular dissection

1. Chuang's angle (Fig. 36.8A) is an angle shaped by the main branch of the cephalic vein on one side and the clavicle on the other side. Some of the deltoid and the clavicular part of pectoralis major muscle attachments can be detached to increase the angle zone. Under the clavicle is the subclavius muscle, and under the subclavius muscle is a space where the posterior cord, lateral cord, and suprascapular nerve can be seen. From this, the suprascapular and infrascapular fossa can be connected through this avascular plane which can be created by a finger dissection without fracturing the clavicle. The clavicle and the subclavius muscle are lifted together by a rolled gauze.
2. The "white line" (see Fig. 36.8B) is an intermuscular septal line between the clavicular and sternal parts of pectoralis major muscle. Opening the line, the underlying pectoralis minor muscle and infraclavicular brachial plexus can be visualized. Some anatomical landmarks are also helpful for anatomical localization infraclavicularly. The first cord encountered beneath the proximal pectoralis minor muscle is the lateral cord. Y-shaped limbs from lateral and medial cords will become the median nerve. The axillary artery (the artery beyond the first rib is axillary artery) can be easily found between the Y-shaped limbs. The posterior cord lying posterior to the subclavian artery has two terminal branches: the larger one is the radial nerve, and the smaller one is the axillary nerve.
3. In the upper arm, the musculocutaneous nerve can usually be found between the biceps and coracobrachialis muscles. The musculocutaneous nerve will penetrate the proximal coracobrachialis muscle. Sometimes it has anatomical variation and comes from the median nerve.
4. The axillary nerve in the axilla can be found at the humeral neck, above the tendinous portion of the teres major, accompanied by the lateral circumflex humeral artery.

Surgical techniques

Surgical methods include neurolysis, nerve grafts, nerve transfers and functioning free muscle, depending on preoperative diagnosis of level of injury and intraoperative findings. The following pages detail our experience with BPI treatment in terms of the level of injury (see Table 36.5).

Level I injury

The incidence of level I lesions is unfortunately very high, about 70%. Most are avulsion injuries. Nerves may be avulsed from the spinal cord (true avulsion), or ruptured at the preganglionic roots and rootlets. Partial Brown–Séquard syndrome is an example of true avulsion.[22] One to all five roots may be avulsed. Root avulsion injuries lack central connection and are considered irreparable. Nerve transfer, pedicled or functioning free muscle transplantation (FFMT) provide the only possibilities for functional restoration.

Nerve transfer (Video 36.3 ▶)

Nerve transfer is a surgical option which intentionally divides a physiologically active nerve (with low donor morbidity)

and transfers it to a distal, more important but irreparable paralyzed nerve. The procedure is best done within a golden time period – within 5 months of the injury,[9,33] in order to reactivate the paralyzed muscle(s) effectively (aiming for M4). Nerve transfer can be broadly classified into four categories: (1) extraplexus; (2) intraplexus; (3) close-target nerve transfer (or distal nerve transfer); and (4) end-to-side neurorrhaphy nerve transfer.

Extraplexus nerve transfer

Extraplexus nerve transfer involves the transfer of a brachial plexus neighboring nerve (from either the ipsilateral or contralateral neck) to the avulsed brachial plexus for neurotization of a paralyzed nerve. The commonly used donor nerves are mostly aimed at motor reinnervation.[33] These donor nerves include the phrenic (Ph) nerve, spinal accessory (XI) nerve (accessed by an anterior neck approach), deep motor branches of the cervical plexus (cervical motor branches, CMB), hypoglossal nerve (XII), and the contralateral C7 (CC7) spinal nerve. Extraplexus sensory nerve transfer such as supraclavicular sensory nerve to median nerve transfer is sometimes used to provide sensation to the paralyzed hand.

Intraplexus nerve transfer

Intraplexus nerve transfer is applicable in cases of non-global root avulsion, in which at least one of the spinal nerves is not ruptured and is still available for transfer – not to its original pathway, but to other more important nerves. For example, in a case of C5 rupture and C6 root avulsion, the C5 fibers are intentionally transferred to C6 (or the anterior division of the upper trunk) for elbow flexion, and the distal C5 (combining the posterior division of the upper trunk and suprascapular nerve) is then reinnervated by the phrenic and/or spinal accessory nerve (extraplexus) nerve transfer (Fig. 36.9). This strategy acknowledges that elbow flexion has priority over shoulder reconstruction. Intraplexus nerve transfer is individualized depending upon the intraoperative findings, the surgeon's philosophy, and the patient's condition and requirements. Extraplexus and intraplexus nerve transfers are both considered as proximal nerve neurotization (see Fig. 36.9).

Closed-target nerve transfer (or distal nerve transfer)

Closed-target nerve transfer is a procedure that provides a direct coaptation at a more distal site, closer to the neuromuscular junction, thus achieving faster recovery of motor outcomes. Closed-target nerve transfer is defined as a procedure outside the supra- and infraclavicular fossa. Examples include spinal accessory (XI) nerve transfer to the suprascapular nerve via a posterior approach; partial ulnar nerve transfer to the biceps nerve; partial median nerve transfer to the brachialis nerve; long head of triceps branch transfer to the anterior division of axillary nerve (Fig. 36.10); intercostal nerve transfer to the biceps nerve or the musculocutaneous nerve, or the nerve of the long head of triceps; anterior interosseus nerve transfer to the radial or posterior interosseus nerve; and branch of the anterior interosseus nerve transfer to the deep motor branch of the ulnar nerve in the forearm. Closed-target nerve transfer is considered as distal nerve transfer.[34] Selecting proximal or distal nerve transfer as a reconstructive strategy is now a subject of much debate (see Table 36.6).

Fig. 36.9 A case of left brachial plexus injury with drop shoulder and elbow. Exploration proved C5 rupture and C6 root avulsion. This patient received C5 nerve grafted (5 cm ×4) to C6 (intraplexus nerve transfer), and phrenic nerve plus spinal accessory nerve both transfer to the distal C5 (extraplexus nerve transfer). **(A,B)** Results after 3 years' rehabilitation showed good shoulder and good elbow recovery.

A cohort of 188 patients with different methods of musculocutaneous nerve neurotization for acute brachial plexus injuries were selected based on inclusive criteria in the author's series.[35] Musculocutaneous nerve neurotization from C5, medial cord, C8, contralateral C7, spinal accessory nerve, or phrenic nerve to obtain elbow flexion were all included into the group of proximal nerve transfer. Musculocutaneous neurotization from partial ulnar nerve and/or partial median nerve was classified into distal nerve transfer. Intercostal nerve transfer to the musculocutaneous nerve was categorized into a separate group. Results showed there were no significant differences in the success rate of recovery of elbow flexion (M>3) between the use of proximal vs. distal nerve transfer (P=0.424). Even though the speed of recovery was faster in

Fig. 36.10 A 17-year-old young male had right brachial plexus injury with C5 and C6 two-root avulsion. He received multiple nerve transfers: spinal accessory nerve transfer to the suprascapular nerve (extraplexus nerve transfer), and triceps branch (to long head of triceps) transfer to the anterior division of the axillary nerve, ulnar nerve fascicle to the biceps branch and median nerve fascicle to the brachialis branch (distal nerve transfer). **(A–C)** Results after 2½ years showed good shoulder and elbow recovery with good shape of supraspinatus, infraspinatus, deltoid, and elbow flexor muscles.

the distal group, 19 months vs. 23.9 months, the difference was also not significant. The only statistically significant difference was the speed of recovery between the use of partial ulnar nerve ± median nerve fascicle and the use of intercostals nerves (P=0.046). However, a selective number of patients had grip strength deficits resulted from distal nerve transfers for many years.

From the author's point of view, the new strategy of distal nerve transfer can provide an exciting alternative of the traditional proximal nerve graft and/or transfer. However, distal nerve transfer should not be applied in situations where proximal nerve graft/transfer is more indicated. Proximal nerve graft/transfer (extraplexus and intraplexus nerve transfer) is still the main reconstructive procedure based on the principle of "No diagnosis, no treatment" (Fig. 36.11). Proximal nerve graft/transfer is usually performed during brachial plexus exploration. It is quite common to find out the proximal ruptured spinal nerve for reconstruction, which is especially true for C5, even with a preoperative diagnosis of total root avulsion. In proximal nerve graft/transfer, if the transferred nerve comes from its original spinal nerve, it is usually more powerful with a huge number of axons. Proximal nerve graft/transfer can avoid iatrogenic injury where the lesion is still in continuity (more are Sunderland third-degree injury) and neurolysis is maybe the only procedure without further cutting the nerve. Other donor nerves such as phrenic nerve, spinal accessory nerve, hypoglossal nerve, cervical motor branches can also be found without additional incisions. However, in proximal nerve graft/transfer, dense scars with difficult dissection will be encountered. Sometimes one needs to trim out the part of C5 transverse process to access the ruptured stump. Oozing and bleeding will occur very often and requires careful diathermy. Long operation time can be expected. The health of proximal ruptured stump is sometimes unpredictable, even accessed microscopically. Interposition of nerve grafts is always required, which can jeopardize functional recovery and longer rehabilitation time is necessary. Proximal nerve graft/transfer can be applied in either complete or incomplete avulsion brachial plexus injuries.

End-to-side neurorrhaphy nerve transfer

End-to-side neurorrhaphy (terminolateral neurorrhaphy) is a technique to transfer the distal end of a paralyzed and irreparable nerve to the side of an intact nerve with an epineurotomy window for both motor and sensory reconstruction.[36] The author has never used this technique for BPI.

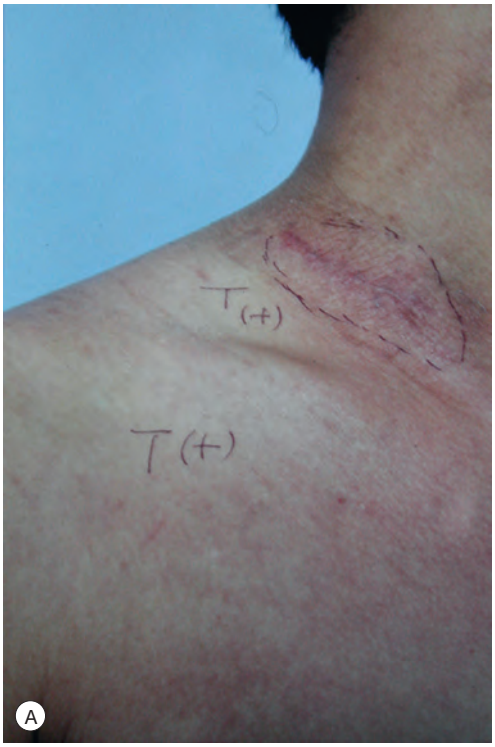

Fig. 36.11 A case of right brachial plexus injury with drop shoulder and elbow for 5 months. **(A)** A healed scar over right neck was seen at the first clinic visit. Intraoperative findings 1 month later showed dense scars around C4, C5 and C6. Only external neurolysis with decompression was performed. **(B,C)** Results after 1-year rehabilitation showed good recovery. This case proved the principle of "No diagnosis, no treatment."

Reconstructive strategies

Shoulder

Reconstruction for shoulder abduction in a level I lesion should take priority over shoulder adduction. If the supraspinatus, infraspinatus, and deltoid muscles are innervated simultaneously, results are predictably better. The Ph and XI are the main donor nerves for shoulder abduction. The XII nerve, CMB, part of C5 or C6, long thoracic nerve, branch to the long head of triceps, medial pectoral nerve, intercostal nerves, and CC7 have also been reported as the donor nerve for shoulder abduction. The recipient nerves for shoulder abduction in order of priority are the distal C5, suprascapular nerve, dorsal division of the upper trunk, then axillary nerve.[33] A study of a series of patients operated on between 2000 and 2003 demonstrated that triple nerve transfers produced the best and most consistently reliable results for shoulder elevation: an average of 160° shoulder abduction was achieved following triple nerve transfers, but 85° following double nerve transfers and 65° following single nerve transfer.[37]

Elbow

In level I injury, reconstruction for elbow flexion is always the first priority in adult BPI (in OBPP, reconstruction for hand function is the first priority). Reported donor nerves for elbow flexion include intercostal nerve, XI nerve with a nerve graft, Ph nerve with or without nerve graft, partial ulnar nerve, partial median nerve, pectoral nerve, thoracodorsal nerve, and CC7. The recipient nerve is the musculocutaneous nerve (mixed nerve), biceps nerve, or brachialis nerve. Elbow extension is usually a lower priority for reconstruction. Ph nerve transfer to the distal C5 or to the posterior division of the upper trunk, or to the radial nerve with a nerve graft, can

Fig. 36.12 (A,B) Example of results of one-stage surgery for C5 rupture, C6–T1 four-root avulsion 5 years after (1) phrenic nerve transfer to the posterior division of the upper trunk and spinal accessory transfer to the distal suprascapular nerve for shoulder elevation; (2) three intercostal nerves (T3–5) transfer to the musculocutaneous nerve for elbow flexion; and (3) proximal C5 transfer to the median nerve using vascularized ulnar nerve graft for finger flexion and sensation.

often yield elbow extension, usually in the third year of rehabilitation. Some authors describe transferring two or three intercostal nerves to the branch of the long head of triceps to achieve elbow extension.[38]

Finger

In global C5–T1 injury (or total limb palsy) reconstructive priority for finger function depends on the procedure used: nerve transfer or FFMT.[39] Traditionally, reconstruction for finger flexion is preferable to finger extension which can sometimes be helped by a dynamic extension splint. In cases of C5 rupture with C6–T1 four-root avulsion, transfer of C5 to the median nerve (Fig. 36.12), or in cases of total root (C5–T1) avulsion, transfer of the CC7 to the median nerve (Fig. 36.13) can be performed to achieve finger and wrist flexion as well as finger sensation. Each procedure requires a vascularized ulnar nerve graft.

In total root avulsion, multiple nerve transfers first vs. FFMT reconstruction first is a subject of much debate (see Table 36.7). In the acute stage of BPI, using multiple nerve transfers to treat the total root avulsion, which is proposed by the author,[40] aiming to achieve a one-stage full reconstruction for shoulder, elbow, and hand functions, is a traditional strategy of proximal-to-distal reconstruction (Fig. 36.14). In these cases, FFMT is used as a secondary adjuvant reconstruction to enhance results at a later stage. Using FFMT to achieve hand function (finger extension and flexion) in the acute stage is a new strategy of distal-to-proximal reconstruction, proposed by Doi *et al.*,[38,39] and is an alternative approach: A long FFMT (usually gracilis muscle) from the clavicle down to the extensor digitorum communis, innervated by the XI nerve, is performed in the first stage, followed by a second long FFMT from the second rib to the flexor digitorum profundus, innervated by intercostal nerves in the second stage. In these cases, nerve reconstruction such as C5 transfer, contralateral C7 transfer, or intercostal transfer is an adjunctive procedure for shoulder function. The biggest remaining deficit in Doi's method is that the reconstructed patients had no or poor hand sensation. Comparison between multiple nerve transfers vs. FFMT to treat total root avulsion of BPI in the acute stage is illustrated in Table 36.7.

Pedicled muscle transfer (Video 36.2 ▶)

Pedicled muscle transfer is indicated in non-global BPI such as C5–6 root avulsion with intact C7–T1. Local latissimus dorsi muscle transfer for elbow flexion or finger flexion, or even for shoulder abduction; local pectoralis major muscle transfer or local pectoralis minor transfer for elbow flexion; part deltoid transfer for elbow extension; and forearm muscle transfer for intrinsic palsy are examples of pedicled muscle transfer. Using a reinnervated muscle transfer as a pedicled muscle transfer is also an issue of debate. Preoperative muscle strength examination is very important. Before a reinnervated muscle can be used, it should be at least M4 muscle strength. Otherwise many of these transfers are useless and wasted. For example, using a local latissimus dorsi muscle transfer for elbow flexion in C5 and C6 (±C7) avulsion injury usually results in M3, but not M4 muscle strength, compared with latissimus dorsi transfer for the traumatic loss of biceps and brachialis, which always results in M4 muscle strength. The reason for this difference in outcome is the state of the thoracodorsal nerve, which originates from C6–8. In the former example, the thoracodorsal nerve is actually an injured

Fig. 36.13 Example of results of one-stage surgery for total root avulsion 5 years after (1) left contralateral C7 transfer to the median nerve using a vascularized ulnar nerve graft for finger flexion and sensation; (2) three intercostal nerves (T3–5) transfer to the musculocutaneous nerve for elbow flexion; and (3) phrenic nerve transfer to the suprascapular nerve for shoulder elevation. **(A)** Shows 90° shoulder elevation; **(B)** M4 elbow flexion; and **(C,D)** M3 finger flexion.

Fig. 36.14 A 17-year-old girl had left brachial plexus injury with total root avulsion. She received multiple nerve transfers simultaneously with right contralateral C7 transfer to the median nerve for finger flexion and sensation, three intercostal nerves (T3–5) transfer to the musculocutaneous nerve for elbow flexion, and spinal accessory nerve transfer to the suprascapular nerve and phrenic nerve transfer to the posterior division of the upper trunk for shoulder. **(A,B)** Results 5 years after showed good shoulder, good elbow, and acceptable hand function and sensation.

nerve, but in the latter example of traumatic muscle loss, the thoracodorsal nerve is an uninjured one. Local pedicled muscle transfer, although an alternative restorative option, is often not reliable due to the presence of a partial nerve injury.

Functioning free muscle transplantation (FFMT)

FFMT is the transfer of a muscle utilizing microvascular anastomoses for revascularization and microneural coaptation to the recipient motor nerve for reinnervation. The use of FFMT in brachial plexus reconstruction is one example of the application of nerve transfer (including extraplexus, intraplexus, and closed-target nerve transfer).[39,41] It has been shown to be effective and has become increasingly popular. The gracilis myocutaneous FFMT is the most common and best choice of donor muscle in brachial plexus reconstruction. The commonly used donor nerves include the XI, the intercostal, the Ph nerve, the CC7 nerve, part of the ulnar nerve, part of the median nerve, or more proximally from the infra- or supraclavicular nerve, which requires nerve elongation (with a nerve graft in the first stage) and then FFMT in a two-stage procedure. The results from FFMT are more satisfactory than those achieved with a local muscle transfer. It is especially useful for elbow and hand function restoration in global plexopathy. Indications for FFMT in BPI include acute or chronic root avulsion, root injury with failed nerve transfer (muscle strength less than M3), or BPI with associated Volkmann's contracture of the forearm.

Level II injury

Level II injury is defined as an injury distal to the dorsal root ganglion (or outside the intervertebral foramen) but between the scalene muscles and proximal to the suprascapular nerve. If the suprascapular nerve is intact, the lesion will be in level III–IV and not in level II. The incidence of a pure level II injury is approximately 8%. Disruption of the spinal nerve with neuroma formation and dense scar tissue involving the scalene muscles (especially the middle scalene muscle) are the main findings in this type of injury. Nerve rupture may occur at one or multiple spinal nerves. The clinical differential diagnosis between preganglionic root (level I) and postganglionic spinal nerve (level II) injury is of great importance with regard to the surgical approach and prognosis. Reconstruction for this level of injury includes neurolysis, nerve repair, nerve grafts, and nerve transfer if associated with level I lesion in other spinal nerves, and palliative reconstruction.

Level III injury

Level III injury involves the trunks and divisions. In the author's series, only 5% of patients were injured purely in this zone. Nerve rupture with neuroma formation and dense scars were the most common findings. Bypass nerve grafting is required to re-establish the connection between the supra- and infraclavicular brachial plexus. A clavicle osteotomy is often required for wound exposure, especially for injuries involving the lower trunk, to allow grafting or direct neurolysis. Multiple nerve grafts are required and need to be harvested from different locations. A C-loop vascularized ulnar nerve graft is sometimes helpful to reduce the amount of nerve grafts, especially in cases of extensive injury.

Level IV injury

Level IV BPI involves the cords and their terminal branches. The incidence is high (17%), second after level I injury. Level IV injury is commonly limited to this zone only and rarely has proximal level involvement. Level IV injuries are mostly encountered with nerve ruptures and rarely with nerve avulsion. Any nerve avulsion here is distal avulsion at the bone margin (suprascapular nerve avulsion at the scapular notch, or axillary nerve at the humeral neck, or radial nerve at the spinal canal inlet), or at the muscle attachment (such as the musculocutaneous nerve from the biceps surface). In closed level IV injury, the nerve damage is variable, ranging from simple isolated nerve injuries (axillary, musculocutaneous, or radial nerve) to lesions of all cords or all terminal branches. Level IV injury has particular characteristics with specific challenges in surgical dissection and repair due to dense scarring. Nerve grafts are more frequently used with less aberrant reinnervation and better prognosis. There is a high incidence of vascular injury, rupture or segmental occlusion of the subclavian or axillary artery – about 30%. For ease of dissection, detachment of the insertion of the pectoralis major muscle by Z-lengthening incision is often required. For penetrating injuries, vascular and nerve repairs are usually performed simultaneously.

The golden time for primary direct repair of a divided nerve without nerve grafts in penetrating injury is within 2 weeks. Traction injuries in level IV are usually associated with fracture of the proximal humerus or the glenoid scapula. The nerve segments have been extensively damaged. Long nerve grafts are usually required to bridge the nerve gap, commonly more than 8 cm in length. Sometimes a C-loop vascularized ulnar nerve graft is harvested from the paralyzed forearm and utilized for median and radial nerve reconstruction. The results are usually good. In nerve avulsion from the muscle, nerve grafting of the proximal nerve stump and direct implantation into the muscle (nerve-to-muscle neurotization) yield fair results (around M3). As described previously, FFMT is another option of reconstruction for such cases.

Postoperative management and rehabilitation

Immediate postoperative splinting for 3 weeks is required after nerve grafts or nerve transfer. Thereafter, retraining and rehabilitation should start, including physiotherapy (to avoid joint stiffness), muscle stimulation (to delay muscle atrophy), brain cognition, biofeedback, and occupational therapy.

Patients should be followed periodically by the surgeon (every 3–4 months) and the physical therapist (twice a month). Patients are encouraged to have electric muscle stimulation at home (twice a day). In cases of intercostal nerve transfer, passive shoulder elevation remains restricted to less than 90° for 6 months. Regular follow-up in the rehabilitation center and outpatient clinic is tremendously important, and should be explained to patients before and emphasized again after surgery.

Induction or motivation exercise is an important muscle exercise for patients with nerve transfer and/or functioning free muscle. The original function of the donor nerve must be practiced to induce movement in the target muscles newly innervated by the transfer. For example, patients who have undergone intercostal nerve transfer must increase their

deep-breathing rate to induce movement in their target muscles. An induction exercise is commenced when movement of the innervated muscles is palpable (M1). The action is comparable to an internal electric stimulator. Various nerve transfers have different induction exercises.[33] Realizing the importance of these exercises is crucial. This explains why good results are commonly achieved by psychologically strong and ambitious patients who cooperate well in terms of their rehabilitation program, while poor results are often obtained by uncooperative patients. Permanent external orthosis to extend the interphalangeal joints of the fingers is always required for intrinsic palsy of the hand to improve the final result of surgical reconstruction and long rehabilitation programs.

Palliative reconstruction for sequelae deformities (Video 36.1 ▶)

Palliative reconstruction procedures include local muscle or tendon transfer, FFMT, tenodesis, and arthrodesis, or alternatively the use of orthotics and prosthetics. Palliative reconstruction can be considered when the injury involves C8 and T1 level (Klumpke's palsy in adults), or when deformities persist after maximum recovery either with or without nerve reconstruction.

Outcome evaluation (Videos 36.4, 36.5, 36.7 ▶)

Although the British MRC scale provides the possibility of homogeneity and consensus in motor evaluation, a considerable degree of heterogeneity exists in the evaluation of functional recovery of the shoulder, elbow, and digits. In the author's opinion, establishing an international consensus on motor evaluation of different movements is vital and imperative for the advancement of our understanding and mutual comparison. The British MRC scheme is used for individual muscle evaluation in plexus injuries, or for evaluation of the transferred muscle in FFMT. Both are evaluated by target joint movement.

Conclusion

Closed traction injuries of the brachial plexus are devastating injuries. For someone who has nothing, a little is a lot. Patients, especially those with total root avulsion, should be encouraged to recognize their disabilities and make use of the regained but not completely recovered limb. This may be shoulder elevation of 60°, M4 elbow flexion strength, and M2–3 strength of finger flexion following reconstruction. In a failed reconstruction, or if the patient perceives the injured limb as a useless dead weight, amputation may be considered as a last option.

Future directions

- Endoscopic-assisted and/or robot-assisted surgery for brachial plexus reconstruction.
- Unifying the level of brachial plexus injuries from level I–IV.
- Unifying outcomes evaluation in a simple, straightforward manner.
- Increasing the accuracy of MRI studies for diagnosis and evaluation.

Pediatric brachial plexus injury (obstetric brachial plexus palsy)

Key points

- OBPP has significant differences from adult BPI, including mechanism of injury, classification of injury, clinical evaluation, intraoperative findings, reconstructive strategy, postoperative rehabilitation and follow-up, result assessments, and pain character. It therefore presents as a separate entity (see Table 36.1).
- OBPP has two distinct phases: (1) infant OBPP (I-OBPP); and (2) sequelae OBPP (S-OBPP). Both have significant differences in management and prognosis, and will be discussed separately.
- I-OBPP includes risk factors, clinical presentation, preoperative evaluation, timing of nerve surgery, surgical exploration of the brachial plexus, reconstructive strategies for nerve surgery, postoperative management, and outcomes assessment.
- S-OBPP includes aberrant reinnervation, shoulder reconstruction, elbow reconstruction, and forearm and hand reconstruction.

Introduction

Clinical tips

- OBPP is an obstetric trauma; risk factors include overweight babies (>4000 g) in cephalic presentation, underweight babies (<2500 g) in breech presentation, or fetal distress (such as septicemia) with loss of protective muscular tone during Caesarean section.
- Infant OBPP focuses on nerve surgery, timing of surgery, and results from nerve surgery.
- Sequelae OBPP focuses on palliative reconstruction for shoulder, elbow, and hand deformities.

There are different but similar terms being used to describe pediatric brachial plexus injury in the literature, such as obstetric (or obstetrical) brachial plexus palsy (OBPP),[42] neonatal brachial plexus palsy (NBPP),[43] or brachial plexus birth palsy (BPBP).[44] In this chapter, pediatric brachial plexus injury is termed OBPP for obstetric brachial plexus palsy.

OBPP almost always results from traumatic delivery, although some other possible causes have been mentioned.[45] Overweight babies (>4000 g) in cephalic presentation, underweight babies (<2500 g) in breech presentation, and fetal distress (such as septicemia) with loss of protective muscular tone during Caesarean section are all susceptible to brachial plexus injury following delivery. It is caused by traction force during delivery, which widens the angle between neck and shoulder and induces the plexus nerves damage. The term "palsy", not "injury" as in adult BPI, has been used to describe pediatric BPI from a very early point in the literature, in 1872, by Duchenne.[45]

There are many differences between OBPP and adult BPI (see Table 36.1). The incidence of stretch (neurapraxia or axonotmesis) and incomplete rupture are more common in OBPP than in adult BPI in which complete rupture or avulsion is often seen. Often there is paresis (incomplete paralysis) rather than flaccid paralysis (complete paralysis) in OBPP. Even when there is complete rupture, the gaps are short and spontaneous regeneration is still possible; while in adult brachial plexus injury the gaps are long and the scars are dense which make spontaneous regeneration impossible. In OBPP, most are Erb's palsy (upper plexus injury), and the lesion is always supraclavicular. Mixed complex neuroma of the upper and middle trunk is frequently seen, and motor recovery with misdirection (or aberrant reinnervation) often occurs in OBPP, particularly in the muscles innervated by the upper and middle trunks. Aberrant reinnervation causes abnormal co-contraction of multiple muscles, especially in the shoulder and elbow. Aberrant reinnervation diminishes function significantly, even in those patients considered to have had complete spontaneous recovery. This is why consequent deformities develop in OBPP and many require reconstruction. In adult BPI, the location of injury varies. Aberrant reinnervation occurs only in cases of penetrating injury of the upper trunk where trunk to trunk repair is performed directly or indirectly with short nerve grafts. Recovery after nerve reconstruction is generally slow in OBPP. Improvement continues for at least 3 years. Poor cooperation and rehabilitation may be a factor. The most improved period after nerve reconstruction is at 3 years of age. This is why second reconstruction is always performed after the age of 4 years. Regarding sensation recovery, it usually greatly exceeds that of muscle and sympathetic function. Central plasticity may be a factor. OBPP patients always show remarkable absence of neuropathic pain.

For the purpose of treatment, OBPP can be subdivided into two distinct phases: (1) I-OBPP, and (2) S-OBPP (or late OBPP with deformity).[46] These patients may present at any time and have a wide variation in clinical presentation. All stages have different management and prognosis. I-OBPP refers to the infant's brachial plexus that has been paralyzed following delivery. Some require early nerve surgery and some do not. Reconstruction is focused on primary nerve surgery, in which timing of intervention and results of nerve surgery are a concern. S-OBPP refers to the sequelae deformities resulting from I-OBPP with or without previous nerve surgery. Many S-OBPP patients request surgical correction for the shoulder, elbow, forearm, and hand.[47–49] Reconstruction in sequelae OBPP is focused on palliative surgeries on bone or joint, tendon or muscle, and no longer on nerve surgery of the brachial plexus.

Infant obstetric brachial plexus palsy

Although the evolution of microsurgical nerve repair has significantly allowed surgeons to perform early intervention for I-OBPP, many rehabilitation therapists[50–51] and even some surgeons[52–53] continue to argue against early nerve surgery. Arguments against early surgery include high rates of spontaneous recovery (70–92% in the literature), high risks of surgery and postoperative care at an early age, and lack of significant functional improvement. Nevertheless, following developments in operative magnification (loupe and microscope), refinements in nerve grafting and nerve transfer, understanding of the brachial plexus anatomy, and pathophysiology of nerve degeneration and regeneration, more microsurgeons[54–58] have begun to choose early nerve surgery as the treatment of choice for I-OBPP. This group found that the rate of spontaneous recovery was actually low (7–50%), and early nerve surgery may potentially decrease or eliminate the late sequelae. The results from the author's series[58] prove that early nerve surgery, when indicated, is still the treatment of choice for I-OBPP patients. In addition, the reconstructions performed in the late group were found to be difficult, and required complex procedures to achieve reasonable results.[47–49]

Risk factors for I-OBPP during cephalic delivery include high birth body weight (>4000 g), shoulder dystocia, cephalopelvic disproportion, forceps or vacuum suction delivery, or poor technique of delivery. I-OBPP may also occur during difficult breech presentation or in fetal distress (such as septicemia) during Caesarean section. Associated injuries with birth palsy can be seen, including fracture (ipsilateral or contralateral clavicle, humerus, femur, or ribs), respiratory insufficiency (asphyxia) due to diaphragm palsy, ecchymosis (neck, chest, face, or upper back), and wry neck (torticollis). Although the cause of I-OBPP is still a subject to debate (some believe it can be of intrauterine origin), the author believes that it is caused by obstetric trauma and not due to intrauterine compression neuropathy. All of the author's intraoperative findings in I-OBPP have been similar to adult brachial plexus traction injury (avulsion, rupture with neuroma and mixed with muscles), not like pictures of compression neuropathy that presents with pseudoneuroma and are rarely mixed with muscle fibers.

Clinical presentation

Determining the relationship between I-OBPP and S-OBPP and predicting the progressive changes in I-OBPP with age is a great challenge.[46] Different surgeons have different opinions about the clinical presentation of I-OBPP. In general, there are five types of clinical presentation in I-OBPP: type 1 (or Erb's) palsy, which involves deficits of C5 and C6, resulting in a posture of shoulder abduction or internal rotation, elbow extension, and forearm pronation (Fig. 36.15A,B); type 2 (or extended Erb's) palsy, which extends further deficits to C7 or C8, resulting in a posture of type 1 with wrist flexion (waiter tip deformity); type 3 and 4 palsies involving the entire plexus (global palsy), resulting in a flail arm without or with a Horner's syndrome, respectively; and type 5 (or Klumpke) palsy, which involves an isolated lower plexus, resulting in only a paralyzed hand (Fig. 36.16A,B). In unoperated cases, type 1 or 2 is much more common than type 3 or 4. But in operated cases, it is reversed: global palsy is more common than Erb's. Type 5 palsy is rarely seen, only in about 1%. In about 1% of I-OBPP cases, the injury is bilateral but predominantly on one side, and it is frequently seen in breech delivery or Caesarean section with fetal distress.

Clinical examination

Newborns are difficult to examine thoroughly. A precise muscle or sensory examination of an infant is impossible. The evaluation chart used for adult BPI (see Fig. 36.5) is not

Fig. 36.15 **(A)** A 2-month-old infant showed improving shoulder abduction of his right upper limb; **(B)** A 3-month-old infant showed improving elbow flexion of her right upper limb. Both were type 1 OBPP with no need for primary nerve surgery.

practical. Evaluation should include parents' observation at home, especially during bathing or dressing, and the examiner's observation in clinic. The infant is placed in the lateral decubitus position with the normal side down. The examiner then tickles the baby (tickling test, Fig. 36.17A), or covers the infant's face with a towel (towel test, see Fig. 36.17B) and uses this to evaluate dynamic movements of the infant's shoulder, elbow, and hand. An M2 (movement with weight eliminated) muscle strength score in a newborn infant is sufficient to predict a good result when the infant grows. In I-OBPP, there is no need to see M4 or M5 muscle strength as in adult BPI. Horner's syndrome with signs of ptosis or miosis may disappear with time, indicating that the T1 has a stretch but not an avulsion injury, or that T1 has a good connection with T2 (postfixed brachial plexus). An ipsilateral clavicle fracture is usually a good prognostic sign due to traction force divergence. However, a contralateral clavicle fracture is usually a bad prognostic sign as this indicates a high energy traction force. Ideally the infant should be followed up after birth and then at 1-month intervals until the decision to operate or not is made.

Neurophysiologic studies are not performed routinely. EMG in I-OBPP is usually positive and too optimistic, and may not be accurate enough to predict useful function. Even intraoperative EMG can be misleading. Improving techniques of MRI are now useful to evaluate level I and II lesions as in adult BPI, and are becoming the author's routine investigation for preoperative imaging (Fig. 36.18A–D). CT myelogram can also be useful.

Timing of surgery

Gilbert[59] recommends surgical intervention for infants without evidence of elbow flexion by 3 months. Terzis and Papakonstantinou[60] emphasize that the presence of total palsy with Horner's syndrome warrants earlier surgical intervention at

Fig. 36.16 **(A,B)** A 4-year-old girl shows isolated type 5 (Klumpke) palsy of her right upper limb.

Fig. 36.17 **(A)** The tickling test; and **(B)** the towel test to examine the I-OBPP.

2 months of age. Clarke and Curtis[61] advocate that failure to perform a "cookie test", to place a cookie in the mouth by 9 months of age is an indication for exploration. Our results[58] indicate that shoulder and elbow recovery were not different when surgery was performed at 2 months or at 11 months of age. Even patients who received primary nerve surgery beyond 1 year of age also showed significant improvement in shoulder and elbow function, but no improvement at all in hand function. In addition, our previous results showed similar improvement of shoulder function in late palliative reconstructions for late OBPP patients compared to those who underwent primary early nerve surgery for I-OBPP.[47] However, recovery of hand function with secondary reconstructive methods was far inferior to those who had early nerve surgery for hand function.[49] The ideal opportunity for improving hand function is by performing nerve surgery early. Our results demonstrate that Gilbert's "rule of 3 months" overestimates the poor results of shoulder and elbow function. However, Clarke and Curtis's "rule of 9 months" underestimates the poor results of forearm and hand function. The presence of poor shoulder and elbow function in I-OBPP is not an urgent indication for surgery. However, hand palsy is an urgent condition, indicating early surgical intervention. Therefore, our recommended timing of surgery falls between that of Gilbert and Clarke. A global palsy with absence of biceps function and little or no hand function is an indication for early exploration within 3 months. However, in the presence of wrist extension and finger flexion, an additional 3 months of observation is recommended. If by 6 months of age there continues to be no improvement in elbow flexion, then exploration is indicated. If poor shoulder or elbow function persists by 1 year of age, surgery is indicated too. However, poor hand function at this late age is not an indication for exploration as it is too late. The observation of M2 wrist extension or interphalangeal extension on clinical examination may imply that C7 may be injured (more often with avulsion), but C8 and T1 are intact, warranting an additional 3-month period of observation until the child reaches 6 months.

Preoperative preparation

Treating an OBPP patient is treating the whole family. A thorough explanation of the risks and benefits of surgery to the patient's family is very important, including preoperative diagnosis, surgical risks, postoperative care and rehabilitation, long-term follow-up, possible outcomes, and possible subsequent operations. After intubation, central venous pressure and arterial lines with long catheters should be secured in the femoral vessels. Those two vessel lines are crucial during the operation and for the first 3 days of postoperative care.

Surgical technique

Incision lines, dissection, and brachial plexus exploration are all similar to adult BPI, except:

1. The platysma in infants is very thin and sparse, resulting in an incision directly superficial to the surface of the sternocleidomastoid muscle.
2. The phrenic nerve should be isolated and well protected. Care should be taken during the operation to avoid excessive traction as this may prolong the extubation time due to transient palsy of the diaphragm.
3. All spinal nerves, C5–T1, should be identified and examined.
4. The scalenus anterior muscle is usually segmentally excised, permitting exposure of the level II spinal nerves and release of compression of the subclavian artery.
5. Lesion-in-continuity of the upper and middle trunks is commonly seen, requiring microneurolysis to evaluate the severity of scarring and judge the degree of nerve injury. If the scar is dense and the axis of the nerve (proximal and distal segments) are badly distorted, resection of the neuroma and nerve grafts are required.
6. When the lesions are more distal involving the divisions (level III injury), the incision is then extended to the deltopectoral groove, exposing Chuang's angle (see Fig. 36.8). The supra- and infraclavicular fossa are connected by opening the space under the subclavius muscle. The clavicle can be elevated easily without clavicle osteotomy.
7. Nerve grafts are commonly harvested from the both sural and saphenous nerves. If necessary, medial cutaneous nerve of the arm, superficial radial nerve, and lateral antebrachii cutaneous nerve from the injured limb are other sources.

Reconstructive strategies

Two groups of spinal nerve injury are classified based on intraoperative findings: (1) pure rupture injury (40%, 47/118); and (2) rupture injury associated with root avulsion (60%, 71/118) (Table 36.8). C5 and C6 tend to be ruptured, but C8–T1 tend to be avulsed (Table 36.9). If C8 is avulsed alone, T1 tends to be avulsed too, but partially. Once C8–T1 two root avulsion occurs, a ruptured C7 tends to have more proximal avulsion injury too. In global palsy, incidence of three-trunk rupture is about 5% (6/118). Preoperative MRI can be very helpful as a diagnostic tool to see level I or II injury.

Pure rupture injury

Except six patients who had rupture of all three trunks, the majority of patients (41/47, 87%) had rupture injury involving the upper and/or middle trunk. The reconstructive procedures consisted of microneurolysis and nerve grafts. Reconstructive strategies in these pure rupture injury groups varied

Table 36.8 Intraoperative findings of obstetric brachial plexus palsy (1992–2004, Chang Gung Memorial Hospital)

based on intraoperative findings and judgment. The majority of patients received C5 nerve grafting to the suprascapular nerve and posterior division of the upper trunk for shoulder, and C6 nerve grafting to the anterior division of the upper trunk for elbow function instead of proximal upper trunk nerve grafting to the distal upper trunk (Table 36.10). Four to six cable nerve grafts (2–3 cm in length) are usually required for coaptation. A ruptured C7 has a high incidence of accompanying avulsion. The proximal stump of C7 was therefore routinely repaired to the distal stump of C7 via nerve grafts. There were few patients who received longer nerve grafting (4–6 cm in length) from supraclavicular spinal nerves to the infraclavicular selected target nerves (posterior and lateral cord). Table 36.10 shows our reconstructive strategies for pure rupture injury.

Rupture injury associated with root avulsion

A total of 72 patients (60%) were included in this series. Once avulsion occurs, it tends to involve at least two roots (75%). This type of reconstruction depends on the number of root avulsions, and the remaining proximal neural resources. In global palsy, restoration of hand function becomes the first priority, followed by elbow flexion and then shoulder function (Table 36.11). In I-OBPP, C5 is usually ruptured, not avulsed (see Table 36.9). The proximal C5 stump can be a source for selective neurotization to the C8 or lower trunk

Table 36.9 Incidence of type of injury on different spinal nerves (1992–2004, Chang Gung Memorial Hospital)

	Rupture	Avulsion

(intraplexus neurotization). The frequency of nerve transfers increases if associated root avulsion increases, including intercostal nerve transfer for elbow or finger flexion, XI nerve transfer for the shoulder, or intraplexus transfer from C5 or C6 to the C8 or median nerve for hand function in three- or four-root avulsion. Intercostal nerve transfer, either to the musculocutaneous nerve for elbow, or to the median nerve for hand function, is an effective procedure in infant patients (much better than in adults). Few patients need contralateral C7 transfer,[40] branch of ulnar nerve transfer (Oberlin method[62]) or combined branch of median nerve transfer (Mackinnon method[63]). Table 36.11 shows our reconstructive strategies for rupture injury associated with root avulsion.

In this series of patients, 10 cases of I-OBPP were operated on late, at 1 year of age or older (range, 1 year to 2 years 6 months). Most of these patients showed poor spontaneous recovery of shoulder and/or elbow function prior to surgery. Primary nerve surgery for these late operative cases showed encouraging results in shoulder and elbow function recovery, but few gained recovery of hand function.

Postoperative management

A rigid premade neck splint is placed on every patient immediately postoperatively (Fig. 36.19). Total operative time is on average 8 h, with a range of 6–10 h. Postoperatively the patient is transferred to the intensive care unit after extubation. The patient is cared for in the head-up position to avoid dyspnea due to any temporary palsy of the diaphragm. The patient is kept in the intensive care unit for 3–5 days, and then transferred to the general ward for an additional 2 days. Total hospitalization is approximately 1 week.

The neck splint is kept in place for 4 weeks. Follow-up at regular intervals (the first month postoperatively and then every 4 months afterwards) is performed for a minimum of 4 years. Home electrical muscle stimulation (twice daily for 15–20 min each time) is started 4 weeks after surgery and performed for approximately 1 year or until muscle function reaches M2 level.

There are two important exercises for prevention of shoulder adduction contracture: pull-up bar exercise (stretching exercise), and swimming (dynamic exercise), where both upper limbs are exercised simultaneously.

Table 36.11 Nerve reconstructive strategy for rupture injury associated with root avulsion

Root avulsion		Nerve reconstructive strategy		
		For shoulder	For elbow	For hand

Outcome assessment

There is a lack of consensus with regard to the optimal method of assessing results. This is partly due to the complexity of the lesions (i.e., aberrant reinnervation), complexity of the repair (i.e., different surgical strategies), complexity of limb involvement (shoulder, elbow, forearm and hand), and finally the young age of the patients, which makes cooperation difficult. The reported methods of functional assessment include MRC muscle grading system, Gilbert and Tassin muscle grading system, Clark and Curtis active movement scale, Narakas' grading system, and others.[42–45] All patients should be followed for a minimum of 4 years. The results are categorized as "good", "fair", or "poor" based on the degree of shoulder abduction, external rotation, elbow flexion and extension, and finger flexion (Table 36.12).

Results

Our overall results in C5 nerve grafting, especially to the suprascapular nerve and posterior division of the upper trunk for shoulder, and C6 nerve grafting to the anterior division of the upper trunk for elbow function were consistently good (Fig. 36.20A–D): shoulder abduction averaged 132° (90–180°), shoulder external rotation averaged 67° (50–90°) and elbow flexion was mostly M3. More than half of the patients (71/118, 60%) had rupture injury associated with at least one nerve root avulsion. Seventy-five percent had at least two-root avulsion. Intraplexus nerve transfer from C5, or C6 to the C8 or to the median nerve resulted in improvement of hand function. Extraplexus nerve transfer by intercostal nerve transfer to the musculocutaneous nerve or median nerve, and spinal accessory nerve transfer to the suprascapular nerve have proved useful for restoring shoulder abduction, elbow and finger flexion (Fig. 36.21A–E).

The sequelae of obstetric brachial plexus palsy

Aberrant regeneration (due to misdirection of regenerated axons), muscular imbalance, and growth are the three main causes of shoulder and elbow deformity in I-OBPP with or without nerve surgery. Flaccid paralysis of the shoulder and

Table 36.12 Postoperative functional assessment of obstetric brachial plexus palsy

	Good	Fair	Poor
Shoulder			
Shoulder abduction	>120°	90–120°	<90°

Elbow extension	Easy (M=3)	Difficult (M=2)	Impossible (M<2)
Finger			
Finger flexion	Easy (M=3)	Difficult (M=2)	Impossible (M<2)

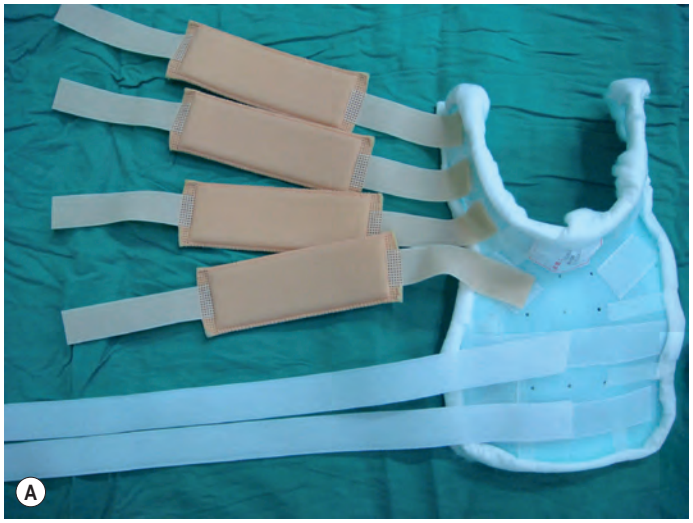

Fig. 36.19 (A,B) Postoperative neck splint.

elbow is rare, but flaccid paralysis is commonly seen in the hand due to root avulsion of C7–T1 without aberrant regeneration. Aberrant reinnervation more frequently occurs in the shoulder and elbow and less in the hand. Therefore contractures (or hypertrophy) of the teres major, pectoralis major, brachialis and biceps muscles are frequently seen and cause the deformity of the shoulder and elbow. In addition, growth is another factor in shoulder and elbow deformities, often found in the form of concomitant skeletal deformity.

There are four main types of co-contractions resulting from aberrant reinnervation causing different types of deformities of the shoulder and elbow:

1. Co-contraction can occur between shoulder abductors (supraspinatus, infraspinatus and deltoid) and adductors (mainly, teres major and pectoralis major). This will result in limitation of shoulder elevation. Shoulder adduction contracture (or internal rotation) will develop when growing.
2. Co-contraction between elbow flexors (biceps and brachialis) and elbow extensors (triceps) can also develop. In the mild type, patients are unable to perform elbow flexion normally, such as pulling up trousers, hand-to-flank or hand-to-spine movement. In the severe type, patients cannot even perform hand-to-mouth movement. Flexion contracture of the elbow eventually develops.
3. Co-contraction between elbow flexors (mainly brachialis) and shoulder abductors (mainly deltoid) is a third possible occurrence. When asked to perform hand-to-mouth movement, the shoulder will be involuntarily elevated, similar to blowing a trumpet (trumpet sign). With this deformity, if the arm-to-body angle is less than 40°, mild cross-innervation is present; if the angle is more than 80°, severe cross-innervation is predicted.
4. Co-contraction among shoulder abductors, elbow flexors, and forearm flexors is the last possibility. When asked to perform shoulder elevation, the elbow and fingers flex involuntarily.

A special chart for S-OBPP examination (Table 36.13) should be completed before planning the reconstructive strategy for the sequelae deformities of shoulder, elbow, and hand. For motor recovery with aberrant reinnervation, release of contractured muscles and augmentation of paretic muscles form the basis of surgical intervention.[46,47]

Shoulder deformity reconstruction

Before 1968, palliative reconstruction for S-OBPP with shoulder deformity was focused on the anatomical deformity (subluxation or posterior dislocation of the shoulder). Osteotomy of the humerus, or release of the contracted internal rotator muscles (concept of muscle fibrosis due to delivery trauma), such as the subscapularis, pectoralis major, or long head of biceps[64–66] was preferred, but the results were disappointing. These techniques improved only the patient's cosmetic appearance but not the function. Some authors performed local muscle transfer such as trapezius and levator scapulae muscle transfers to restore some shoulder abduction[56] using the concept of dynamic reconstruction for muscular imbalance. However, the concept of aberrant reinnervation has now been well accepted by the author as the main cause of shoulder deformity in S-OBPP.[47] All reconstructive methods should be aimed at minimizing the influence of aberrant reinnervation. If perioperative physical examination demonstrates the existence of muscle recovery by aberrant regeneration, the author's studies demonstrate the following procedures are good for shoulder abduction: (1) release of antagonistic muscles (pectoralis major and teres major muscles); (2) augmentation of paretic muscles (transferring teres major to the infraspinatus muscle, re-routing both ends of the clavicular part of the pectoralis major muscle laterally). In addition, latissimus dorsi transfer to the teres minor insertion (or lateral humerus) is good for shoulder external rotation. The ideal age for the reconstruction is between 4 and 10 years. The average shoulder abduction following the muscle transposition was 151° (i.e., average gain 77°), and that of external rotation was 72 °(average gain 48°). Comparing with the S-OBPP patients who had no surgery and with early

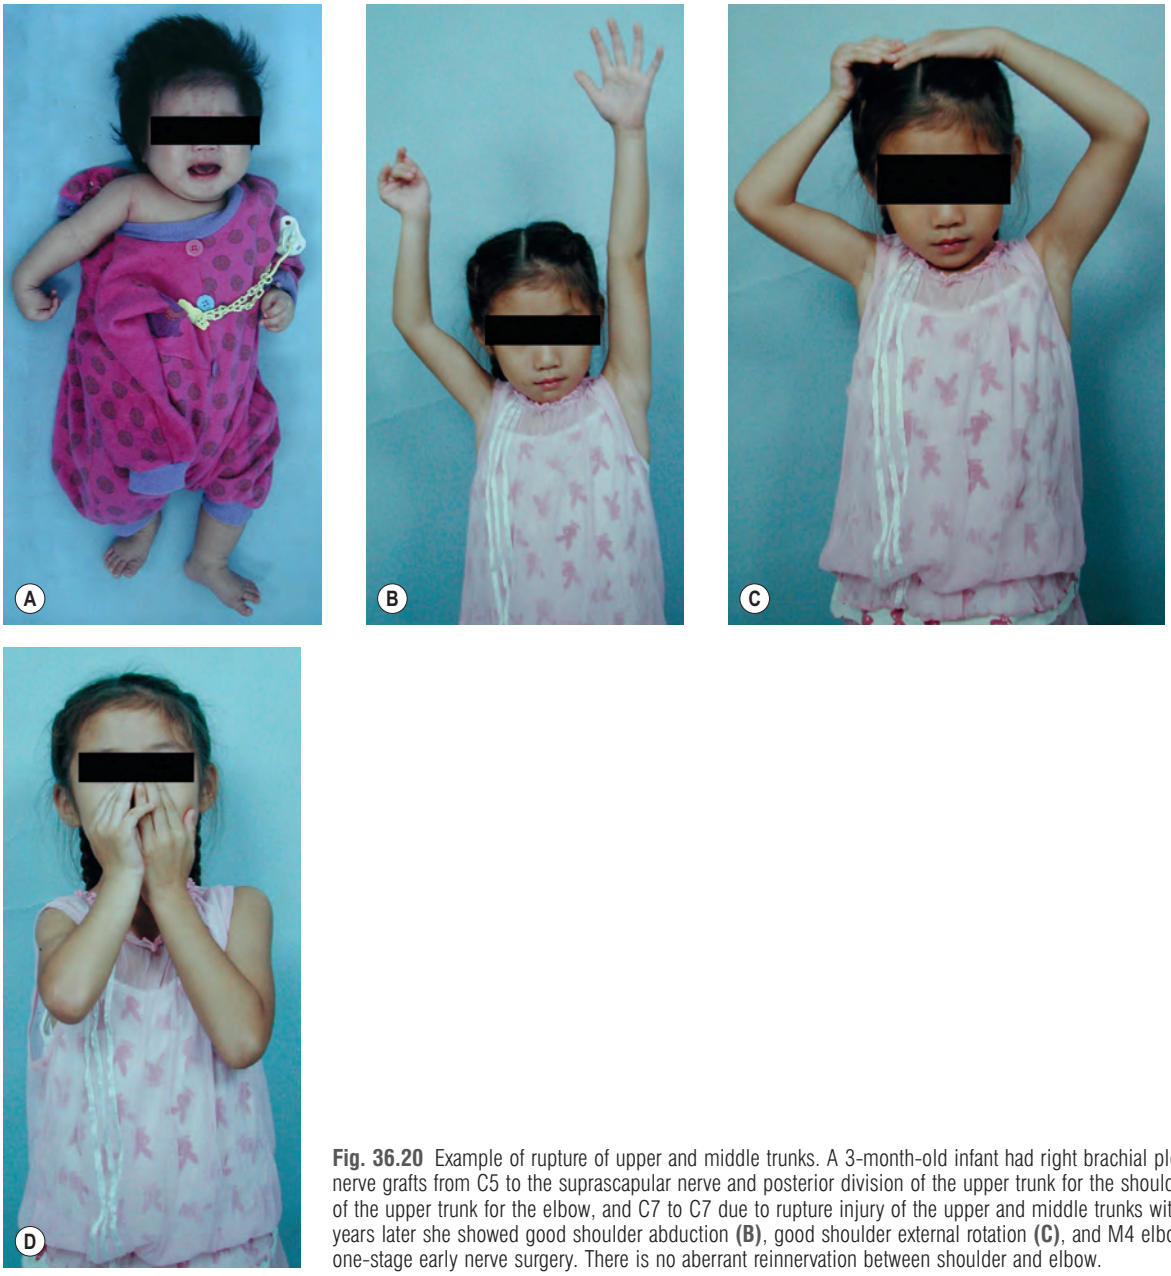

Fig. 36.20 Example of rupture of upper and middle trunks. A 3-month-old infant had right brachial plexus injury **(A)**, receiving nerve grafts from C5 to the suprascapular nerve and posterior division of the upper trunk for the shoulder, C6 to the anterior division of the upper trunk for the elbow, and C7 to C7 due to rupture injury of the upper and middle trunks without C8–T1 avulsion. Six years later she showed good shoulder abduction **(B)**, good shoulder external rotation **(C)**, and M4 elbow flexion **(D)** following one-stage early nerve surgery. There is no aberrant reinnervation between shoulder and elbow.

nerve surgery for the infant OBPP, the results of our reconstructive strategy for the shoulder appear to be significantly improved.[47]

Elbow deformity reconstruction

The common deformities of the elbow in S-OBPP include: (1) aberrant reinnervation between elbow flexors and extensors, which causes weak elbow extension and weak elbow flexion; (2) aberrant reinnervation between shoulder abductors and elbow flexors, resulting in a severe "trumpet sign" with angle greater than 80° between the medial arm and trunk on hand-to-mouth movement; and (3) no motor recovery with muscle paralysis or paresis of biceps and brachialis muscles.[48] Traditionally, elbow flexion has always been top priority and triceps-to-biceps transfer is a commonly used method for achieving elbow flexion. However, this results in loss of elbow extension, a significant functional problem for a growing child and one that is especially frustrating when shoulder elevation has been restored after shoulder correction. In addition, the loss of muscular imbalance at the elbow frequently leads to progressive flexion contracture (40°, range 30–70°) and/or dislocation at the elbow. Restoration of elbow extension following triceps-to-biceps transfer has been disappointing, whether performed by regional muscle transfer (such as latissimus dorsi transfer), or by free muscle transplantation. Because of these drawbacks, we have discontinued the use of the triceps-to-biceps transfer. For motor recovery with aberrant reinnervation between elbow flexors and extensors, reconstruction of elbow extension should precede that of elbow flexion. This is achieved either by biceps-to-triceps transfer with preservation of an intact brachialis muscle, or by

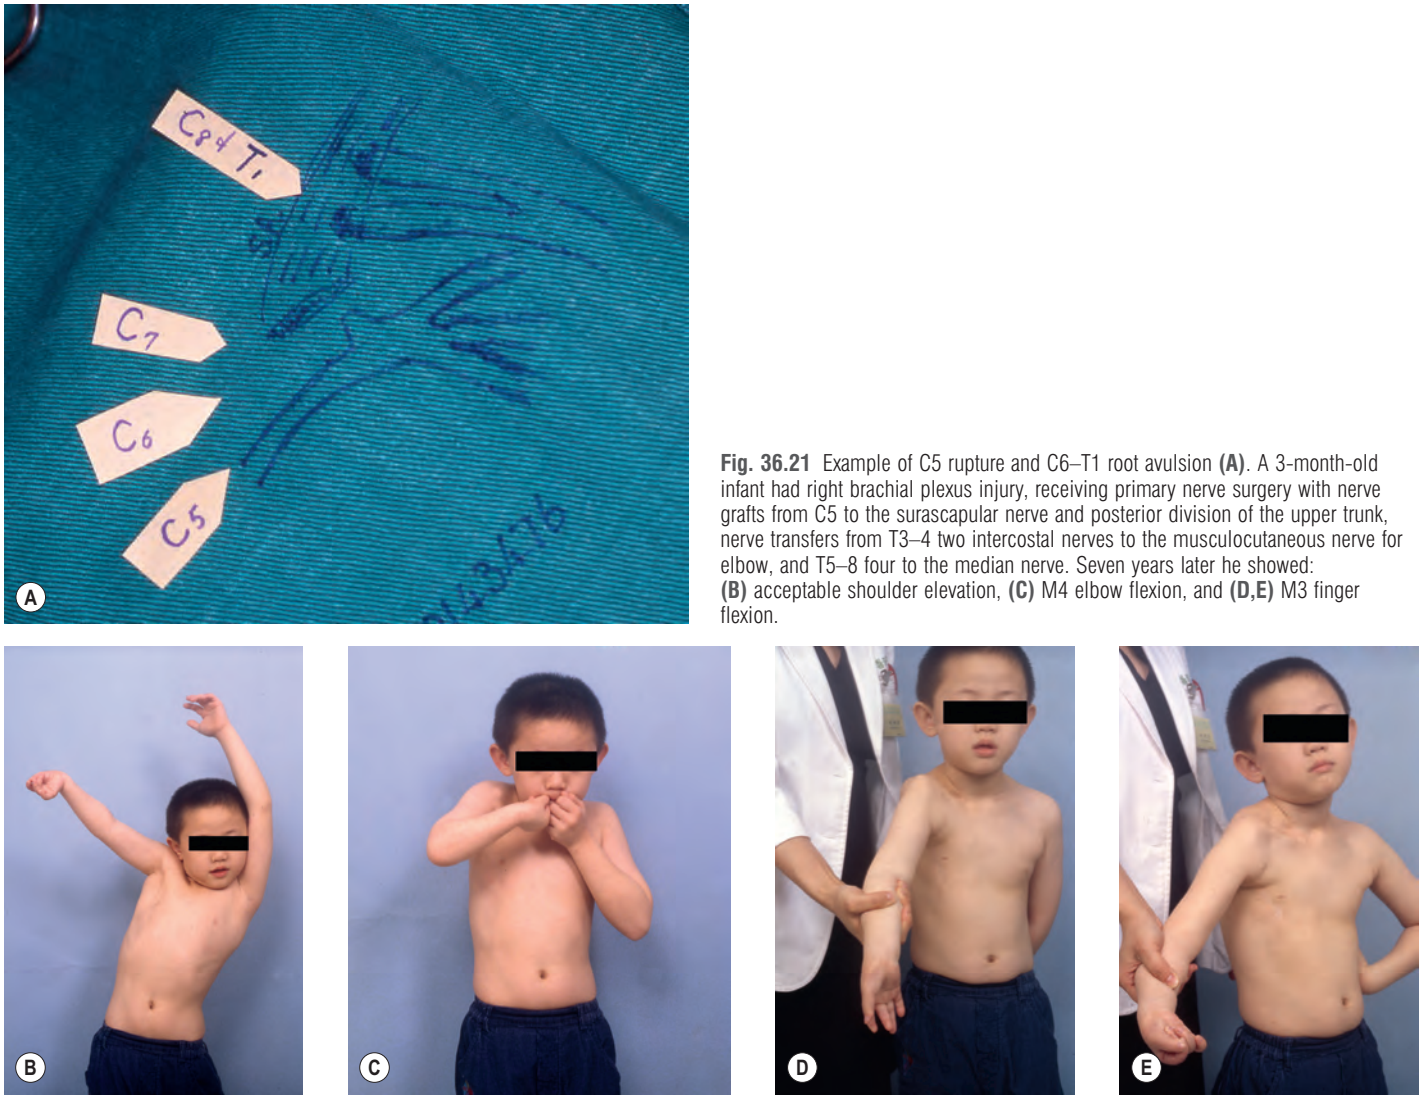

Fig. 36.21 Example of C5 rupture and C6–T1 root avulsion **(A)**. A 3-month-old infant had right brachial plexus injury, receiving primary nerve surgery with nerve grafts from C5 to the surascapular nerve and posterior division of the upper trunk, nerve transfers from T3–4 two intercostal nerves to the musculocutaneous nerve for elbow, and T5–8 four to the median nerve. Seven years later he showed: **(B)** acceptable shoulder elevation, **(C)** M4 elbow flexion, and **(D,E)** M3 finger flexion.

brachialis-to-triceps transfer with preservation of an intact biceps when elbow shows flexion contracture.[48] Half of our patients can achieve acceptable elbow flexion and extension in a single-stage procedure. The other half require a second stage procedure, either by FFMT or by Steindler flexorplasty. Existence of brachioradialis muscle power is a determining factor. A powerful brachioradialis can decrease the need for the second procedure.

In patients with a paralyzed biceps due to C5–7 root avulsion, Steindler flexorplasty or FFMT[67] is the option for restoration of elbow function. When shoulder–elbow co-contraction is a major issue, the anterior half of the deltoid is transferred to the distal biceps tendon with a fascial lata graft for biceps augmentation to decrease the "trumpet angle". However, patients with intrinsic deformities of the elbow joint (i.e., dislocation of the radial and/or ulnar head) are not good candidates for the above-mentioned regional elbow muscle transfer. Altered joint anatomy and abnormal joint biomechanics may create instability of the elbow joint, which contributes to untoward results in these patients. In patients with deformities of shoulder and elbow due to motor recovery by aberrant regeneration, simultaneous reconstruction of the shoulder and elbow can be safely performed.

Forearm and hand deformity reconstruction

S-OBPP in the forearm and hand includes weakness or absence of wrist or metacarpophalangeal or interphalangeal joint extension; weakness or absence of finger flexion; forearm supination or less commonly pronation contracture; ulnar deviation of the wrist; dislocation of the radius or ulna; thumb instability; or sensory disturbance of the hand.[49] Palliative reconstruction of these forearm and hand manifestations is more difficult than for the shoulder or elbow because of the lack of powerful regional muscles for transfer. The phenomenon of aberrant reinnervation is less significant. Continuous physical therapy with a rehabilitation program to optimize the residual muscle strength in the forearm and hand is vital for later management. Surgical treatment is highly individualized. The optimal age for forearm and hand reconstruction is therefore usually later (school age, 6–13 years old) than for shoulder and elbow reconstruction (preschool years, 4–6 years old).

Table 36.13 **Special chart for S-OBPP examination**

Name:	**Chart no:**	**Age:**
Address:		
Date of exam	History:	
Site of injury: R L		
Shoulder function		
Shoulder abduction (deltoid, SS): _____ degree; M _____ (muscle strength)		
Cross-innervation: PM, TM (+ LD); biceps, triceps; forearm (flexors, extensors)

	Midarm	_____	_____
	Upper forearm prominence	_____	_____
	Midpalm	_____	_____

Planning:

Multiple procedures for forearm and hand function are often performed. Sometimes they are done simultaneously with reconstructive procedures to improve shoulder and/or elbow function. Traditional tendon transfer techniques do not provide satisfactory reconstruction for these deformities. Many of the author's patients required more complex techniques such as FFMT[67,68] to augment traditional techniques of tendon and/or bone management.

For wrist and metacarpophalangeal extension, powerful wrist or finger flexors and/or pronator teres can be useful donor muscles for flexor-to-extensor transfers. Sometimes two wrist flexors, flexor carpi radialis and palmaris longus, are woven together, becoming a more powerful unit, and are transferred to the extensor digitorum communis to achieve both wrist and finger extension. For forearm supination contracture, re-routing the biceps muscle, as described by Zancolli,[69] is effective for mild cases. For weakness or absence of finger flexion, wrist extensors are usually too weak to be transferred. FFMT for flexor digitorum profundus replacement using intercostal nerves as the donor nerve is required. Sensory disturbance of the forearm and hand in late obstetric brachial plexus palsy seems a minor problem and further sensory reconstruction is unnecessary.

Conclusions

In I-OBPP, early primary nerve surgery provides therapeutic advantages. Surgery within 3 months is strongly indicated in patients with total palsy, but only relatively indicated for patients without elbow flexion but good hand function. Better results can be achieved when numerous short nerve grafts are used for rupture injuries. Cases associated with multiple root avulsions benefit from intraplexus nerve transfer for hand function and extraplexus nerve transfer for shoulder and/or elbow function. This approach affords patients a one-stage functional reconstruction of the upper limb. In S-OBPP, secondary reconstruction for shoulder and elbow deformities can achieve acceptable function. For forearm and hand, surgical treatment and result are highly individualized, and multiple procedures are often required.

Future directions

- A change in the reconstruction priority may become evident. Since the use of FFMT for biceps replacement is much easier and more effective than for triceps replacement[41,67] in the later reconstruction, the reconstruction priority for I-OBPP may be changed. Restoration of hand function should become the first priority, followed by shoulder function and then elbow flexion. This is different from adult BPI in which elbow flexion is always the first priority for restoration.
- The classification of I-OBPP will need consensus.
- Endoscopic or robot-assisted diagnosis of I-OBPP injury at very early stage may triage treatment.
- Early nerve surgery on more selective patients may be recommended.

Restoration of upper extremity function in tetraplegia

Carina Reinholdt and Catherine Curtin

Access video and video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Suffering a spinal cord injury causes a huge life transition, where simple everyday tasks become a challenge. When patients with tetraplegia were asked which function they would most like to regain, they ranked hand and arm control as the most important.[1] For people with tetraplegia, restoration of independence is the primary goal.
- There is no treatment to cure spinal cord injuries, but highly specialized care can rehabilitate and partially reconstruct some of the lost functions.
- Restoration of function requires a team approach combining physical and occupational therapy, assistive devices, and surgery including tendon transfer, nerve transfer, tenodesis, and arthrodesis.
- Patients with tetraplegia due to spinal cord injury often greatly benefit from grip and elbow extension reconstruction. These procedures have been shown to improve functional independence.[2,3]
- Early active mobilization improves outcomes after surgical reconstruction.
- A resolution was established in Philadelphia in 2007 (at the International Congress of Tetraplegia Hand Surgery and Rehabilitation) that patients who have sustained spinal cord injuries with tetraplegia should be examined, assessed, and informed about possible reconstruction of motor function in their upper extremities.[4]
- These reconstructive procedures are currently underutilized.[5]
- Strengthening connections between spinal cord injury specialists and upper limb surgeons represents an opportunity to improve access to this care.

Introduction

Surgery on the upper limb of people with tetraplegia requires special consideration because the hand represents a critical residual resource.[6] After cervical spinal cord injury, upper limbs take on new unique functions different from any other patient in that they must "walk on their hands". Given the importance of the upper limb, surgery requires a multidisciplinary team approach as part of a comprehensive rehabilitation plan. The patient must realistic expectations and understand that surgical intervention will not result in a "normal arm" but as Dr. Sterling Bunnell said, "for those who have nothing, a little is a lot".[7]

Basic science/disease process

Today, the most common mechanisms of cervical spine injury (SCI) are motor vehicle accidents, falls, especially in the elderly, and sports injuries. The most common level of injury C5/C6.[6] The anatomic level and completeness of injury determine the functional deficits. Modern acute care of these injuries allows most patients to survive their injury and thus face a lifetime in a greatly altered state of existence. Every patient with tetraplegia suffers some loss of upper limb function. Their upper limbs represent a critical residual functional asset.

Although upper limb surgeons often do not participate in the initial management of the SCI patient, the acute rehabilitation focuses on the upper limbs. Special care is taken to prevent contractures of fingers, wrist, or elbow. Even a relatively mild elbow contracture can inhibit independent transfers.[8] Fortunately, well-educated therapists are aware of the need for protective splinting right after injury. The shoulder must also be protected as the patient learns to adjust to their injury. Pulling patients, poor posture, or falls during rehabilitation can result in shoulder injuries that ultimately limit independence. Indeed the majority of people with tetraplegia have shoulder pain at the end of their acute rehabilitation.[9] Early attention to the upper limb provides the best long-term function.

Classification of the tetraplegic upper extremity

Cervical spinal cord injury has been classified in many ways, including by the skeletal level of injury or according to the most distal functioning cervical root. However, this

Table 37.1 International classification for surgery of the hand in tetraplegia

ICHST group	Motor characteristics	Description/ function
0	No muscles below elbow suitable for transfer	Flexion/supination of elbow
1	BR	
2	ECRL	Extension of wrist (weak or strong)
3	ECRB	Extension of wrist
4	PT	Extension and pronation of wrist
5	FCR	Flexion of wrist
6	Finger extensors	Extrinsic extension of fingers, partial or complete
7	Thumb extension	Extrinsic extension of the thumb
8	Partial digital flexors	Extrinsic flexion of the fingers, weak
9	Lacks only intrinsics	Extrinsic flexion of the fingers
X	Exceptions	

Caution: it is not possible to determine ECRB strength without surgical exposure.
Each patients is also checked for sensibility and placed in ocular or Cutaneous groups.
O, Ocular; Cu, cutaneous; BR, brachioradialis; ECRL, extensor carpi radialis longus; ECRB, extensor carpi radialis brevis; PT, pronator teres; FCR, flexor carpi radialis.

classification system is too general for hand surgeons because no two patients are exactly alike. Injury pattern can differ between those with the same skeletal level of injury and each patient often has different function between the right and left arm. In order to develop useful algorithms for treatment of the upper limb, it was necessary to develop a more precise classification method of these patients upper limb issues. From this need arose the International Classification (IC), which is based on the limb's remaining useful motor and sensory resources (Table 37.1). The motor function identifies the number of strong muscles under volitional control below the elbow. To be counted, the muscle must have grade 4 or 5 Medical Research Council (MRC) strength. The grade 4 level was chosen because a grade 4 muscle can be transferred with the expectation that it will be able to perform useful work. A grade 3 muscle loses so much of its power in transfer and is not reliable as a donor for transfer.

Moberg[10,11] encouraged also accounting for remaining sensory resources. If sufficient proprioception remains in any part of the hand (typically the thumb and index fingers), the patient can control his/her hand without having to keep it in view. If the hand lacks proprioception, the patient needs his/her eyes to direct the hand. Lack of proprioception limits the ability to perform bi-manual activities, but it is not a contraindication to reconstructive hand surgery. Patients benefit from grip reconstruction even though they lack sensation. A hand without a sensibility is more useful with a grip than without a grip.[12] Today, static two-point discrimination of less than 12–15 mm is acknowledged as indicating the presence of proprioception. The IC accounts for the presence or absence of proprioception by including codes to indicate whether afferent control resides in the hands, termed "cutaneous", or "Cu", or only in the eyes of the patient, termed "ocular", and abbreviated as "O".

Later, the IC scheme was extended to include a determination of the presence or absence of active elbow extension. The IC system is used by essentially all surgeons involved in the care of the upper extremities of these patients.

Patient presentation and patient selection

Forming a team

Moberg stressed the need to develop a "critical mass" of likeminded professionals into a team that should include physiatrists involved in the rehabilitation and long-term care of people with tetraplegia. Critical to the success of an upper limb team are well-trained therapists, either physical therapists or occupational therapists (preferably both). The hand and upper extremity surgeon provides the technical expertise. Others including social workers and psychologists may offer additional support to the team. The patient's support group including family or attendant is the key to success. The central member of the team is the patient.[14–16]

The roles of the professionals in this team are relatively clear. The physiatrists assist in determining the appropriateness of the patient for surgery as well as when to time surgery relative to overall rehabilitation goals and schedules. The therapist frequently serves as the patient's advocate. He or she knows the patient better than anyone else and, most importantly, the patient's expectations, voiced or not.

For the patient, upper extremity surgery can have a large emotional impact. Some patients are concerned about altering their anatomy because they are waiting for the cure for SCI. While the goal of surgical reconstruction for the upper extremity is greater function, the patient must be willing to lose temporarily some of their hard-won independence during the postoperative rehabilitation. For family and attendants, this greater period of dependence translates into more inconvenience and effort. All the team members must play a role in the decision-making process and must share in the frustrations as well as the rewards.

The hand and upper extremity team should become part of the routine evaluation of newly injured patients. The cervical cord injured patient arrives at a rehabilitation facility or spinal cord injury unit usually with fairly supple upper limbs, although with no or only minimal volitional movement. The upper limb assessment becomes clearer. Once the patient's vertebral injury is stabilized and the patient can sit in a wheelchair, an assessment by the upper extremity team takes on new meaning, and the rehabilitation of the hands starts. By the fourth month following injury, the eventual functional level is usually clearly established for the majority of patients.[17] At this time, the training of the patient's upper limb function has mainly proceeded into training of managing daily life, by

Fig. 37.1 A patient pushing her wheelchair after grip reconstruction.

coordination training of perceived functions, adaptive grasping patterns, technical aids, and assistive devices.[18–20] The aim is optimal use of the hands to maximize independence, despite lack of active grasp function.

Timing

Hand or upper extremity surgery is rarely indicated during the initial months of rehabilitation following injury. The patient needs time to experience neurologic, psychologic, and social stability. From a practical standpoint, there are simply too many more important rehabilitation activities going on. On the other hand, a dogmatic philosophy such as "never operate on a patient before 12 months" has no basis in science. Some patients are clearly candidates for surgery prior to this calendar date. For example, early surgical intervention to relieve the pathologic effects of a fixed elbow flexion contracture may allow a patient to participate more vigorously in necessary rehabilitation activities.[8] Early release of a fixed elbow flexion contracture can be done with a simultaneous transfer of the contracted biceps muscle to the triceps. This removes a pathologic or deforming force and reinforces or restores some power to the antagonist. Botox is another important tool in the early rehabilitation armamentarium. It is especially helpful for patients with concomitant brain injury who may not comply with splinting or therapy and have increased tone.

Once the patient has achieved neurological and psychological stability, a formal evaluation to establish the appropriateness of upper extremity surgery can be accomplished by the team. The evaluation should focus on both tangible evidence of recovery by assessing remaining motor and sensory resources and the important intangibles such as motivation and intelligence. There is increasing recognition of the co-occurrence of traumatic brain injury with spinal cord injury and the impact of brain injury on rehabilitation.[21] Cognitive deficits need to be understood before embarking on upper extremity reconstruction given the intensive post-surgical therapy. The initial patient assessment should include an evaluation on how the patient uses the hand to accomplish tasks of daily living (Figs. 37.1 & 37.2A,B). Tendon transfers

Fig. 37.2 Postoperative results after single-stage grip release reconstruction. **(A)** Writing before reconstruction; **(B)** writing after reconstruction.

may alter the position of the hand and fingers. After reconstruction, the hand or arm must be protected in a splint. This protection entails difficulties to perform critical daily activities such as wheelchair propulsion and bed transfers (Fig. 37.3). It is best for patients to plan for temporary greater dependence and learn safe transfer techniques before surgery.

Fig. 37.3 Splint to allow for as active rehabilitation as possible, e.g., propulsion of wheelchair, use of computer or cell phone (with the little peg).

The timing of surgery is important and it is critical that the patient has the right expectations and is motivated for not only the surgery but also the rehabilitation. Some patients, especially women, seem to wait longer before making a decision for surgery, probably due to family matters.[22] Tendon transfers can be performed a long time after the injury; our record is 38 years post-injury with good outcomes. One caveat to this is the emerging use of nerve transfers, which may have a tighter time window than tendon transfers. Though the best timing of nerve transfers for these patients remains unknown, we believe it is somewhere around 18 months.

Patient evaluation/selection

The upper limb examination includes assessment of motor strength and a sensory evaluation. The exam also identifies pathologic conditions such as contracted, painful, or unstable joints that may impact surgical results. There is also a sensory evaluation, which includes measuring two-point discrimination in the digits to assess proprioception. The currently used grip patterns are assessed. Occasionally, spinal cord injured patients will have focal areas of severe neuropathic pain that will make the exam painful and potentially limit surgical results.

The patient's global functional status in daily living is assessed, including mobility, personal care, domestic life, type of wheelchair, and other adaptive devices. Is s/he dependent or independent in bed mobility? How are transfers performed? Does s/he use a manual or electric wheelchair? What adaptive devices are used for dressing, grooming, feeding? If surgery is to be performed, is there sufficient support to get the patient through a period of greater functional dependence or will the extra burden of care result in the patient's attendant quitting? For some patients, upper extremity surgery means restriction to an electric-driven chair. Can this be made available? Does the home situation permit the use of an electric wheelchair? Are the controls of the chair mounted on the non-operated side? The patient's primary caregiver can help answer these questions. Most patients can use their manual wheelchair provided that they use protective orthoses during the postoperative rehabilitation time. Preparation before surgery will prevent complications such as pressure sores and social consequences such as divorce and make the patient able to focus on the important postoperative rehabilitation.

Finally, the patient's goals for surgery are reviewed. We prefer using the Canadian Occupational Performance Measure (COPM).[23] It enables specific tasks to be identified, e.g., "I want to eat the triple decker sandwich at Joe's by myself." This instrument helps the surgeon and therapist understand if the patient has reasonable expectations and can help tailor the procedures. It also serves as an important evaluation tool.

Treatment/surgical technique

General guidelines for reconstruction

Five surgical procedures are applicable for improving upper limb function in tetraplegia:

1. Arthrodesis: permits stabilization of joints lacking muscle stabilization.
2. Tenodesis: performed to stabilize a joint or so that a proximal movement, e.g., wrist extension, will result in the tightening of the tenodesis and movement of a more distally located joint, e.g., thumb flexion.
3. Tendon transfer: the transfer of the power of an expendable muscle–tendon unit under good volitional control to compensate for the absence or ineffectiveness of function of another muscle–tendon unit.
4. Nerve transfers: the transfer of functional nerve branches from active muscles to paralyzed muscles to provide muscle function.
5. Spasticity-reducing surgery: tendon lengthening or muscle releases to reduce spasticity by making the tendon–muscle unit longer. This allows for better volitional control.

Tendon transfers are the workhorse procedures for reconstruction of the upper extremity in tetraplegia. These techniques have been refined over the last 80 years and several basic principles have evolved: (1) First is *correction of any joint contracture*. Tendon transfers are often biomechanically disadvantaged and will not be able to overcome a contracted joint. (2) The *donor muscle must have adequate strength*. Transferred muscles will generally lose a grade of strength after transfer. Therefore it must be strong preoperatively to be able to perform functional tasks postoperatively and should have a MRC>4. (3) The *donor muscle must be expendable*. (4) For the best biomechanical advantage, the most *effective routing of muscle insertion is a straight line*. (5) The *soft tissue bed must be stable*. These surgeries must be performed in a supple bed with adequate skin coverage. Scarred beds will prevent tendon gliding and will impair the result. (6) The *donor muscle should have adequate excursion* to perform the desired function.

For patients with tetraplegia, spasticity must also be considered. The donor muscle must have volitional control and not have too much tone. Overall level of spasticity can be improved with physical therapy and medications. A small amount of spasticity and tone is acceptable and sometimes beneficial to reconstructive procedures. The surgeon should assess the level of spasticity and make sure it is optimized before intervention. Spasticity should always be treated before tendon transfers are considered. Most patients with incomplete tetraplegia have spasticity and can be treated with tendon lengthening and muscle releases when conservative treatment is not sufficient.[4]

The surgical procedures can be grouped using the IC system (Table 37.2). For these procedures, it is critical that each patient, and indeed each upper extremity, be evaluated and then each treatment plan individualized.[24]

For high cervical spinal cord injuries, there are no expendable muscles available for transfer in the arm. For patients with lower injuries, such as a C7 injury, many potentially expendable, and thus transferable, muscles of grade 4 or 5 power exist. The choice of procedure depends primarily on the residual resources and, secondly, on the many intangibles such as patient desires, motivation, and support. The surgical techniques used in tetraplegia are the same procedures as reconstructions after peripheral nerve injuries, but the difference between these procedures is the preoperative preparation and matching the patient to the correct procedure. A cautious approach while one gains experience pays great dividends in terms of obtaining the acceptance of team members and patients that surgery can promote greater independence. A

Table 37.2 Algorithm for surgical treatment in tetraplegia

ICSHT group O/Cu	Available muscles below elbow	Suggested or possible procedure
0	No muscles	Nerve transfer, triceps reconstruction
1	BR	BR–ECRB, passive key pinch, triceps reconstruction, nerve transfer
2-3	ECRL, ECRB	BR–FPL or FDP and passive key pinch, triceps reconstruction, House procedure, nerve transfers
4-5	PT, FCR	Single-stage grip release procedure, triceps reconstruction, nerve transfer
6-8	EDC, thumb extension, partial finger flexors	Single-stage grip release procedure with options: EDM–APB, active IO
9	Lack only intrinsics	Active interossei – FDS IV to IO
x	Mixed pattern	Combinations
Spasticity	Mixed pattern	Tendon lengthening, muscle release, ECU-tenodesis, distal ulna intrinsic release

poor outcome early in the team's experience creates a tremendous hurdle.

Surgical reconstruction

Elbow extension

Erik Moberg highlighted the importance of active elbow extension for the spinal cord injured patient. A wheelchair user depends upon good shoulder and elbow power to push a manual wheelchair, transfer from bed to chair, and to perform pressure releases to prevent pressure sores. Without active elbow extension, a patient cannot stabilize the arm in space such that the hands fall into his face when lying supine, which makes eating and daily hygiene challenging (Fig. 37.4). Restoring elbow extension can increase the reachable space by an additional 12 inches resulting in 800% more functional space and can assist with simple tasks such as turning on a light switch. There are two surgical procedures advocated for restoring active elbow extension – biceps-to-triceps and deltoid-to-triceps transfer.

Biceps-to-triceps transfer

This procedure is a common and straightforward technique.[25–28] It is the procedure of choice when there is a pre-existing flexion contracture of the elbow greater than 45° because transferring the biceps also addresses the deforming flexion force. The advantages of biceps-to-triceps transfer include no need for an interposition graft and one tendon repair site. Disadvantages include a more challenging rehabilitation program and the potential for loss of elbow flexion strength.

Surgical technique

The biceps tendon is detached from its insertion on the greater tuberosity of the radius, the muscle–tendon unit routed either medially[29] or laterally,[30,31] and the tendon attached to the triceps aponeurosis or directly into the olecranon.

The incisions that are employed depend in large measure on whether a wide exposure to the anterior aspect of the elbow joint is needed to allow adequate release of contracture. The distal extent of the incision should allow complete dissection of the tendon of the biceps allowing detachment at the level of insertion on the bicipital tuberosity of the radius (Fig. 37.5A).

The incision is carried through the subcutaneous tissue, protecting the large tributaries of the basilic and cephalic veins. The soft tissues overlying the lacertus fibrosis are elevated and the lacertus is either divided off the primary tendon or dissected distally as far as possible to provide another point of fixation to the triceps (see Fig. 37.5B).

The primary tendon of the biceps is dissected to its point of insertion on the radius. Flexing the elbow and supinating the forearm assists in this exposure. The tendon is sectioned as far distally as possible. The biceps muscle is dissected proximally from within its dense investing fascia, the dissection proceeding proximally until the cutaneous portion of the musculocutaneous nerve is identified as it courses between the overlying biceps and the deeper brachialis muscle. This

Fig. 37.4 Postoperative elbow extension allowing for stabilization of the arm to assist with combing the hair.

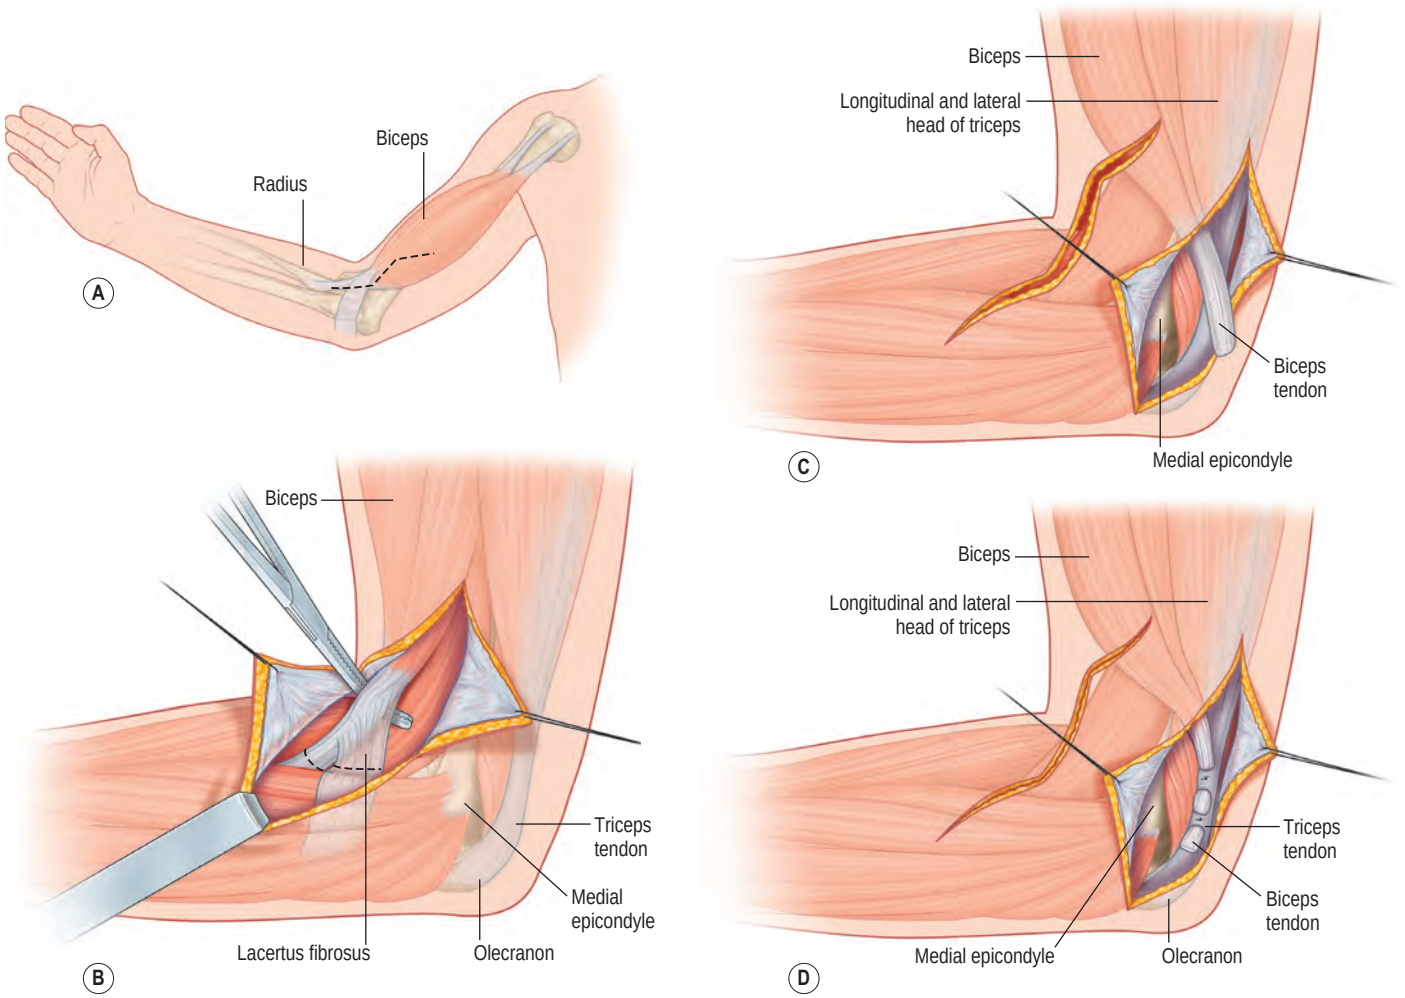

Fig. 37.5 Biceps-to-triceps transfer by the medial route **(A–D)**. *(Redrawn from Hentz V, Leclercq C.* Surgical Rehabilitation of the Upper Limb in Tetraplegia*. London: Harcourt Health Sciences; 2002, with permission.)*

nerve is protected while dissection of the biceps proceeds proximally until the most distal motor branches coming from the musculocutaneous nerve are visualized.

Both medial and lateral routing of the transfer have been described. Since the ulnar nerve is typically non-functional in this population, we have preferred to route the biceps medially. It is necessary to dissect widely the arcade of Struthers and all other fascial communications about the medial intermuscular septum. One must be concerned about compression of the radial nerve when the lateral route is chosen.

A second incision located posteromedially is made in order to expose the medial aspect of the triceps insertion. Through this incision, the medial border of the triceps is elevated and dissected to its insertion on the olecranon. The biceps muscle and tendon are then passed from the anterior to the posterior incision through the widely dissected subcutaneous tunnel (see Fig. 37.5C). The anterior incision may be closed at this point.

The biceps tendon typically just reaches the tip of the olecranon but there is often not enough tendon length to permit a strong attachment into the olecranon. Instead, the tendon of the biceps is woven into the medial border of the triceps tendon and anchored in multiple locations with stout sutures (see Fig. 37.5D). We have judged that the proper tension is achieved when the biceps is pulled distally enough to permit the end of the tendon to touch the olecranon with the elbow in about 20° of flexion. Once the tendon-to-tendon junctures are made, the elbow is fully extended to relax the site of approximation.

Postoperative rehabilitation

Regardless of what elbow extension reconstruction technique chosen, the elbow is immobilized in full extension using a light plaster or fiberglass cylinder cast for 3½ weeks. An overhead, chair-mounted sling is fitted to the patient's wheelchair and is used whenever the patient is in the wheelchair and until the cast is removed.

The initial cast is left undisturbed for 3½ weeks if preoperatively the elbow had normal passive extension. If the elbow had a preoperative flexion contracture between 15° and 30°, the elbow is extended as much as possible at the time of surgery and casted in that position. This cast is then removed between 10 and 14 days postoperatively. Great care must be taken to keep the elbow extended during this maneuver. Typically, the elbow can then be further extended at this time by

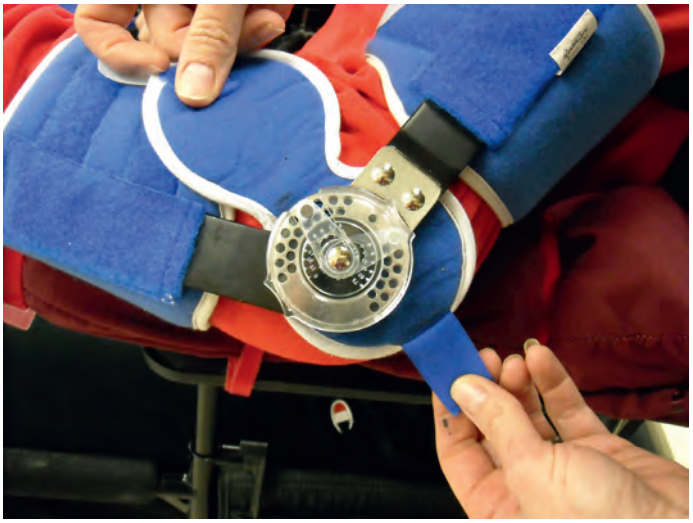

Fig. 37.6 Hinged orthosis to protect the repair across the elbow. The degree of flexion is gradually flexed over time.

slow stretch and the arm is recasted, now typically in near full extension. After removal of the cast, the elbow is slowly allowed progressive elbow flexion in a specially designed flexion-stop brace (Fig. 37.6). Although the biceps seems to be an antagonist to elbow extension, by teaching the patient to conjointly supinate the forearm and extend the elbow, the patient can be re-educated to use the supinator function of the biceps to extend the elbow. Electrical stimulation and biofeedback therapy has been used on occasion with improved results. Six months of cautious use are necessary to prevent overstretching of the transfer and maximal strength is obtained after many months.

Deltoid-to-triceps transfer[32]

Surgical technique (Fig. 37.7)

Hints and tips

1. Detach the deltoid from the humerus with as much fascia and fibrous insertion as possible, including some of the fascial origin of the brachialis muscle.
2. Ensure the triceps fascia is intact to protect the radial nerve.
3. Attach the deltoid to the triceps at maximum tension with the shoulder abducted 90° and the elbow as straight as possible and the forearm pronated. When the elbow is flexed 10–15°, the tendon transfer should be maximally tight. Make sure the elbow is not flexed more during the procedure. Let the assistant keep the elbow extended.
4. Cast elbow in full extension and keep the arm abducted at the shoulder during healing.

The surgical landmarks at the shoulder include the tip of the acromion superiorly, the interval between the posterior margin of the deltoid and the triceps muscle posteriorly, and the estimated point of insertion of the deltoid on the humerus. The landmark at the elbow is the tip of the olecranon. The surgeon should keep in mind the neurovascular anatomy of the region including the course of the axillary nerve and the circumflex humeral artery and the radial nerve and its relationship to the insertion of the deltoid.

The upper incision is centered half way between the midaxial line of the humerus and the posterior margin of the deltoid. The skin incision is carried to the level of the muscle fascia and the skin and subcutaneous tissues are elevated anteriorly to just past the midaxial line of the humerus. Posteriorly, the skin flap is elevated to the confluence of deltoid and the long head of the triceps. The plane between these two muscles is developed by sharp or finger dissection. As the finger strikes the humerus, the fingertip tip can be insinuated upward through the fibers of the deltoid, separating the muscle into relatively equal anterior and posterior halves. At least a third of the posterior deltoid is needed for the transfer.

Detaching the insertion of the posterior half of the muscle from its point of insertion onto the humerus is done by sharply incising a rectangle of periosteum at the point of attachment and elevating the periosteum and the fibers of attachment off the humerus. We include as much fascia and fibrous insertion as possible, including some of the fascial origin of the brachialis muscle. The radial nerve will be emerging from behind the humerus several centimeters distal to this point. Injury to this nerve has been reported as a rare but devastating complication of this procedure.

A suture is placed in the fibrous origin of the posterior half of the deltoid muscle and the dissection is carried superiorly until the branches of the axillary nerve are visualized. The superior dissection should stop at this point.

Several methods have been proposed to attach the posterior deltoid to the triceps or olecranon including:

- Autogenous tissue such as fascia lata, toe extensors,[33] tibialis anterior tendon,[11] or extensor carpi ulnaris (ECU)[34]
- A turned up strip of the central part of the triceps tendon with synthetic reinforcement[35]
- Bone to bone attachments[36]
- Various synthetic materials.[37]

We prefer autologous tibialis anterior tendon because its thickness and proximal fan shape, which matches the deltoid aponeurosis well.

The tibialis anterior tendon is harvested through two incisions, at the insertion site and a longitudinal incision lateral to the tibia. The tendon is detached from the muscle, and sutured with side-to-side sutures to the deltoid aponeurosis and to the triceps tendon. The tibialis tendon graft does not need to be tunneled through olecranon.

In walking patients with incomplete tetraplegia, the fascia lata is preferable. The fascia is harvested through several transverse incisions placed over the iliotibial band. The ideal width is about 2.5 cm. The fascia lata is encircled about the fibrous insertion of the deltoid using mattress sutures of nonabsorbable braided suture, tubed over its remaining length and tunneled subcutaneously to the olecranon.

The olecranon is exposed just distal to the triceps insertion. The triceps tendon is split longitudinally to further expose the tip of the olecranon and a 5-mm drill bit is used to create an oblique tunnel through the olecranon. A Bunnell tendon stripper is a useful instrument to "polish" this channel so that the tubed fascia lata can be passed smoothly in a proximal to distal direction.[38] The fascia lata is passed into the distal

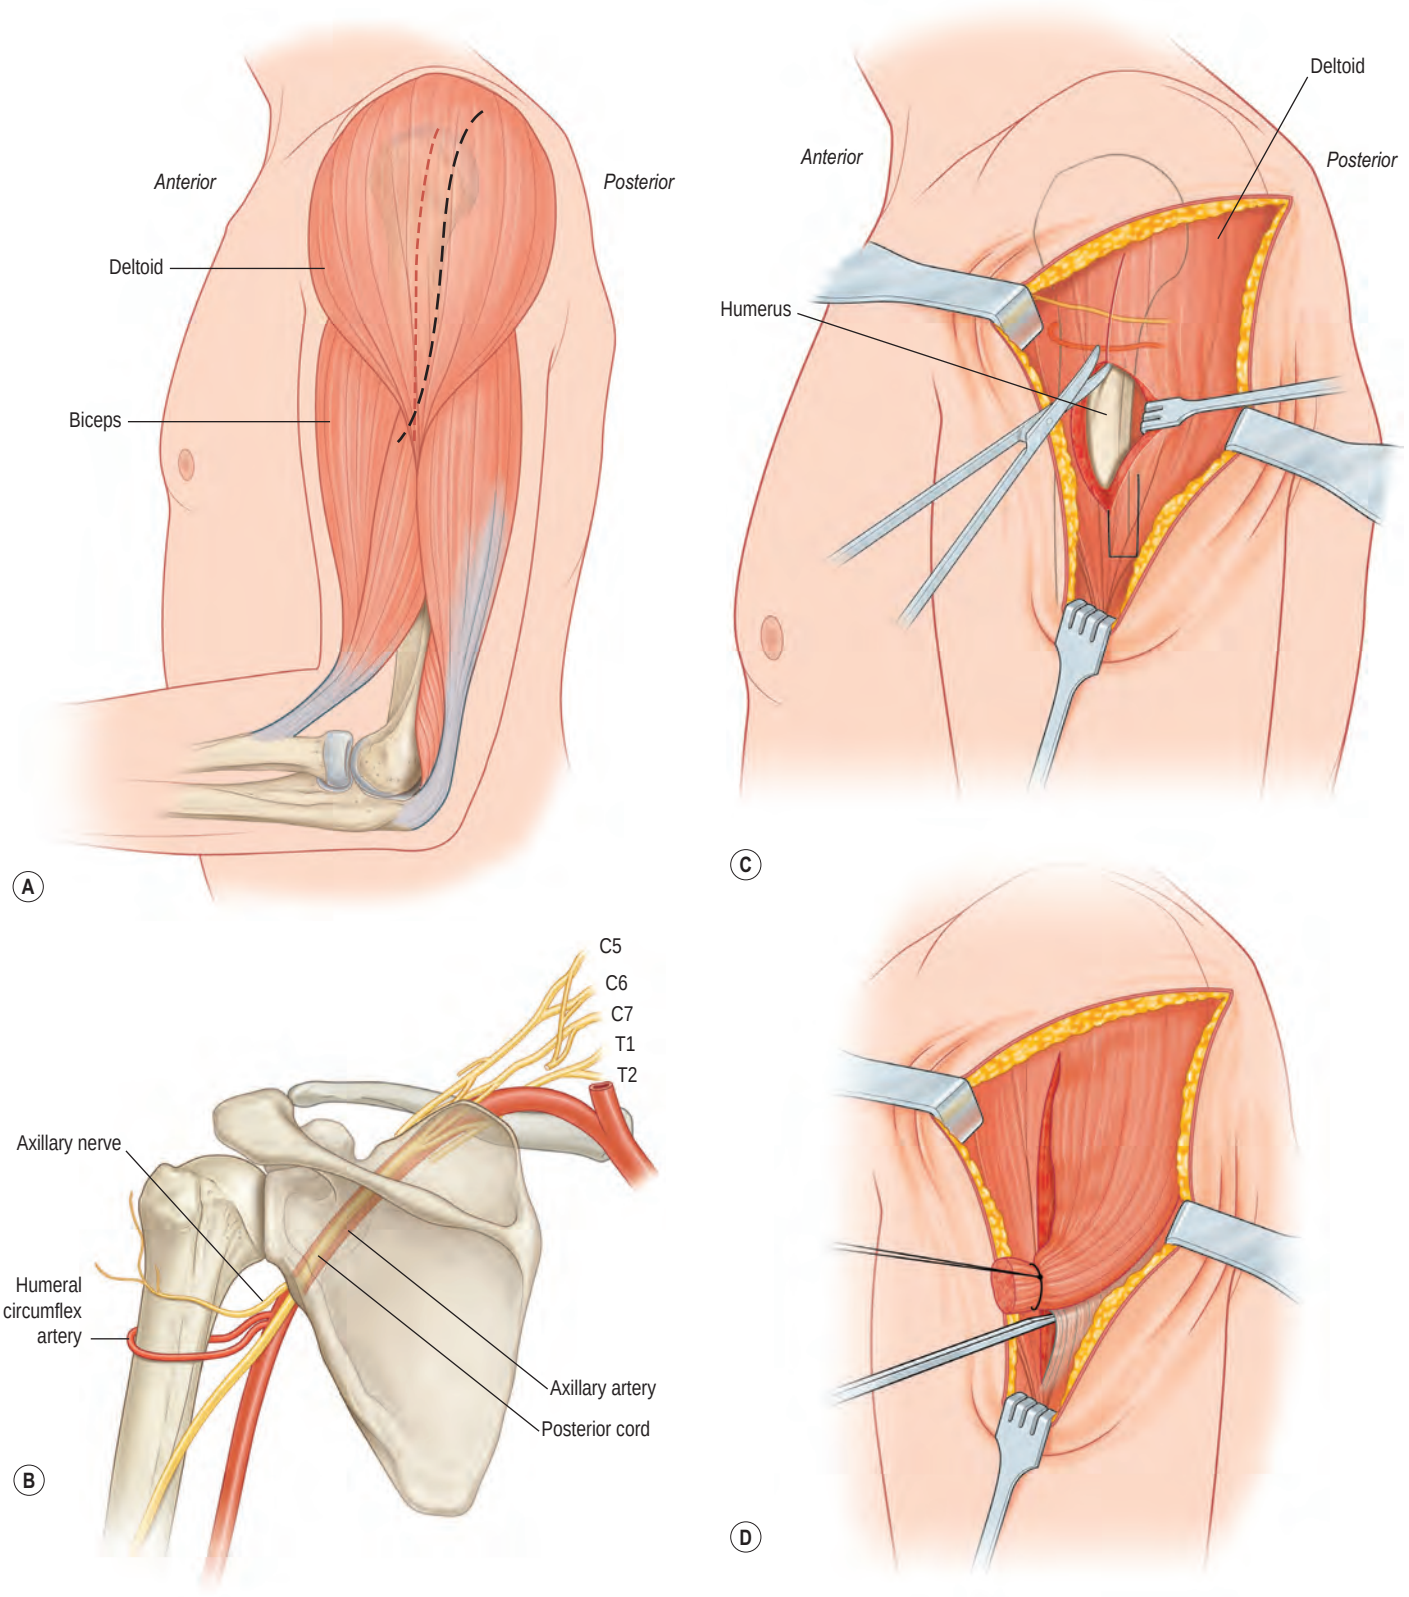

Fig. 37.7 (A–H) Deltoid-to-triceps transfer with fascia lata. *(Redrawn from Hentz V, Leclercq C.* Surgical Rehabilitation of the Upper Limb in Tetraplegia*. London: Harcourt Health Sciences; 2002, with permission.)*

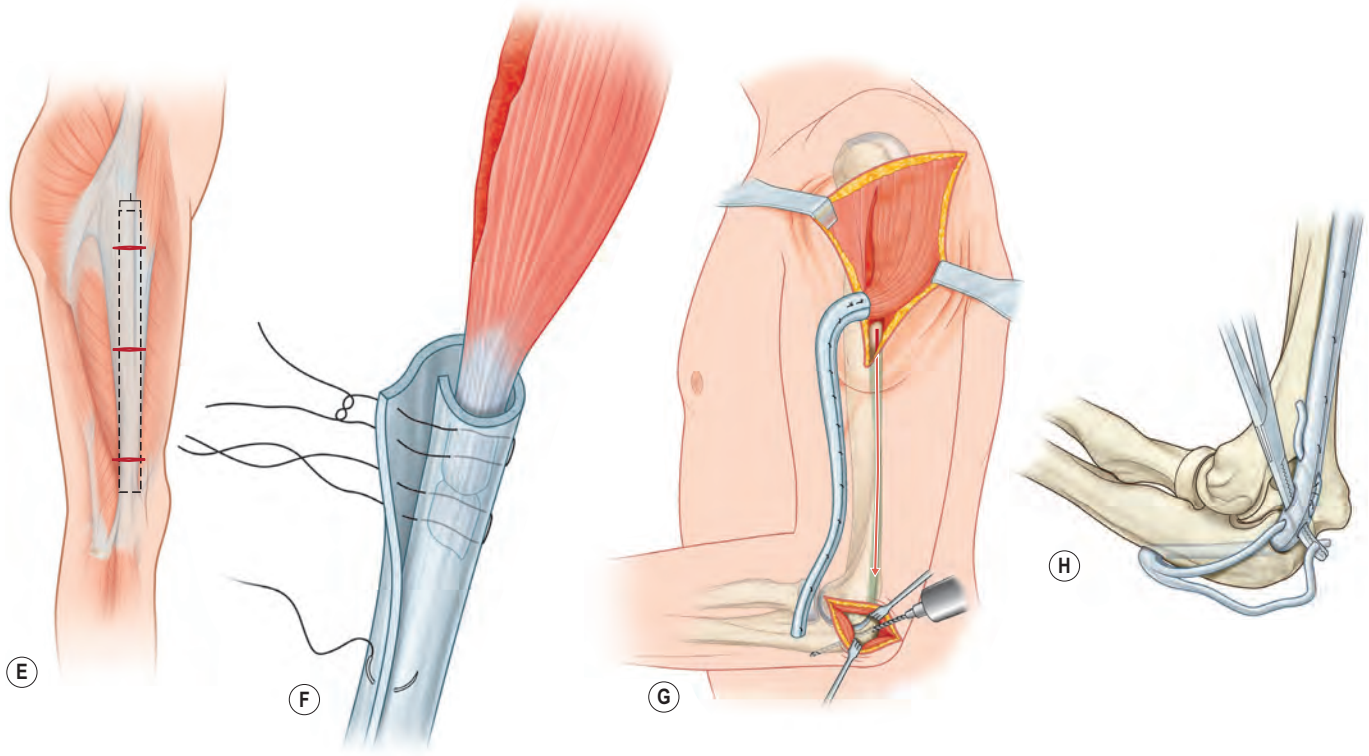

Fig. 37.7, cont'd

exposure, separated into two tails and the tails are passed through the bone channel.

The shoulder is abducted about 90° and the elbow is extended as much as possible. The two fascia lata tails are then pulled to *maximally* tense the transfer and these tails are turned proximally and woven into the fascia lata tube and anchored with non-absorbable sutures. Once suturing is complete, the fascial tube should be under moderate but definite tension. The wounds are closed and a cylinder cast is placed as is described in the biceps-to-triceps transfer with the elbow fully extended.

Postoperative rehabilitation

Postoperative care is quite similar to the biceps-to-triceps transfer. However, for deltoid to triceps transfer, shoulder position is more of a concern. The shoulder is kept somewhat abducted and the patient and other caregivers are cautioned to not allow the shoulder to accidentally flop across the chest. The wheelchair frame is critical because it holds the arm approximately 30° elevated and helps to keep the arm approximately 30° abducted from the body. This position relaxes the deltoid, prevents distal edema, and maintains seating stability.

After 3 weeks, the patient gets a dynamic elbow orthosis and start flexing the elbow 15° per week, starting at 30–45° of flexion depending on where the first resistance appears. Full load is allowed 8–10 weeks postoperatively. Complications are rare provided the patient follows the exercise protocol and does not overstretch the transfer by too rapidly regaining full elbow flexion. Even though the rehabilitation can be relatively lengthy, the functional gain is substantial, predictable, and easily appreciated by the patient.[39]

IC groups 0, 1, and 2

For the IC group 0 patient with no muscles functioning at the grade 4 or greater level distal to the elbow, few reconstructive possibilities exist. These patients benefit from a triceps reconstruction. A new procedure using nerve transfers to reconstruct wrist extension has been introduced.[40] When active wrist extension is regained, a passive key grip can be added.

Improving wrist extension: the IC group 1 and 2 patient

In the IC group 1 patient, the brachioradialis (BR) is typically the only muscle with grade 4 strength distal to the elbow. However, grade 2+ to grade 3+ radial wrist extensor function is typically present as well. The patient may be able to extend the wrist against gravity but cannot generate useful force between digits and thumb through any existing natural tenodesis effect or cannot utilize a wrist-driven flexor hand splint unless it is equipped with a ratchet mechanism. For this patient, wrist extensor strength can be augmented by transferring the power of the BR into the more central of the radial wrist extensors, the extensor carpi radialis brevis (ECRB) tendon.[41–43] From several biomechanical studies[44,45] it has been determined that the BR becomes a more effective wrist extensor following transfer if the patient can stabilize the elbow in space. If no active elbow extension is present, the BR may waste some of its excursion and power by flexing the elbow

rather than in extending the wrist. For this reason, we prefer first to reconstruct active elbow extension and after that transfer the BR to the ECRB for wrist extension, which will work as a motor for a passive key grip. Further balancing of the thumb can often be useful and additional procedures such as arthrodesis of the first carpometacarpal (CMC) joint and a split tenodesis of the flexor pollicis longus (FPL) to extensor pollicis longus (EPL) can be considered. We will describe these techniques later.

A wide dissection of the distal BR muscle and tendon from its insertion at the radial styloid up to the very proximal forearm level is necessary to obtain the most effective excursion of the muscle. Fridén has shown that the BR tendon needs to be released 12–15 cm to get an excursion of 4 cm of the BR tendon.[46] The tension on the BR should be adjusted to re-establish the normal resting length of the muscle with care taken not to overstretch this muscle. In adjusting the tension, it is important to place the elbow in some flexion. Moberg[11] recommended that the elbow be set at about 40° of flexion and we have followed this guideline.

Postoperative rehabilitation

All patients start early active mobilization the first postoperative day. (A prerequisite for early active training is side-to-side suture technique: see next paragraph.) During the first 3–4 weeks, patients perform unloaded functional training to allow for movement of the tendon transfers, tenodeses, or tendon lengthening. This is important to avoid swelling, edema, and adhesions. A resting splint protects the hand between training sessions. The patients perform a self-directed training protocol at home. After 3–4 weeks the patients return for task-oriented training under supervision of a trained therapist. Night splints and weight-bearing restrictions are kept until 10 weeks postoperatively. The elbow is not splinted since data has shown secure safety margins for tension of the BR.[47]

Side-to-side sutures

Side to side sutures are used in tendon transfers and in tendon lengthening. The tendons are sutured side-to-side with cross-stitches running along both sides overlapping 5 cm of donor and recipient tendons (Fig. 37.8). *In vitro* studies have shown that failure to load is more than 20 kg on this attachment,[48] which is twice as strong as the Pulvertaft weave.[49] In our unit we have used side-to-side sutures for several years now for all tendon transfers without any ruptures.

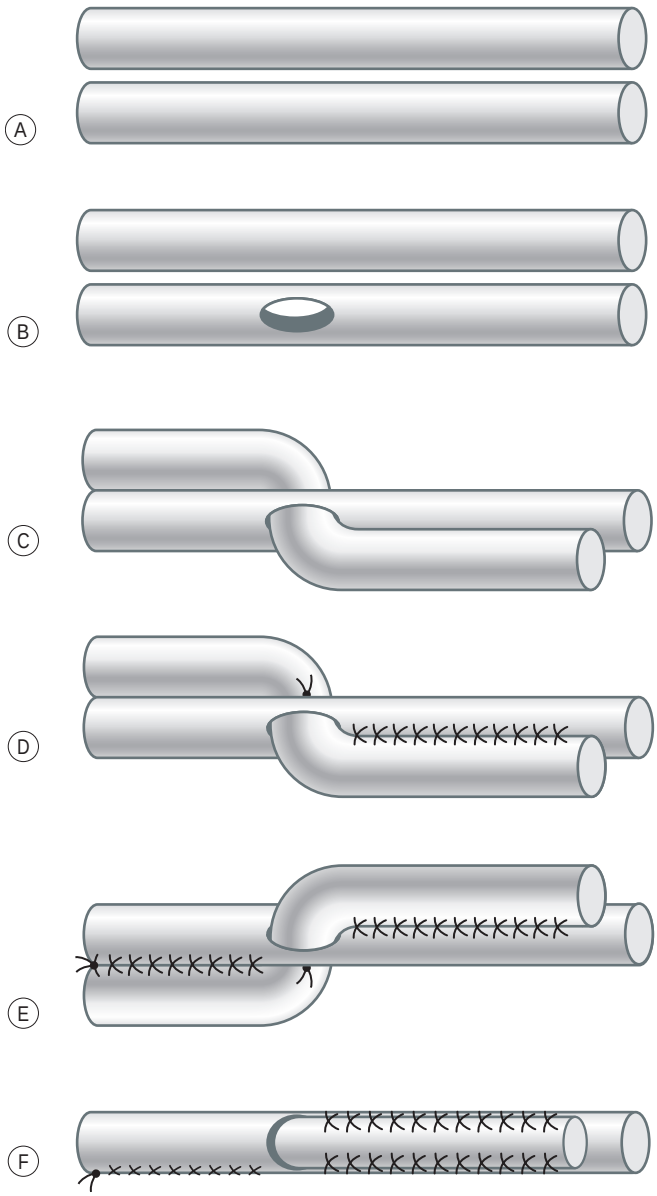

Fig. 37.8 Side-to-side suture technique.

Restoring key pinch: the IC group 1 and 2 patient

Hints and tips

1. Do not release the A1 pulley of the thumb if the metacarpophalangeal (MP) joint flexes beyond 45°.
2. Routinely perform the split FPL-to-EPL transfer or the extensor pollicis longus shortening procedure.
3. If the thumb collapses into supination as the wrist is extended, perform the Brand modification of Moberg's procedure.
4. Always put a test suture to test the right tension in a tenodesis or transfer.

Patients at the IC group 1 or 2 level are candidates for active wrist extension, BR-to-ECRB transfer, and creation of a lateral or key pinch as described by Moberg.[32] Conceptually, this is a very simple operative procedure and, importantly, it represents an automatic pinch in that the tendon of the thumb flexor, the FPL, is anchored to the palmar surface of the radius under such tension that with wrist extension the thumb tip is pulled against the side of the index finger. The other fingers are usually left supple and the patient frequently must learn to roll these digits into some flexion in order to provide a platform against which the thumb can act. Gravity is needed to flex the wrist, releasing tension on the tenodesed FPL and allowing opening of the grip.

Provided that wrist extension power is adequate, the key steps of the procedure have evolved to currently include:

- Stabilization of the interphalangeal joint of the thumb
- Fixation of the tendon of the flexor pollicis longus to the radius at the correct tension

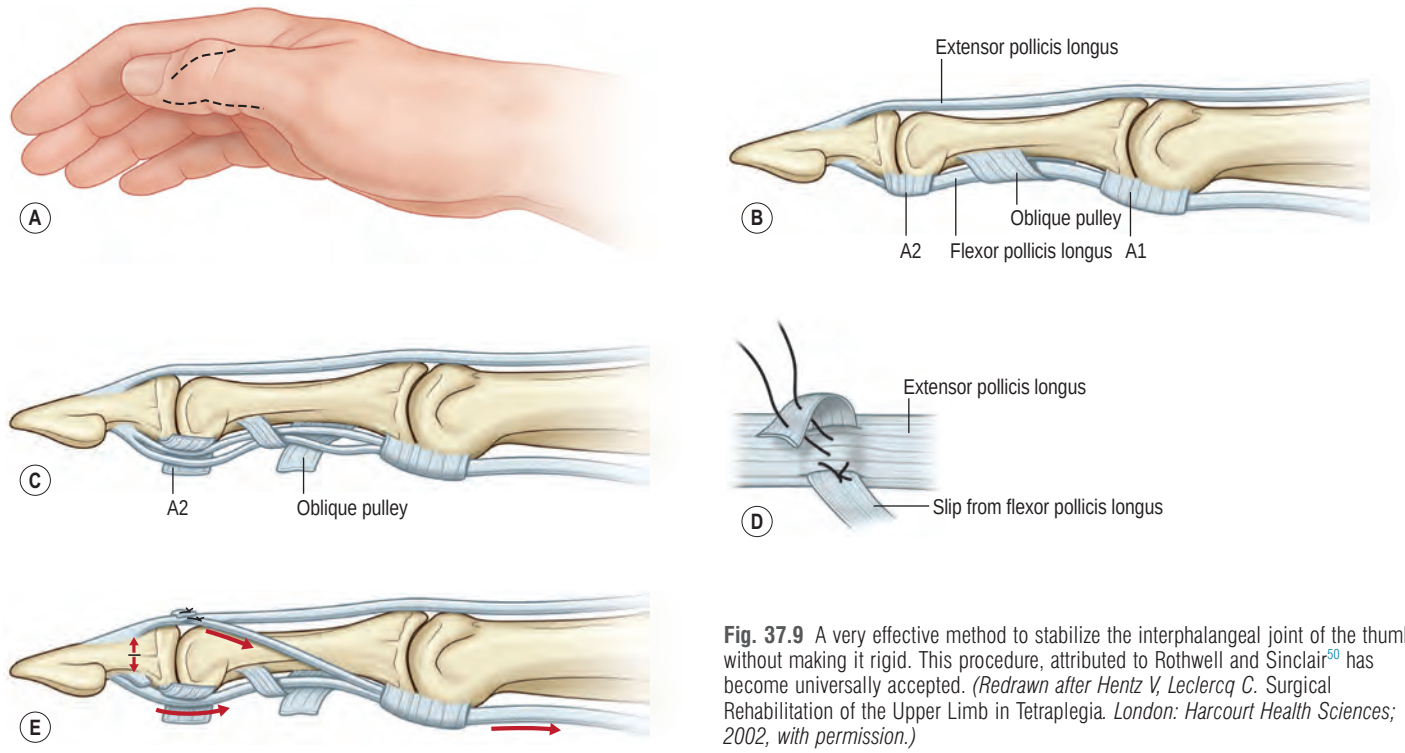

Fig. 37.9 A very effective method to stabilize the interphalangeal joint of the thumb without making it rigid. This procedure, attributed to Rothwell and Sinclair[50] has become universally accepted. *(Redrawn after Hentz V, Leclercq C.* Surgical Rehabilitation of the Upper Limb in Tetraplegia*. London: Harcourt Health Sciences; 2002, with permission.)*

- Usually stabilization of the thumb's carpometacarpal joint against excessive flexion.

The first step is stabilization of the interphalangeal joint of the thumb. The split flexor pollicis longus transfer as described by Mohammed *et al*.[50] or the ELK-tenodesis described by Fridén *et al*.[51] These techniques eliminate the need for long-term hardware and preserve some active and even greater passive interphalangeal joint movement.

Split FPL-to-EPL interphalangeal stabilization

For an optimum result, the critical pulleys, including the oblique pulley of the flexor sheath of the thumb, must be preserved. The procedure may be carried out using the incisions outlined in Fig. 37.9A, or using just one incision along the radial midaxis of the thumb.

The zig-zag incision is made and the neurovascular bundle on the radial side of the digit is dissected. The neurovascular bundle is included within the skin flap to protect it. Frequently, there is a small annular ligament or pulley located at the level of the interphalangeal joint. This can be incised to visualize the flexor pollicis longus tendon (see Fig. 37.9B,C).

A blunt probe is used to find the naturally occurring midline split in the tendon's structure. This split is lengthened both distally and proximally. When the distal dissection reaches the insertion of the tendon, the radial half of the split flexor pollicis longus tendon is divided at its bony insertion. The tendon end is delivered into the wound. The proximal split is extended to the level of the MP joint. Finally, a small window into the flexor sheath is created just proximal to the oblique pulley and the detached radial half of the tendon is brought through this window.

If a second incision is used, it is located on the mid-dorsum of the thumb, over the course of the extensor pollicis longus. The radial half of the flexor pollicis longus is tunneled under the intervening skin, *deep* to the radial digital nerve and brought out the dorsal incision.

The tendon slip is passed under the tendon of the extensor pollicis longus and then brought back over onto itself (see Fig. 37.9D). The thumb interphalangeal joint is temporarily stabilized in about 20° of flexion with a 0.045 Kirschner wire placed across the joint. The transferred slip of tendon is pulled distally until a noticeable slackening of the remaining tendon half is noted and then relaxed slightly so that there is equal tension on the slip of transferred tendon and on the original remaining half of the tendon (see Fig. 37.9E). Pinning the interphalangeal joint before final adjustment of tension makes this step much more easily accomplished. The transferred half of the tendon is sutured to itself and to the extensor pollicis longus with absorbable 4-0 sutures.

ELK-tenodesis

The interphalangeal joint of the thumb may also be stabilized by a shortening the EPL tendon on the dorsum of the thumb[51] (Fig. 37.10). The joint is supposed to hyperextended after the procedure and will return to a more flexed position with the addition of a BR motor to the FPL.

Flexor pollicis longus tenodesis (passive key pinch)

The proximal tendon of the FPL is anchored to the distal radius augmenting the natural tenodesis of the thumb pinch with wrist extension.

The incision is made and in the interval between the flexor carpi radialis (FCR) and the palmaris longus (PL). The FPL muscle–tendon junction is just deep to this interval. The tendon is identified and the muscle–tendon junction divided as far proximal as possible. Next the FPL tendon is anchored to the

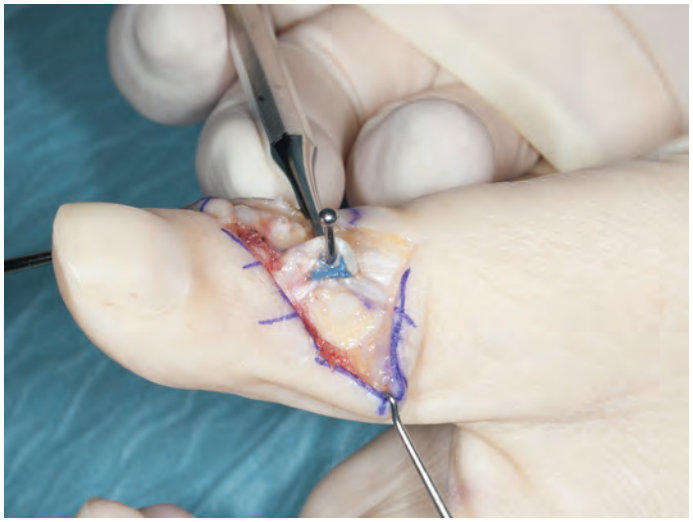

Fig. 37.10 Extensor pollicis longus-loop-knot (ELK)-tenodesis. The extensor pollicis longus is duplicated and sutured to itself, bringing the interphalangeal joint into hyperextension. The brachioradialis to flexor pollicis longus transfer will correct it into slight flexion.

radius at the proper tension. A 3- or 4-mm drill point is used to drill a hole from volar to dorsal through the radius, avoiding the radial wrist extensor tendons. A dorsal incision is designed at the site where the drill point exits the dorsal aspect of the radius. A loop of 30-gauge (3-0) monofilament wire is passed through the drill hole in a dorsal to palmar direction and the FPL tendon is placed in the loop and drawn through the radius. By pulling on the tendon, the tension can be adjusted so that the pulp of the thumb just contacts the radial side of the flexed index finger when the wrist is in the neutral position. When the wrist is flexed, the tension of the FPL is relaxed and the thumb ray will extend in response to the dorsal tenodesis/viscoelastic forces. After satisfactory tensioning of the FPL tendon, the FPL is anchored to the radius.

Postoperative rehabilitation

On the first postoperative day the patient starts early active mobilization of the new functions as described above. We have found the results of this technique predictable. We can measure the gain in pinch strength and it is typically proportional to the strength of the wrist extensor power but somewhat depends on the stability of the thumb and finger joints. Pinch strengths of 1–5 kg have been uniformly achieved.

IC group 2 and some IC group 3

Restoring active key pinch by brachioradialis (BR)-to-FPL transfer

Hints and tips

- Assess if arthrodesis of the thumb CMC joint will provide a more functional position (Fig. 37.11).
- Avoid CMC fusion if there is a stiff MP joint.
- Take care setting the BR tension.
- Always stabilize the interphalangeal joint of the thumb (as described earlier).

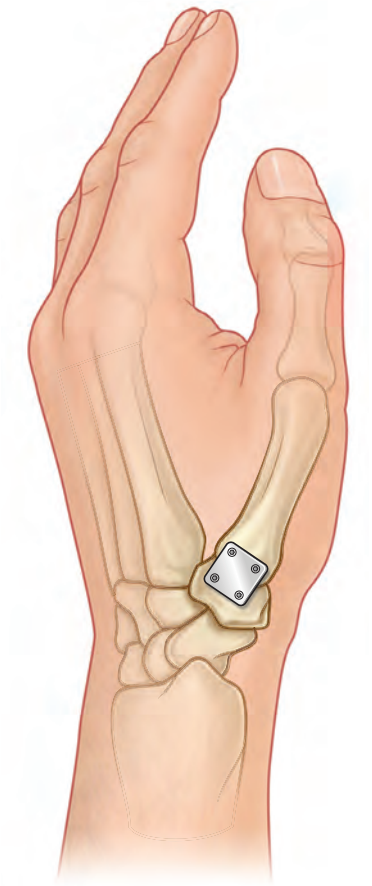

Fig. 37.11 Thumb carpometacarpal joint arthrodesis. Note the position of the thumb ray.

Patients in IC group 2–3 have by definition a functional BR and active wrist extension. Below are steps for reconstruction of the IC 2–3 (Fig. 37.12):

1. The CMC is evaluated and, if there is excess laxity, a CMC arthrodesis is performed to pre-position the thumb tip to contact the index finger middle phalanx.
2. The EPL tendon is anchored to the fibrous tissue in the third compartment on the dorsum of the wrist.
3. The brachioradialis is transferred to the tendon of the FPL.
4. The split FPL-to-EPL transfer or the EPL shortening is performed.
5. Interosseus stabilization (described below) for fingers to meet thumb in lateral key pinch.

Operative procedure

The operative steps are carried out via one longer and three or four smaller incisions as illustrated in Fig. 37.12A. An FPL-to-EPL interphalangeal joint stabilization procedure is completed as illustrated in Fig. 37.12B. If needed, the CMC joint is then exposed through an incision made along the juncture of the glabrous and hair-bearing skin over the palmar–radial aspect of the thumb's thenar eminence. The thenar muscles are reflected off the capsule of the CMC joint and the capsule opened. The adjacent joint surfaces are prepared for arthrodesis by sharp excision of all cartilage and by perforating the

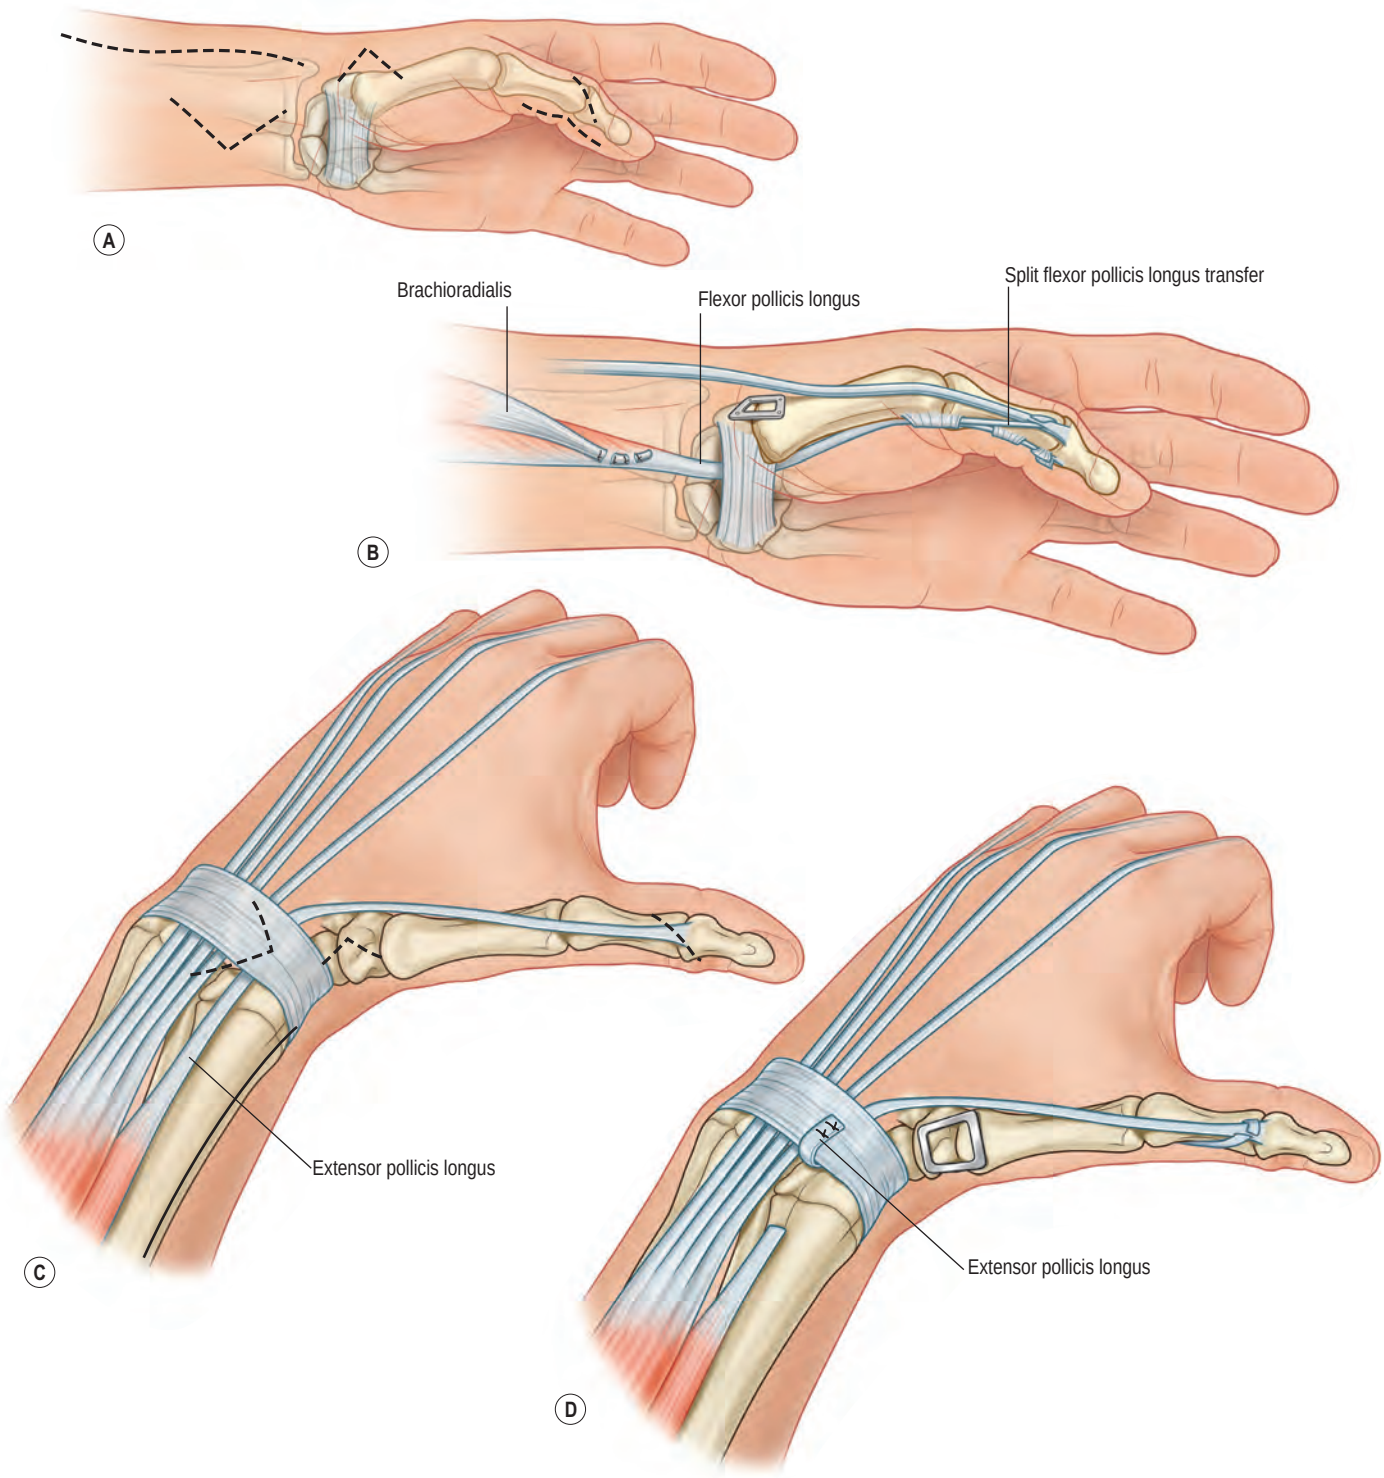

Fig. 37.12 A procedure to restore active key pinch. The carpometacarpal joint of the thumb is stabilized by fusion, the thumb interphalangeal joint by split flexor pollicis longus (FPL) to extensor pollicis longus (EPL) tenodesis, the EPL is tenodeses to the radius so that the thumb extends with wrist flexion and the brachioradialis is transferred to the FPL to provide potential voluntary pinch irrespective of wrist position. *(Redrawn after Hentz V, Leclercq C.* Surgical Rehabilitation of the Upper Limb in Tetraplegia*. London: Harcourt Health Sciences; 2002, with permission.)*

dense subchondral bone in several areas on the metacarpal base and the face of the trapezium. Bone is removed with a small osteotome, curette, or powered burr equally from both sides of the joint. This maintains the relative contours of metacarpal base and trapezium and good bone-to-bone contact between the two surfaces.

Correct positioning of the CMC fusion is a critical step. Both palmar and radial abduction are considered and final position is determined by the preoperative flexor tenodesis pattern and the passive range of motion at the thumb's MP joint. The ideal position goal is to have the pulp of the thumb contact the radial side of the index finger middle phalanx with wrist extension. Opening of the grip depends upon wrist flexion and occurs almost exclusively at the MP joint. The ideal candidate has a well-preserved tenodesis pattern and passive MP flexion exceeds the range of CMC extension. For such a patient, the thumb ray should be positioned in only about 20° of palmar abduction, and almost maximum radial abduction. A thumb ray fused in too much palmar abduction will interfere with transfers and pressure-relief efforts. If the patient has poor finger flexion as the wrist is extended, the CMC joint should be arthrodesed in a slightly less palmarly abducted posture. If MP flexion is limited, the CMC joint should be fused in less than maximal radial abduction. If too radially abducted, the patient with a poorly flexible MP joint will not achieve firm contact between pulp of thumb and index finger.

The CMC joint is temporarily pinned with a 2-mm Kirschner wire to test positioning. If the position seems ideal, the joint is further stabilized. A small four-corner plate or a locking-plate has provided sufficiently rigid bone-to-bone contact. Locking-plates provide more stable fixation and are associated with fewer non-unions than conservative fixation methods.[52]

The third step involves creating a firm tenodesis of the EPL. Since the CMC joint is now fused, no particular EPL re-routing is needed. Through a transverse incision made just proximal to Lister's tubercle, the tendon of the EPL is located and divided at its muscle–tendon junction, withdrawn at the level of the MP joint, passed proximally and under the tendons of the first dorsal compartment, and then toward the third compartment. This provides an extensor–abductor vector when the wrist is flexed. The EPL is anchored to the dense fibrous tissue between the third and fourth extensor compartment using with several non-absorbable sutures. The thumb should reach maximum extension as the wrist reaches 45° of flexion but the pulp of the thumb should contact the radial side of the index finger as the wrist reaches the neutral position.

The last procedure involves BR-to-FPL transfer.[53] The FPL is identified in the volar forearm, either through the same incision used to dissect the BR or through a separate volar incision. The FPL is divided at its muscle–tendon junction and the two tendons are directed in as straight a line as possible toward one another. The end of the BR tendon is passed through the FPL tendon and a side-to-side suture is performed. The ideal tension for the transfer is established as described for BR-to-ECRB transfer. The juncture is created with the elbow in 40° of flexion, the wrist in a neutral position, and the index finger held flexed at MP and proximal interphalangeal joints. The BR is pulled distally to a point midway between maximum passive stretch and fully relaxed (zero-tension) tension and the FPL tendon is pulled proximally so that the pulp of the thumb just touches the radial side of the index finger. The assistant maintains this posture of both tendons while the surgeon joins together the two tendons with a test suture. The tension of the FPL transfer and the EPL tenodesis is tested by gently moving the wrist between 45° of flexion and 45° of extension. It is important that the thumb still fully extends at the MP joint with wrist flexion after BR transfer. The wounds are closed and the limb solidly immobilized in a below-elbow cast that maintains the wrist in a neutral position and the thumb MP joint in some flexion. We typically place the thumb in contact with the flexed index finger.

Other options

The BR can be transferred to the deep flexors (flexor digitorum profundus [FDP] index–ring) for active grip and the thumb may get a passive key pinch driven by an active wrist extension. We have done a few patients with this combination with promising outcomes.

Postoperative rehabilitation

On the first postoperative day the patient starts early active mobilization of the new functions as described above. At the beginning of the third or fourth postoperative week, the patient starts task-oriented training under supervision of a trained therapist. The therapist constructs a small hand-based splint to protect the CMC joint fusion. The use of night splints and weight-bearing transfers on the hand are restricted until about 10 weeks postoperatively.

IC groups 3, 4 and 5

Restoring active key pinch, grasp, and release in one operative stage

Historically these patients were treated using a two-stage technique first establishing hand opening and then a second procedure for closing/grasp. However, the higher-volume centers have found that this can be completed in a single stage. Both techniques utilize two expendable muscles for transfer, the ECRL and the BR may be performed.[54] Outcomes have shown stronger grip strength and better opening after the single-stage procedure.[55] Prerequisites for these procedures include near-normal passive wrist movement and reasonably flexible fingers. These patients may possess useful triceps function. If not, this function should be restored.

The single-stage grip and release procedure[54] (Video 37.1 ▶)

Hints and tips

- It is critical to be certain of the true strength of the ECRB before transferring the ECRL.
- Before detaching ECRL from its insertion the ECRB insertion should be visualized to avoid mistakes.
- While tensioning the tendon slips in the House procedure the position of joints are important: 60° flexion of metacarpal joints (MCP) and fully extended interphalangeal joints (IP).

Surgical order of procedures:

- Split FPL-to-EPL transfer or EPL shortening[51]
- Thumb CMC joint arthrodesis
- Intrinsic substitution procedure (House[56] procedure)
- BR transfer to the FPL
- ECRL transfer to the FDP II–IV
- Re-routed passive tenodesis of the thumb (EPL)
- ECU-tenodesis to correct for radial wrist deviation deformity.[57]

The very strong IC group 3 patient will have at least one of the two radial wrist extensors at MRC grade 5. The other will probably be MRC grade 4. The surgeon must proceed with care as it is a grave error to transfer the ECRL and lose strong wrist extension. This is a real risk since it is impossible to perfectly isolate and assess ECRB strength in preoperative testing. However, these patients commonly have some function of the pronator teres (PT). If the PT is intact one can assume both wrist extensors are functional.[58] Another method to assess if both wrist extensors are functional (grade 4 or more) is that a groove occurs between the bellies of the ECRL and ECRB, known as "Bean's sign".[50] If there is any question of the ECRB strength, it can be tested intraoperative. The ECRB tendon is exposed just distal to the extensor retinaculum under local anesthesia, a probe is slipped under the tendon and the patient is asked to forcefully extend the wrist. If the muscle is MRC grade 4 or 4+, the tendon cannot be displaced by the surgeon's probe. This can be done at the start of the surgery and if the ECRB is judged to be sufficiently strong and direct the next steps of the procedure.

The ECRL and BR tendon transfers start with a long dorsal incision (as described for BR transfer). The ECRL and BR tendons are mobilized and then passed volarly. The BR is sutured to the FPL (side-to-side). The tendons of the FDP are synchronized. Some advocate setting the finger cascade with slightly more opening of the ulnar sided digits: a "reverse cascade". The theory is that this allows easier ability to get hand around object. The tendon of the ECRL is passed obliquely through the synchronized FDPs and attached with side-to-side sutures. The FDP of the little finger is left out of the transfer, but will be passively flexed by connections between the muscles of the little and the ring finger. Tension of this transfer is adjusted so that a relatively natural posture of the fingers is achieved with wrist flexion and extension. A bandage roll (4 cm in diameter) placed in the palm facilitates the tensioning of the fingers and the creation of a normal finger cascade. It is preferable to tension this transfer after intrinsic stabilization is performed (see below.) The BR-to-FPL transfer is tensioned so that with the wrist in neutral, the thumb pulp just touches the side of the flexed index finger. Early active mobilization is very important when performing several simultaneous procedures.

Intrinsic stabilization

The intrinsic muscles are critical to hand function. Without intrinsics, grip strength is considerably weakened and finger abduction at the metacarpophalangeal joint is lost. Even though the long flexors of the fingers can flex all the intervening joints, without the synchronizing effects of the intrinsic muscles, in flexion the fingertips touch only to the bases of the fingers rather than the center of the palm. This rolling up of the fingertip seen when intrinsics are lacking tends to push large objects out of the grasp.

The second major biomechanical function of the intrinsic muscles is assisting the extrinsic extensors to extend the interphalangeal joints. Without intrinsic muscle activity, the extrinsic muscle action at the metacarpophalangeal joint is unopposed, hyperextending the MP joint. Furthermore, this MP hyperextension increases the viscoelastic tone of the long flexors, inducing flexion at the interphalangeal joints. This imbalance gives rise to the "claw hand" characterized by metacarpophalangeal hyperextension and interphalangeal joint flexion.

For most people with tetraplegia, the absence of intrinsic muscle function may also result in an imbalance between the paralyzed extrinsic flexors and extensors. The preoperative hand of patients in IC groups 1–5 possesses only residual passive tenodesis grasp and release. For these patients, the tendency for the finger to claw as the wrist is flexed may represent only a cosmetic annoyance. However, reconstructive procedures to improve digital flexion and extension may accentuate the clawed posture by adding tone to both extrinsic extensors and flexors. In this circumstance, the claw deformity frequently becomes a functional liability.

House and Walsh[59] found that some type of intrinsic substitution improves the grasp in the tetraplegic patient who undergoes candidate for a grasp-release procedure. Since most people with tetraplegia do not possess sufficient transferable muscles to allow intrinsic substitution by standard tendon transfer procedures, static procedures are utilized. Two procedures have been described: the first attributed to Zancolli[60] and termed the "lasso" procedure, and the other described by House *et al*.[57]

Zancolli "lasso" procedure

In IC groups 3, 4 and 5, the flexor digitorum superficialis (FDS) muscles are paralyzed, typically at the upper motor neuron level. As such, they retain some stretch reflexes through the intact spinal reflex arc and relatively normal viscoelastic properties. Zancolli[60] proposed using these paralyzed muscles as an elastic tenodesis to reduce metacarpophalangeal joint hyperextension and lessen the clawed posture of the tetraplegic hand (Fig. 37.13A–F). In this technique, superficialis tendon of a clawed finger is released distally and inserted into the flexor sheath at the distal margin of the A1 pulley or the proximal part of the A2 pulley. The tendon is placed under slight tension. The superficialis tendon now becomes a flexor of the MCP joint.

The mechanical basis for this dynamic tenodesis procedure is debated. Zancolli believes that the transfer must be fixed under significant tension in order to still provide MCP flexor tone even with the wrist near-maximally flexed. If this transfer is performed as part of the flexor phase, it is preferable to first perform the "lasso" procedure before adjusting the tension of the finger flexor transfer.

House intrinsic tenodesis

This procedure, described by House *et al*.,[55] is a modification of Riordan's tenodesis procedure.[61] In the patient with tetraplegia, the procedure (Fig. 37.14) is usually performed on all four fingers. However, it is sometimes performed for only the index and middle finger, since these fingers are the most

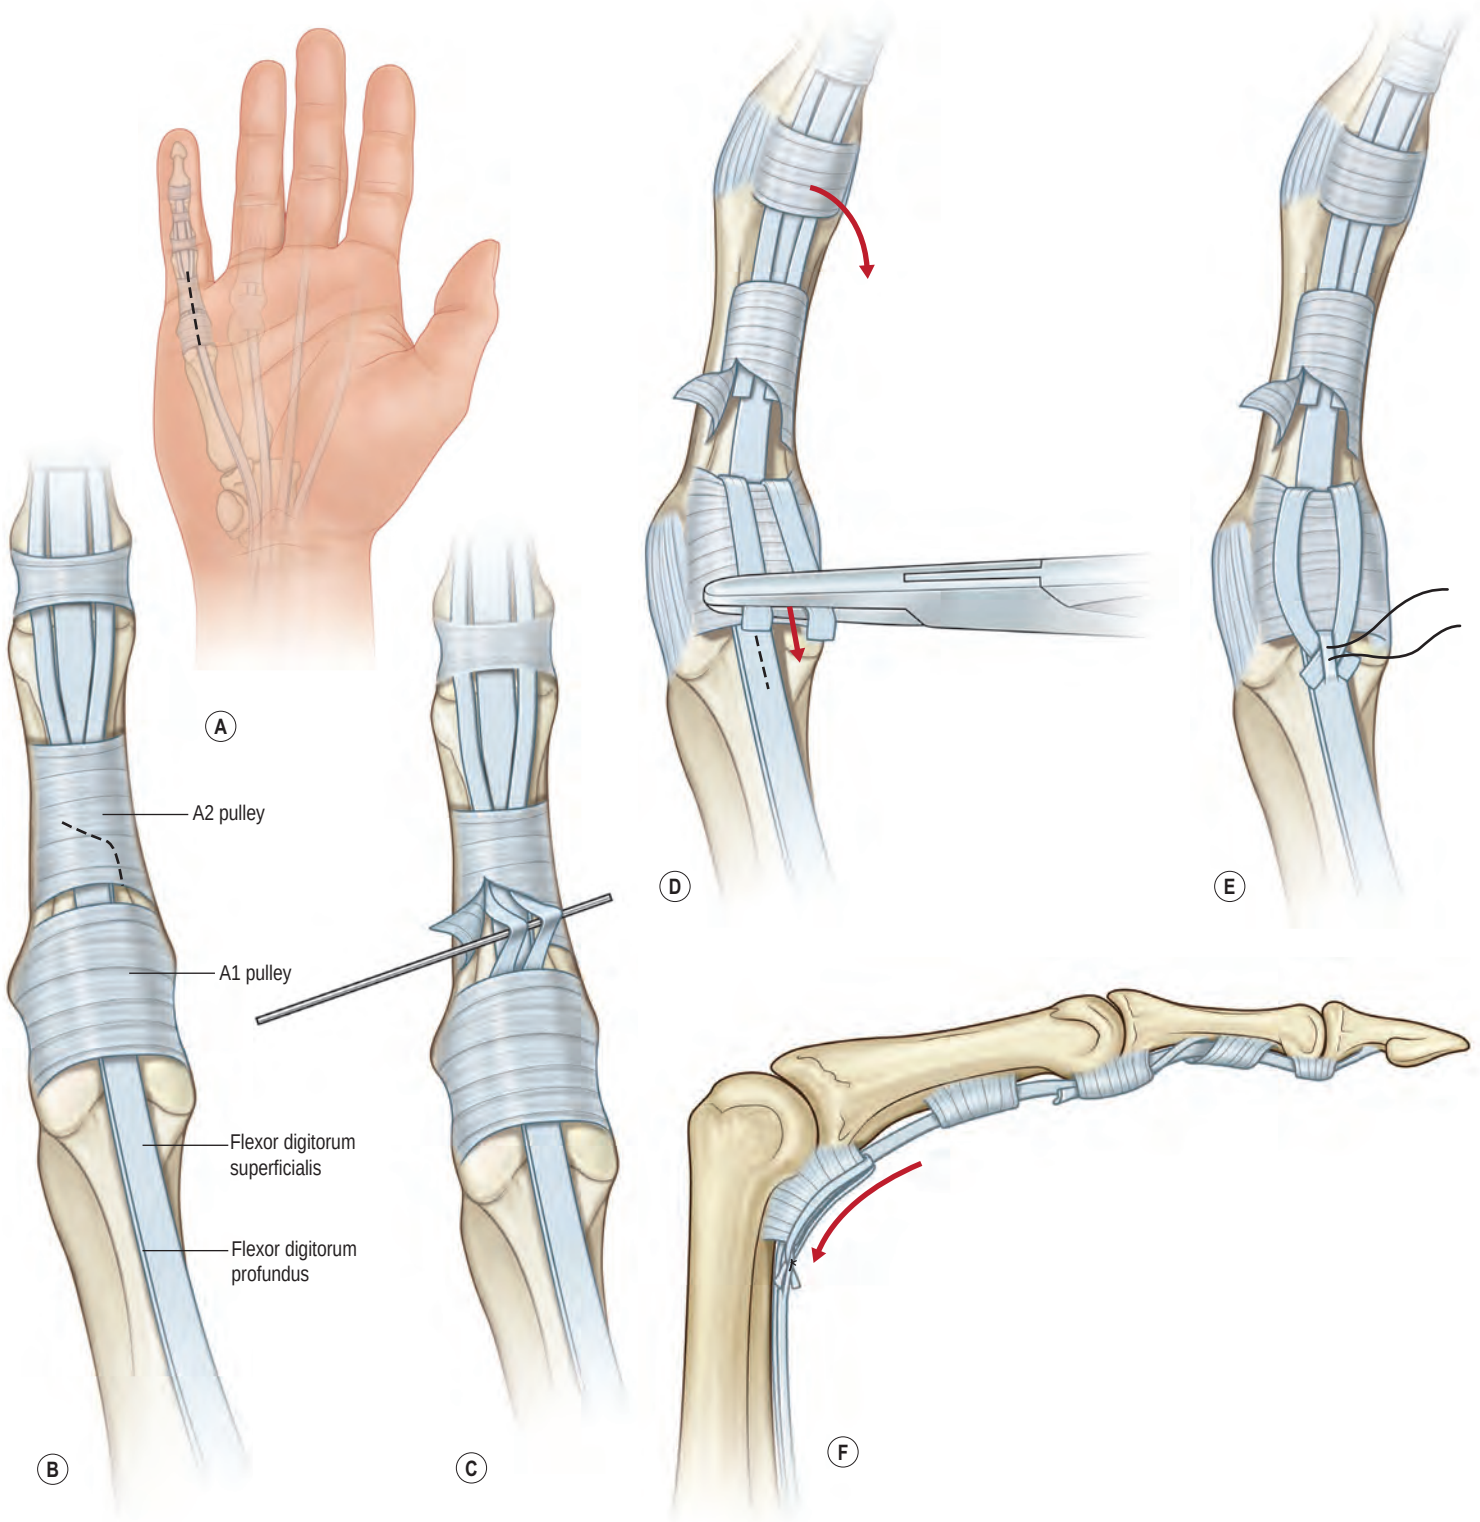

Fig. 37.13 The Zancolli "lasso" procedure **(A–F)**. Either several longitudinal incisions or one longer transverse incision can be made. The flexor digitorum superficialis is divided distal to the A1 pulley, looped about the pulley, and sutured to itself proximal to the pulley under strong tension. If the metacarpophalangeal joints remain nearly fully flexed with the wrist in neutral, proper tension has been achieved. *(Redrawn after Hentz V, Leclercq C.* Surgical Rehabilitation of the Upper Limb in Tetraplegia*. London: Harcourt Health Sciences; 2002, with permission.)*

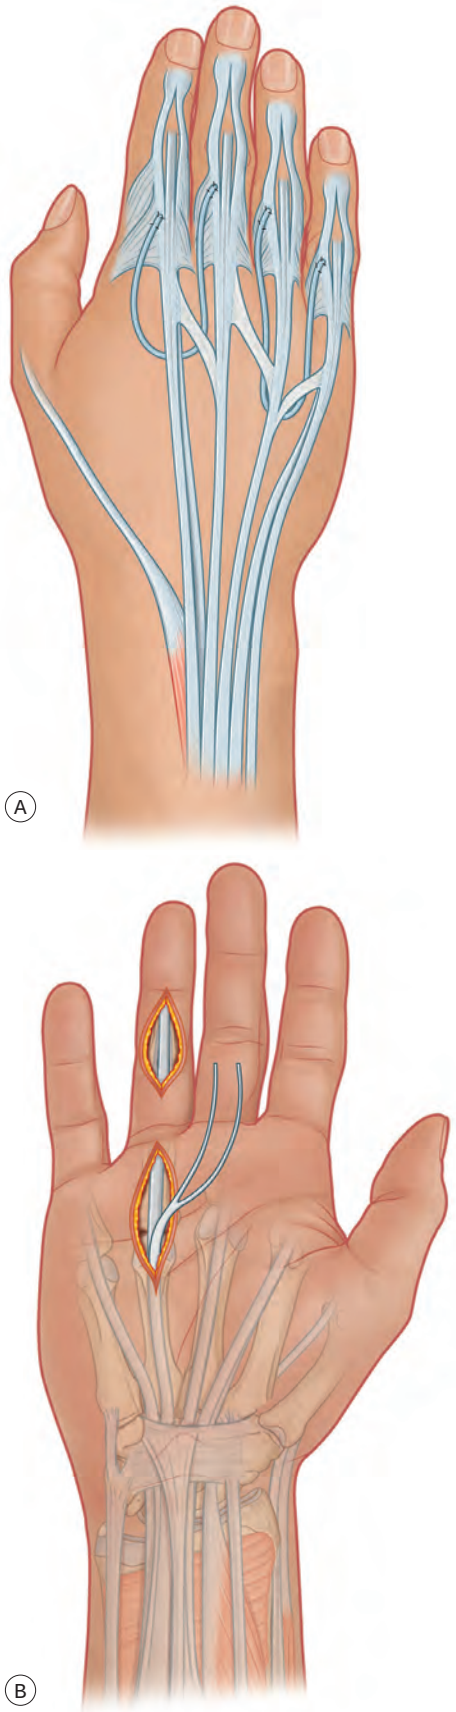

Fig. 37.14 The House intrinsic substitution procedure. The tendon loops have to go volar to the intermetacarpal ligaments.

critical in grasp and release functions. A tendon graft is needed: PL or FDS ring is harvested and split into two slips. Mediolateral or oblique incisions are made on the proximal phalanx of each finger and two small incisions on the dorsum of the hand. With the MCP in 60° of flexion and extended IP joints, the first slip is tunneled from the radial side of the phalanx of the index finger under the insertion of the first dorsal interosseous, and then under tendons of the extensor communis of the index and the extensor indicis proprius. After that the tendon slip is tunneled through the lumbrical canal, volar to the intermetacarpal ligaments, and sutured onto the lateral and central band. The other tendon slip is tunneled through lumbrical canals of the fourth and fifth digits.

ECU-tenodesis

The ECU-tenodesis is a passive tenodesis.[6] Patients with tetraplegia typically present with a radial deformity of the wrist, which impairs grip strength.[57] The correction starts with a curved incision made over the ulnar head and the sixth extensor compartment is opened. The dorsal sensory branch of the ulnar nerve is protected. The wrist is ulnarly deviated and the ECU is lifted with a tendon elevator, the tendon is then shortened until the radial deviation deformity is gone. The excess tendon is secured onto the ulnar head with a couple of mattress sutures (Fig. 37.15). This is usually the last procedure in the single-stage grip release reconstruction.

Finally before closing the wounds the tenodeses and the passive interosseous function should be tested to allow for adjustments.

Postoperative rehabilitation

On the first postoperative day the patient starts early active mobilization. After the intrinsic stabilization procedure, the patient is restricted from full finger flexion for 4 weeks. The protocol allows for flexion up to a digit–palm distance of 3 cm. After 4 weeks, the patient is allowed to gradually flex all the way. Full load is allowed after 8 weeks. Despite the full finger flexion restriction, the task-specific training starts at 3 weeks postoperatively including active wheelchair maneuvering and all types of daily activities. Complications are rare, provided that the patient follows the rehabilitation protocol and the gains are highly appreciated by the patients.[62,63]

Other procedures

In IC group 4, the PT is strong and available for transfer. In IC group 5, the flexor carpi radialis (FCR) is strong, but experience has shown that it should not be used as a transfer. Therefore, the surgical options are similar for both IC groups 4 and 5.

The PT is the only functioning pronator muscle in these IC group 4 and 5 patients. However after transfer, the PT will retain most of its pronator function if the transfer pull is the same direction as the original tendon's pull. The PT can be safely transferred to the FPL though an interposition tendon graft may be needed. The BR is then available for another functions, such as transfer to extensor digitorum communis (EDC) and EPL for finger and thumb extension. This is done if other techniques failed to provide adequate hand opening and there is enough volar stabilization of the wrist (FCR with MRC strength 3 or above). If BR-to-EDC/

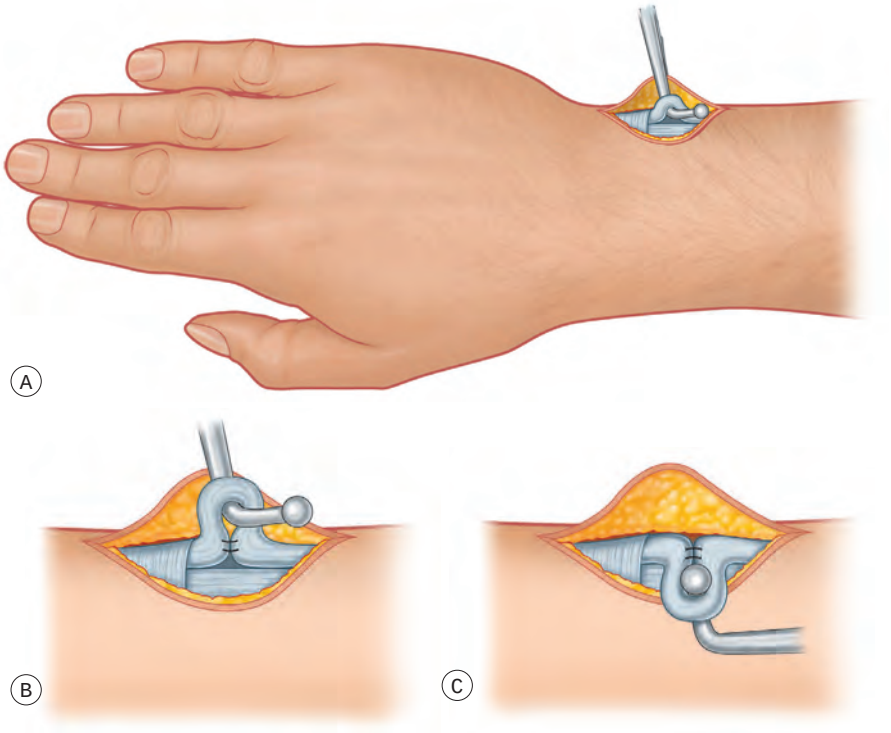

Fig. 37.15 Extensor carpi ulnaris tenodesis to correct for wrist radial deviation deformity.

EPL is chosen, tension is set with the elbow in 40° flexion, the wrist in a neutral position, and the MP joint in about 20° of flexion. Tension should be such that, during passive flexion of the wrist, the MP joints start extending when the wrist reaches neutral from an extended position. The tension on the EPL tendon should be adjusted last and its tension is typically set slightly looser than that of the EDC. The fingers should exhibit full passive flexion when the wrist is fully extended.

Alternative procedures for IC groups 4 and 5 include various combinations of procedures already described. Since patients differ, it is important to be able to plan for variations in patient presentation and individual functional objectives. The greatest variation in hand use has been a consequence of the management of the thumb's CMC joint. A fused CMC joint, while predictably pre-positioning the thumb, does limit the size of objects easily grasped within the first webspace. If the CMC joint is left mobile, the postoperative position of the thumb ray is less predictable, sometimes significantly so, but larger objects can be pushed into the first webspace and held.

IC groups 6, 7, 8 and 9

Patients classified at the IC 6 level possess active digital extension but lack thumb extension, interosseous function, and grip strength. They require the multiple tendon transfers to achieve balanced thumb pinch and strong finger grasp as described earlier as well as adding an extensor force for the thumb. Transfer of extensor digiti minimi (EDM) to abductor pollicis brevis (APB) is a good option for better thumb movement.[64] Volar abduction of the thumb is useful for fine motor skills and usually much appreciated by the patients. We have used EDM with grade 3 muscle strength with satisfactory results; as volar abduction does not require much strength.

Patients with an even greater number of remaining resources, such as patients in IC groups 7–9, can be reconstructed similarly to patients with a lower peripheral nerve injury. The surgical procedures performed for these patients are directed at reconstructing some aspects of hand intrinsic muscle function and balance. The interosseus function can be made active by using an active superficial flexor digitorum (FDS) tendon of the ring finger, splitting it into four slips if the tendon size allows it. Alternatively, FDS long and ring can be split into two slips each. This Stiles–Bunnell transfer[7] may be considered in cases with incomplete tetraplegia or in group 8. There are relatively few patients with tetraplegia in these categories compared to the IC 2–5 categories.

Group X and spasticity

Group X has a mixed pattern and many patients with incomplete tetraplegia belong to this group.

Up to 78% of patients with traumatic spinal cord injury develop spasticity and this is primarily treated with conservative treatment methods such as physiotherapy, splints, baclofen, and botulinum toxin A injections. Before surgery is considered, conservative treatment must be thoroughly explored. Surgical treatment reduces spasticity by lengthening of tendons, releasing muscles, and sometimes correcting deformities.[65] Short-term (1 year follow-up) outcomes are encouraging. The patients open their hands well and also gain grip strength even though the tendons are lengthened. We have ongoing studies to evaluate the durability.

Future directions

Nerve transfers

Nerve transfers have long been a treatment of choice for patients with brachial plexus injuries, but have recently been explored for the tetraplegic population. Bertelli described using a brachialis nerve branch to triceps to restore elbow extension in 2012.[66] Fridén used a brachialis nerve branch to restore wrist extension for a patient in IC group 0.[40] Mackinnon presented cases in 2013 using peripheral nerve transfers for tetraplegia[67] and Van Zyl described a triple nerve transfer[68]: teres minor nerve branch to long head of triceps, brachialis nerve branch to anterior interosseous, and supinator nerve branch to posterior interosseous. These transfers successfully restored elbow extension, grasp, release, and key pinch.

In our center we have performed supinator nerve branch to posterior interosseous nerve transfer. This procedure requires minimal postoperative restrictions: a plaster splint for 2 weeks to protect the nerve coaptation. Preoperative testing of muscle function and electromyography assesses whether the target muscle can be stimulated. There is debate as to what is the appropriate timing of nerve transfers in this population. Early evidence suggests that timing of nerve transfers for patients with tetraplegia is similar to peripheral nerve injury (earlier reconstruction is better). However, recruiting these complex patients so soon after their injuries is challenging.

Another challenge for nerve transfers is the long wait before functional gains are seen. After tendon transfer surgery, the patient can see the new movement the day after surgery whereas a year may pass before the patient sees results from a nerve transfer. We believe an approach using all the available tools: nerve transfers combined with tendon transfers will provide the best results.[69] An active finger extension for release combined with tendon transfers for a strong grip and key pinch seems as an attractive combination.

Functional neuromuscular stimulation

Functional electrical stimulation (FES) is an exciting adjuvant for improving arm function in these patients. The initial commercially available system was an eight epimysial electrochannel device called the Freehand System. This system allowed patients with very high spinal injury to activate and control a pre-programmed sequence of muscle contractions and achieve a useful grasp for one hand.[69–72] Research continues on this system and current models have the ability to stimulate 12 muscles.[73] These systems of electrodes are often the only option to restore useful function in limbs heretofore deemed unreconstructable by standard surgical techniques. We hope that as further research proceeds, these devices may again become commercially available (Fig. 37.16).

Outcomes and complications

These procedures have evolved over time and can provide predictable improvement in function. The surgery also provides a great impact on activity and participation aspects in the patient's life.[74,63,39] Both practical issues in daily life and psychological aspects have shown to improve.[63] A systematic review provided data on the average outcomes for the most common of these procedures – posterior deltoid-to-triceps transfer and procedures to restore pinch. For the deltoid to triceps, the average postoperative strength was 3.3 MRC. This would certainly allow stabilization of the arm in space. Complications were not infrequent at 25%, with the most frequent being rupture or stretching of the repair. Since we implemented side-to-side sutures we have not seen any ruptures or elongations of attachments. Pinch-reconstruction procedures were divided into those with active motors, such as a BR, or those that were simply a FPL tenodesis or Moberg procedure. The mean postoperative strength after both types of pinch surgery was 1.9 kg. The mean postoperative strength after FPL tenodesis was 1.17 kg, and for those using an active motor, postoperative strength was 2.32 kg. There was a 40% rate of complications

in this review. The most common complications were flexion contracture of the elbow or of the thumb, stretching or rupture of repair, and loosening of pins across the thumb IP joint. Two of these complications, flexion contracture of the thumb and loosening of pins, are no longer applicable as the procedures have evolved to address these complications (we no longer fuse the IP joint and do not release the A1 pulley).

These procedures are also very durable.[22,75] Hentz *et al*. examined 45 patients who had been operated at least 10 years prior to evaluation. A total of 21 of these patients had undergone elbow extensor reconstruction; 15 patients had posterior deltoid to triceps transfer; and 10 had bilateral transfers. Fifteen required a motorized wheelchair as their primary means of movement before surgery. At 10 years after surgery, nine now used a pushchair as their standard chair and four others used a pushchair at least some of the time. There were three patients who had undergone bilateral posterior deltoid-to-triceps transfer who were able to self-transfer in the early postoperative period. All three continued to be able to perform this monumental, for a tetraplegic, task. In the six patients that had biceps-to-triceps transfer (all needing contracture release), two could use a pushchair, but not exclusively so. None had developed a recurrence of elbow contracture.

The second goal was the restoration of some hand function. IC group 2 patients typically had key grip fashioned by tenodesis of the FPL to the radius. Seven were evaluated for more than 10 years. Five had maintained pinch strength essentially equivalent to that demonstrated 6–12 months following surgery. The IC group 3 patients typically had transfer of BR to FPL to restore dynamic voluntary key pinch. Six were evaluated and all had maintained useful power, which averaged 20 N.

Historically, groups 3, 4 and 5 were treated in two stages: the flexor and the extensor phase. For 10 years a Swedish group has performed the single-stage grip and release procedure as described above (Video 37.2 ▶). A traditional (staged) group of 18 hands were compared with the single-stage procedure (16 hands). All patients had early active mobilization. The single-stage group had a significantly stronger grip strength postoperatively, 6.5 kg, compared to the historical group, 1.6 kg, and significantly better opening of the hand: 5.5 cm vs. 3.0 cm. The key pinch was about the same: 2.8 kg vs. 2.0 kg.[55] Several surgeons found, as did House and Walsh,[59] that those patients who had had some type of intrinsic stabilization, either by Zancolli lasso[60] or by House *et al*.'s intrinsic reconstruction procedure,[56] had, on average, more powerful grasp. This may be a product of pre-selection as the stronger patients may have been chosen for intrinsic substitution. The last years have brought several case reports of different nerve transfers. This is an exciting new field to be further researched as it is still too early to assess the outcomes.

Conclusions

Carefully planned upper limb reconstructive procedures in tetraplegia are both effective and durable. Systematic post-injury evaluation of their upper limbs should become a standard part of care of the person with tetraplegia. Aside from their brain, the upper limbs remain the most important residual resource for people with tetraplegia. The value of greater independence is difficult to quantify, but many of our patients express relief for being able to feed themselves and perform their daily activities. Patients have said "Everything goes faster now"; "I don't need to bring my personal assistant on dates anymore"; " I can send my own texts"; "I've started to work again"; "I can visit restaurants again and eat by myself, even cutting beef." These surgeries can be the pinnacle of hand surgery restoring function to those in great need.

Upper extremity vascularized composite allotransplantation

Jaimie T. Shores, Joseph Lopez, Gerald Brandacher, and W. P. Andrew Lee

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Vascularized composite allografts are composed of multiple tissue components of variable immunogenicity such as skin, lymph nodes, bone marrow, nerves, vessels, muscles, and bone.
- After non-salvageable upper extremity loss, transplantation can restore upper extremity appearance, anatomy, and function by replacing and restoring missing tissue without compromising donor site morbidity or requiring multiple reconstructions.
- Vascularized composite allotransplantation (VCA) is not a life-saving procedure but it can significantly enhance a patient's quality of life. Unlike solid organ transplantation, recipients are otherwise healthy without significant comorbidities. The risk–benefit consideration for patients must include the potential side effects of long-term immunosuppression – treatment that is necessary for graft survival.
- The conventional immunosuppression protocols used in upper extremity VCA are similar to those used in solid organ transplantation and have prevented early graft loss but not acute rejection.
- Acute rejection in vascularized composite allografts can be monitored visually, which allows for timely intervention. Acute rejection events, when properly managed, do not appear to impact long-term allograft function or survival.
- During the past two decades, over 100 upper extremity transplants have been performed around the world in over 70 patients with encouraging intermediate to long-term functional and graft survival outcomes.
- In order to broaden the application of this life-changing reconstructive modality, future research should focus on investigating novel immunomodulatory approaches that aim to enable long-term allograft survival while minimizing the need for life-long immunosuppression.

Fig. 38.1 appears online only.

Introduction

Millions of individuals each year sustain major upper extremity trauma, undergo resection of upper extremity tumors, or are born with major congenital defects that require multiple, complex reconstructive surgeries to repair large upper extremity defects. Conventional management of these tissue deficiencies includes prosthetic rehabilitation or surgical reconstruction (with autologous tissues), but these modalities are often hampered by highly variable outcomes.[64] There are several factors that negatively impact surgical outcomes with traditional approaches including the prolonged process and cost of rehabilitation, multiple surgeries, limited autologous tissue for reconstruction, and secondary morbidity from extensive autologous donor-site surgery. For such complex injuries not amenable to conventional reconstruction, vascularized composite allotransplantation (VCA) can achieve near-perfect primary restoration of tissue defects with improved functional and aesthetic outcomes. VCA is a newly developed focus area in transplantation medicine and combines the time-tested techniques of reconstructive microsurgery with the immunologic principles of transplantation. The overall goal of VCA is to improve the quality of life of patients with significant composite tissue defects, and use the plastic surgery principle of replacing "like with like" with the goal of maximizing not only upper extremity functional outcomes but also aesthetic results.

In the United States alone, approximately 1 285 000 upper extremity amputations are performed per year.[65] In 2005, there were approximately 1.6 million individuals living in the US with upper or lower extremity limb loss.[66] Of these 1.6 million patients, nearly 540 000 individuals have had upper extremity amputations. Even if only 1% of these patients were deemed candidates for upper extremity allotransplantation, this would mean that over 300 patients could potentially benefit from this life-changing treatment. Thus far, only over 70 patients have undergone upper extremity allotransplantation in the last two decades. However, despite the

Historical development and milestones

The earliest accounts of organ transplantation date to the Chinese physician Pien Chi'ao, who in 500 BCE performed a dual-heart transplant on warriors Gong Hu and Qi Ying.[1] In addition, in the *Sušruta Samhita*, a surgical report written by the Indian surgeon Sušruta who lived around 480 BCE, Sušruta describes in detail the techniques of rhinoplasty and pedicled autografts from the forehead, neck, and cheek to restore mutilating injuries of the nose and ear.[2–4] About 870 years later, the patron saints Cosmas and Damian are credited with performing the first limb allotransplantation.[5–9] Legend has it that around the year 348, they successfully transplanted the right leg of a dead Moor onto the Roman deacon, Justinian, after amputating his cancerous/gangrenous leg (Fig. 38.1). The first description of skin allografting was done by the 16th century Italian surgeon, Gaspare Tagliacozzi, from Bologna, who in his book *De Curtorum Chirurigia per Insitionem* ("On the Surgery of Mutilation by Grafting"), described a novel method of nasal and aural allo-reconstruction, where he used skin from the inner aspect of the arm from a slave to reconstruct the nose of a wealthy patient who injured it during a sword fight.[10–12] In this book, Tagliacozzi goes on to describe one of the first description of tissue rejection, when he discusses the practical difficulty of binding two different individuals (referring to tissue rejection) to one another for a sufficient length of time.

Fig. 38.1 St. Cosmas and Damian perform the first human extremity allotransplantation. Per mythology, Christian Roman deacon Justinian had a malignant growth on his leg and fell asleep while praying for a cure in the Church of Cosmas and Damian in Rome. In his dreams, the saints amputated the diseased limb and transplanted the leg of a Moor, brought to the church for burial. The patient awoke and gratefully observed a now healthy leg, though black in color. *(Reproduction with permission from Württembergisches Landesmuseum, Stuttgart.)*

It took another 300 years before these "practical difficulties" in transplantation began to be elucidated. During this time, advancements in antisepsis, anesthesia, hemostasis, organ preservation and, most importantly, microvascular surgery led to the rapid progress of reconstructive microsurgery. Alexis Carrell in 1902 described the surgical technique of vascular anastomosis, thus laying the foundation for conventional vascular and microsurgery.[13] Carrell successfully obtained the revascularization of experimental organ allografts,[14,15] but failed to achieve permanent graft acceptance. Carrell attributed this "organ failure" to vascular complications because he had no knowledge of the process of rejection. In 1932 and 1937, the first attempts at skin grafting were performed between identical twins.[16,17] Again, no mention was made of rejection. In 1944, Hall published the first detailed theoretical account of cadaveric donor upper extremity transplantation (at the mid-humeral level).[18] In his protocol, Hall described that an experienced surgical team within a well-equipped hospital was needed to perform the procedure. Additionally, his protocol included important and innovative descriptions of organ preservation, osteosynthesis, and vascular anastomoses. Lastly, potential complications related to thrombosis and infections were discussed, but, again, no reference was made to the occurrence of rejection. Strikingly, Hall was not aware that Sir Peter Brian Medawar, a young zoologist in Britain, and Thomas Gibson, a plastic surgeon, had made the historic discovery of the immunologic phenomenon of skin allograft rejection that very same year (1944).[19] The challenge of skin transplantation led to the exploration of new frontiers in organ transplantation. In 1954, a plastic surgeon, Joseph E. Murray, with his team members – John P. Merrill and J. Hartwell Harrison – in Boston, performed the first successful human kidney transplantation between identical twins.[20,21] This was followed, in 1957, by the first clinical attempt at allotransplantation of an *en bloc* composite digital flexor tendon mechanism by a plastic surgeon, Erle E. Peacock, Jr.[22,23] Indeed, it was Peacock who coined the term "composite tissue allograft" to differentiate these transplants that were composed of multiple tissues unlike solid organs.[24]

Our understanding of the immunologic behavior of allografts lagged behind technical developments in surgery. It was only the knowledge gained from landmark discoveries in the past century[25–33] that facilitated the manipulation or suppression of the immune response, allowing successful prolongation of graft survival. After Medawar's demonstration that rejection was an immunologic event, the next logical question was: Why not prevent this phenomenon by suppressing the immune system? In the 1950s, corticosteroids and irradiation were used for immunosuppression.[34,35] In the 1960s, the antimetabolites 6-mercaptopurine and its derivative azathioprine were introduced, along with agents such as antilymphocyte globulin. These drugs were used either alone[36,37] or in combination with corticosteroids.[38–40] Graft survival improved, but surgical outcomes were dismal because these drugs acted indiscriminately and were associated with severe organ-specific and systemic adverse effects.

In 1964, the first hand transplantation was performed using pharmacologic immunosuppression.[41–43] Dr. Gilbert

in Guayaquil, Ecuador, transplanted the right forearm of a 28-year-old sailor who had lost his limb at the wrist level caused by a hand-grenade explosion the previous day. The donor was a laborer who had died of hematemesis (with gastric bleeding) a few hours earlier. The recipient was given heparin, dextran, and a broad-spectrum antibiotic after the surgery and was maintained on a combination regimen of prednisone and 6-mercaptopurine (6-mercaptopurine was replaced 24 h later by azathioprine). These drugs are considered primitive according to present day standards, and unfortunately, signs of acute allograft rejection occurred after 2½ weeks. The patient was then moved to Peter Bent Brigham Hospital in Boston, where, at 3 weeks, aggressive rejection set in, and the forearm had to be re-amputated at 4 cm above the wrist level. Unfortunately, the advanced state of necrosis prevented any histopathologic evaluation of the graft. This bold and pioneering attempt at hand transplantation laid the foundation to the successful attempts yet to come.

In 1976, another major breakthrough in transplantation came with the discovery of the immunosuppressive properties of the calcineurin inhibitor cyclosporine A.[44,45] In 1978, cyclosporine was first used clinically in organ[46] as well as bone marrow transplantation with remarkable results. The US Food and Drug Administration (FDA) approved cyclosporine A in 1983. Cyclosporine A, along with agents like anti-CD3 antibody (OKT3, introduced in 1981),[47] effectively reduced the reliance on high-dose steroids for the prevention of rejection. The calcineurin inhibitor tacrolimus (FK 506) was discovered in 1987,[48] clinical trials were conducted in 1989,[49] and FDA approval came in 1994. Tacrolimus led to dramatic improvements in solid organ transplantation,[50–53] allowing highly immunogenic grafts such as the small bowel to be transplanted.[54–56] The success of the calcineurin inhibitors cyclosporine A and tacrolimus made them the cornerstone drugs of the modern era of transplantation.[57] The 1990s saw the introduction of novel drugs such as the antimetabolite mycophenolate mofetil[58] (MMF, approved by FDA in 1995) and rapamycin[59] (sirolimus, discovered in 1976 but FDA approved only in 1999). Combining these drugs with a calcineurin inhibitor[60–63] were found to significantly reduce rejection and improve solid organ graft survival with a reduction in adverse effects.

fact that surgical, immunological, and functional results are highly encouraging, the need for long-term and high-dose immunosuppression to enable graft survival and to treat/reverse acute skin rejection episodes remains a rate-limiting obstacle towards widespread application.[67,68] The risks of immunosuppression are not benign. These include infection, cancer, and metabolic derangements. All these risks greatly affect the recipient's quality of life, alter the risk profile, and jeopardize the potential benefits of upper extremity transplantation. Furthermore, unlike in solid organs, clinical success is dictated not only by graft acceptance and survival but also by nerve regeneration, which determines ultimate functional outcomes. Novel strategies such as cellular and biologic therapies that integrate the concepts of immune regulation with those of nerve regeneration have shown promising results in small and large animal models. Clinical translation of these insights to upper extremity reconstructive transplantation could further minimize the need of immunosuppression and optimize functional outcomes, enabling greater feasibility and wider application of these procedures as an option for upper extremity amputees.

Evolution of upper extremity vascularized composite allotransplantation

Immunology of vascularized composite allotransplantation

Research findings in small and large animal models have vastly improved our knowledge of the immunologic aspects of vascularized composite allografts. These studies have demonstrated that the allograft is composed of different tissues, each with its own degree of antigenicity as a result of differing antigen expression and presentation mechanisms.[69] Each component in a vascularized composite allograft expresses different amounts of major histocompatibility complex (MHC) and tissue-specific antigens – important factors that elicit a recipient's cellular-mediated immune response.[70] Antigen recognition and targeting by the recipient's immune system also differs among the allograft tissue elements due to differential vascular and lymphatic supply. Altogether, these factors help explain the pattern of rejection that is observed in whole limb transplanted allografts. For instance, transplanted muscle evokes mainly a cell-mediated immune response, whereas skin induces both cellular and humoral responses.[71] Furthermore, skin and bone marrow appear to reject earlier and more aggressively than muscle, bone, cartilage, or tendon. Having an appreciation and understanding of the relative antigenicity of vascularized composite tissue components can facilitate the development of strategies aimed at decreasing the antigenicity of these specific components. In addition, understanding the relative antigenicity of specific allograft components enables the tailoring of immunosuppression, thus limiting the amount of immunosuppression needed when treating rejection.[72] Over the last few decades, our understanding of relative antigenicity and humeral/cellular immunity has allowed the testing of several tailored immunosuppressive regimens in small animal (rat) and large animal (porcine, canine, and non-human primate) VCA models.

Experimental background and scientific basis for upper extremity transplantation

In early rodent limb transplantation studies, recipients treated with various combinations of immunosuppressive doses of 6-mercaptopurine, or its derivative azathioprine, and prednisone all died from drug-induced side effects before the onset of macroscopic signs of rejection.[73] Even after the introduction of cyclosporine A, the use of high doses of cyclosporine A demonstrated no improvement in limb or animal survival.[74–78] In fact, cyclosporine A monotherapy was found to be uniformly unsuccessful in prolonging vascularized composite allograft survival in both small animal and non-human primate models.[79] Further studies in non-human primate models demonstrated that acute rejection could only be prevented with cyclosporine A when trough levels were 3–4 times the level achieved in human solid organ transplantation – levels that are associated with significant peri-transplant infections and malignancies.[80–83]

In 1996, Benhaim and colleagues demonstrated that a combination of cyclosporine A with an antimetabolite (such as mycophenolate mofetil) could successfully prolong rat hindlimb allograft survival.[84] Benhaim and his team were the first to show that predictable, long-term, functional limb allograft survival could be achieved. Using a similar regimen, others went on to demonstrate, using a swine model, that long-term survival of fully mismatched composite allografts was technically feasible.[85,86] Since swine and humans share immunological similarities including the structure of MHC and the expression of MHC class II antigens (on endothelial cells, epithelial cells, and dendritic cells),[87] these findings provided sufficient sound evidence, in both small (rodent)[88,89] and large animal VCA models,[85,86] that human upper extremity allotransplantation was feasible.[90]

Our extensive experience with organ transplantation has provided valuable information about the immunologic consequences of organ transplantation and the efficacy and toxicity of immunosuppressive drugs. The field of transplantation evolved from transplanted kidneys[91] and hearts[92,93] to livers,[94] lungs,[95] pancreas,[96] small bowel,[97] multiple abdominal viscera,[98] bone marrow,[99] and, most recently, vascularized composite allografts.[100,101] As expected, the initial results of allograft and patient survival after organ transplantation in the 1960s were poor. Editorials in major clinical journals,[102] including the *New England Journal of Medicine*,[103–105] questioned the feasibility and ethical basis of organ transplantation. There was great concern for the adverse effects of chronic immunosuppression, especially the risk of opportunistic infections and malignancies. During the next four decades, due to improvements in immunosuppression and in the management of post-transplant complications, this pessimism abated. Similarly, attempts at upper extremity transplantation,[106,107] after three decades of quiescence since the first attempt in Ecuador,[46,47] has also been met with vigorous skepticism. Interestingly, most of the criticism has come from hand surgeons.[108–114] Most argue that the risks of immunosuppressive therapy are justifiable in potentially life-saving organ transplantation, but not in upper extremity allotransplantation. Furthermore, many hand surgeons argue that the

immunological, ethical,[115,116] and psychological[117] issues associated with hand transplantation still need to be addressed.[118]

The rationale for proceeding with clinical trials of upper extremity transplantation using modern immunosuppression have been based on scientific progress on: (1) the availability of novel immunosuppressive drugs that have improved the efficacy and lower risk profile of immunosuppression; (2) the availability of highly efficacious treatments for opportunistic fungal or viral infections (such as *Pneumocystis carinii* and *Cytomegalovirus*); (3) the development of novel therapeutics for post-transplant malignancies (such as rituximab for post-transplant lymphoproliferative disorder, PTLD); (4) research on immunosuppressive drug regimens based on years of experience with solid organ transplantation; and (5) the success of human transplantation of all individual component tissues of the hand, including skin, muscle, tendons, vessels, nerve, bone and joint.[119]

Chronology of clinical upper extremity allotransplantation

In September 1991, the first conference on VCA was held in Washington, DC to "determine the clinical feasibility of transplanting limbs in patients with limb loss" and the "direction in which clinically oriented limb transplantation research should head."[120] In November 1997, the first International Symposium on VCA was convened in Louisville, Kentucky, to discuss the "scientific, clinical and ethical barriers standing in the way of performing the first human hand transplant." International experts at the meeting predicted that limb transplantation was not far from "becoming a clinical reality".[121] Within the next 22 months, 34 years after the first hand transplantation was performed,[46,47] surgeons in Lyon, France, performed the world's second unilateral hand transplant in September 1998.[106,107,122,123] In January 1999, the first unilateral hand transplant in the United States was performed in Louisville, Kentucky.[124,125]

Following these attempts, numerous centers in Europe, Asia, and the US have performed over 70 upper extremity transplantations. Most of these transplantations were wrist to mid-forearm amputations, except for two partial hand grafts in China, one partial hand graft in the US, and two cases of above-elbow transplantation.[126,127]

Clinical experience with upper extremity allotransplantation

Program, patient, procedural and protocol-related considerations

Program establishment and implementation

Starting a hand transplant program poses numerous challenges.[128,129] Solid organ transplantation and hand replantation are time-tested procedures and are now the standard of care. Hand transplantation is the amalgamation of the scientific principles of reconstructive surgery and the concepts of organ transplantation. Therefore, the success of any hand transplant program lies on its ability to foster collaboration between a multidisciplinary team comprised of a core group of hand (plastic or orthopedic) and transplant surgeons, psychiatrists, physical therapists, social workers, and transplantation nursing staff to name a few. Although the transplant clinical process is well established, it is also bound by tight regulation; this may come as a surprise to reconstructive plastic/hand surgeons who wish to start a hand program. Therefore, the experience of the solid organ transplantation members is essential when negotiating through the regulatory process. Such a joint effort can overcome the challenges that are inherent in a complex therapeutic option that integrates multiple specialties during the planning, procedural, and post-transplant phases.

Donor and recipient selection

The overall success of VCA relies on many factors. However, our own experience with upper extremity allotransplantation has taught us that proper evaluation, selection, and management of donors and potential recipients is probably the most important determinant of outcomes. Recipient screening and selection is a multistage process, which takes a multidisciplinary look into the patient's past medical history and pre-transplant life.[130] Data on psychological and social factors must be collected and evaluated prior to determining patient eligibility. While these psychological and social aspects of screening are critical, they are also the most difficult to assess. The worldwide experience with upper extremity allotransplantation has shown that only patients who are physically and mentally healthy, with adequate psychological and social support, and are highly motivated to undergo long-term (>6 months) intensive rehabilitation and therapy, are "good" candidates for upper extremity transplantation.

Decades of experience with solid organ transplantation has provided the field of transplantation medicine with well-established criteria for donor and recipient selection. Given that the field of upper extremity allotransplantation is still in its infancy, parameters for inclusion and exclusion of donors and recipients have yet to be fully established.[131,132] Tables 38.1 and

Table 38.1 **Donor considerations in upper extremity allotransplantation**

Demographic and phenotypic characteristics
Skin color, tone, and texture match Limb size and dimension (bone length and diameter match) Age, sex, race and ethnicity match if possible
Donors must be deceased (brain death declared)
Donor limb dissection and procurement must not interfere with organ recovery
Limb usually prepped first, perfused under isolated tourniquet, dissected after cross clamp and retrieved in sequence with heart and lung recovery. This minimizes overall ischemia time
History of malignancy (recent or remote) may be an exclusion
Paralysis of ischemia or traumatic origin, inherited peripheral neuropathy, infectious, post-infectious or inflammatory neuropathy, toxic neuropathy (i.e., heavy metal poisoning, drug toxicity, industrial agent exposure) or mixed connective tissue disease, severe deforming rheumatoid, or osteoarthritis in the limb may be exclusions

38.2 highlight the general selection criteria that has been used in upper extremity allotransplantation. Patients below the age of 18 years are generally excluded due to issues of informed consent of an experimental procedure. Furthermore, from experience in solid organ transplantation, it is known that pediatric patients are more likely to develop immunosuppression-related complications like PTLD than adults.[133] Patients over the age of 65 are also generally excluded because of increased immunosuppression-related complications, limited years of potential gain from the transplant, and decreased nerve regeneration potential. Medical screening of recipients includes a complete medical history and physical examination; routine laboratory studies; blood typing and cross-matching; human leucocyte antigen (HLA) typing; testing for panel-reactive antibodies; and serology for Epstein–Barr virus, cytomegalovirus, HIV, and viral hepatitis. Other tests include radiography (to plan for osteosynthesis), angiography (to exclude abnormal vascular patterns), electromyography, nerve conduction velocity, and functional magnetic resonance imaging (fMRI).

Procedural aspects

Donor limb procurement

Once an immunologically appropriate donor has been identified by the Organ Procurement Organization (OPO), further "matching" is necessary to ensure adequate skin color, gender, age, and length/circumference.[134] The level of procurement depends on the specific deficit on the recipient. Each recipient should receive a "custom" operation tailored to its respective anatomical deficits. For distal forearm and mid-forearm transplants, an elbow disarticulation provides enough soft tissue, vessel length, nerve length, and extra skin/bone for transplantation. For proximal trans-humeral transplants, a proximal humeral procurement at the most proximal level possible that can still maintain tourniquet control is usually adequate.[135] Proximal arm procurements may often require intra-thoracic cannulation and control of the subclavian vessels by the thoracic procurement team. The limb is perfused with cold histidine–tryptophan–ketoglutarate (HTK, Custodiol) or University of Wisconsin (UW) solution based on the individual center preference. Depending on the stability of the donor, level of procurement, and operating room space, upper extremity procurement may occur concurrently, before, or after standard organ procurement. We recommend procurement of the upper extremity before visceral organ procurement to minimize ischemia time as much as possible. Upon completion of hand retrieval (Fig. 38.2), the donor stump is closed, and the body can be fitted with a cosmetic prosthesis, allowing the family the option of an open-casket funeral. Following retrieval, the limb (wrapped in moist sterile gauze and placed in a polyurethane bag) is transported in a sterile container (provided by the OPO) with iced water at 4–6°C. Donor spleen and lymph nodes are collected and cell suspensions cryopreserved for future immune assays.

Fig. 38.2 Donor graft after isolated perfusion and disarticulation.

Table 38.2 Recipient considerations in upper extremity allotransplantation

Subjects can be of any race, color, ethnicity in good health
Age range for eligibility is variable but usually over 18 years and under 65 years
Subjects with congenital defects (e.g., transverse arrest) are currently excluded
The impact of the lack of pre-existing cortical recognition is unknown
Blindness is an exclusion in some programs
Eyesight necessary to follow the rigorous rehabilitation process. Additionally, visual feedback is critical for functional recovery
Rigorous psychosocial assessment is mandatory
Used to determine the motivation for transplantation, emotional and cognitive preparedness for the procedure, body image adaptation, level of realistic expectations regarding post-transplant outcomes, anticipated comfort with the transplant, personality organization/risk of regression, history of medication compliance/substance abuse, potential for compliance, and social support system/family structure
Use or attempted use of prostheses prior to transplant is a suggested requirement

Recipient surgery

The recipient operation is carefully planned prior to procurement and involves close communication between donor and recipient teams. After confirming donor match, the recipient undergoes placement of regional blocks, preparation for general anesthesia and induction therapy (most commonly with basiliximab, Simulect; anti-thymocyte globulin (ATG); or alemtuzumab, Campath-1H). Hand transplantation does not differ greatly from replantation. Instrumentation and technique are similar. A two-team approach is used. The donor team prepares the donor limb once received on the back table, tailoring the graft to the needs of the recipient and tagging the structures (Fig. 38.3). The two main hand transplant surgeons and assistant hand transplant surgeons (dissecting the donor limb) are assisted by one scrub nurse per extremity, two circulators per room, and at least one anesthesiologist. Based on the preoperative assessment of the recipient, tissue requirements from the donor will be known. The team dissecting the recipient must know exactly what measurements are necessary for the donor team to proceed. The recipient team will need to clearly identify the amount

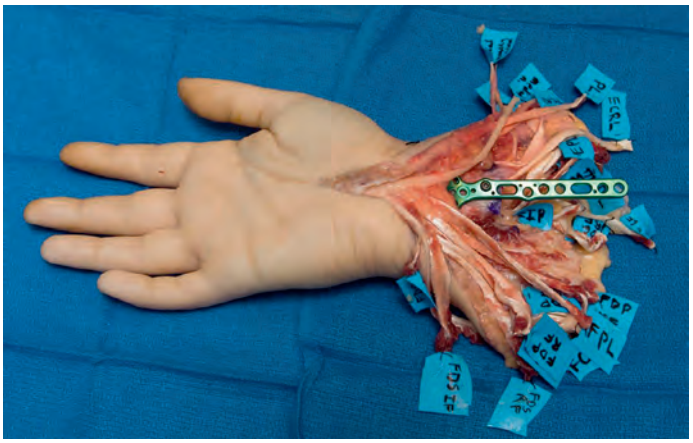

Fig. 38.3 Tagging of structures in the donor graft following back-table dissection improves technical success and reduces ischemia time.

Fig. 38.4 Reperfusion after extensor tendon reconstruction but prior to flexor tendon reconstruction.

of nerve, artery and veins required for transplantation. The sequence of tissue repair is to minimize ischemia time and could depend on surgical preference (Fig. 38.4). Commonly, it includes bony fixation → artery repair → vein repair (revascularization) → tendon repair → nerve repair → skin closure.

Our experience over the past two decades has elucidated specific principles that are important for the recipient operation. In general, nerve approximation should be performed as distally as possible. Over-dissection of donor arteries should be avoided to prevent postoperative bleeding and to minimize the risk of a persistent inflammatory reaction. The limb should be kept on sterile ice at all times with an interface between the ice and tissue to prevent thermal injury. Lastly, the authors typically use an implantable venous Doppler on the anastomosed veins and use pulse-oximetry probes on the transplanted hand for oxygenation monitoring.

Clinical tips

Distal forearm allotransplantation

Distal forearm allotransplantation often relies on the recipient's native extrinsic musculature, but this requires the careful approximation of median and ulnar motor fascicles for recovery of intrinsic function. Recipient incisions should create volar and dorsal skin flaps, while donor incisions should create radial and ulnar skin flaps for interdigitation. Tendon approximation can be performed using the Pulvertaft weave technique, facilitating immediate postoperative active/passive range of motion. The osteosynthesis can be performed with standard distal radius and ulna fixation techniques. The authors typically perform osteosynthesis first, taking great care to create a stable distal radioulnar joint (DRUJ), followed by arterial and venous anastomoses, followed by reconstruction of the extensors, then flexors, then nerves.

Clinical tips

Mid-forearm allotransplantation

Mid-forearm transplants require a critical assessment of recipient flexor and extensor tendons/muscle (Fig. 38.5). If the flexors and extensors are considered of adequate length with minimal damage, then muscle/epimysial/fascial/tendon repairs can be performed. Unfortunately, these repairs do not lend themselves to vigorous immediate postoperative therapy. The same sequence described above for the distal forearm allotransplantation procedure is used for the mid-forearm procedure. If the recipient extensors and flexors are deemed inadequate, the mid-forearm procedure follows the steps as performed in the proximal forearm allotransplantation procedure (see below), while maintaining the distal level of skeletal osteosynthesis.

Clinical tips

Proximal forearm allotransplantation

Proximal forearm allotransplantation requires the transplantation of donor flexor/extensor muscle groups in order to obtain meaningful digital excursion and strength in the hand. Volar and dorsal skin flaps are created on the recipient limb to protect the antecubital fossa and olecranon while donor limb skin flaps are elevated radially and ulnarly. The new flexor/pronator origins are fixed with bone anchors and sutures on top of the native flexor/pronator muscle mass at the medial epicondyle (Fig. 38.6A–D). Similarly, the extensor origin is fixated with bone anchors into the lateral epicondyle. Additionally, the annular ligament and radiocapitellar joint capsule of the donor are sutured to the extensor origin of the recipient. The radial nerve can be usually dissected to individual muscle groups such as the extensor carpi radialis branch, posterior interosseus branch, and extensor carpi radialis longus branch. We use an end-to-side brachial-to-brachial artery anastomosis to preserve maximum blood flow to the proximal ulna, radius, and native flexor/extensor motor groups. Veins are anastomosed in end-to-end fashion.

Clinical tips

Trans-humerus allotransplantation

Trans-humeral transplants can be categorized as distal, middle, and proximal. Distal humerus allotransplantation is performed with primary repair of the donor brachialis fascia and biceps/triceps tendon to the recipient brachialis fascia and biceps/triceps tendons (see Fig. 38.6E–H). End-to-end brachial artery/vein anastomoses (in addition to several superficial vein anastomoses) are performed. Fixation is achieved by utilizing single-plate osteosynthesis with the authors preferring a tapered 4.5/3.5 mm stainless steel locking compression plate. Skin flaps are elevated while maintaining skin integrity at the antecubital fossa and olecranon. In mid-humerus transplantation, one must decide whether the remnant flexor/extensor muscle groups will be adequate for active elbow motion. If one decides to maintain the native biceps and triceps to power the elbow, then muscle-to-muscle approximation is performed with as much tendon/fascia substance as possible. The use of fascial/tendon graft or allograft may be beneficial for strengthening the repair. The brachialis, due to its extensive origin on the humerus, can be transferred with the donor limb and be expected to function if the musculocutaneous nerve is adequately coapted. The same osteosynthesis, nerve repair, and vascular reconstructions are performed as described for the proximal humerus procedure. If one decides to transplant the donor flexor and extensor masses, then the steps for the proximal humerus allotransplantation are followed.

For proximal humerus allotransplantation, one may be required to transplant the entire flexor/extensor muscle compartments of the antebrachium (Fig. 38.7). Both the biceps short head and the biceps long head tendons are dissected off their origins on the donor limb. Both of these muscles can be sutured or woven into the recipient short head and long head/conjoint tendons, respectively. This level of transplantation also requires the division of the recipient pectoralis tendon with tagging for future repair. Osteosynthesis is performed utilizing a 4.5 mm locking compression plate, which is placed anterolaterally. Once osteosynthesis is complete, the most posterior compartment structures are reconstructed with the recipient and donor triceps muscle/tendons sutured to one another with some tension with the elbow in extension. Next, the radial, ulnar, and median nerves are coapted. Attention is then directed to the arterial and venous anastomoses. The brachial artery on the recipient is anastomosed to axillary artery of the donor limb and the brachial and cephalic veins are anastomosed proximally as well. Lastly, after reperfusion is complete, the biceps long and short head proximal tendons are woven and/or sutured with the elbow in flexion and under some tension, followed by musculocutaneous nerve coaptation. Once this is complete, the pectoralis tendon may be repaired or reinserted with bone anchors if necessary.

Protocol-related considerations

Maintenance immunosuppression

The current immunosuppression protocols applied to upper extremity allotransplantation are extrapolated from regimens used in solid organ transplantation. The overall amount of immunosuppression required to ensure graft survival is comparable with that used in renal transplantation. Such conventional immunosuppression has resulted in >95% patient and graft survival at 1 year after upper extremity transplantation.[126] The majority of hand transplant patients received either polyclonal (ATGs) or monoclonal (alemtuzumab, basiliximab) antibody preparations as induction therapy followed by a high-dose triple-drug combination for maintenance therapy including tacrolimus, mycophenolate mofetil (MMF), and steroids, although the dose and trough levels of each drug differs by center. Such regimens have proven sufficient to prevent early immunologic graft loss but have yet to prevent acute rejection episodes. Some programs follow steroid-avoidance regimens, while others rely on monotherapy immunosuppression. Successful reversal of acute rejection episodes (see Fig. 38.8) has been achieved using topical clobetasol or tacrolimus ointment with or without short-term bolus steroid doses.[136,137]

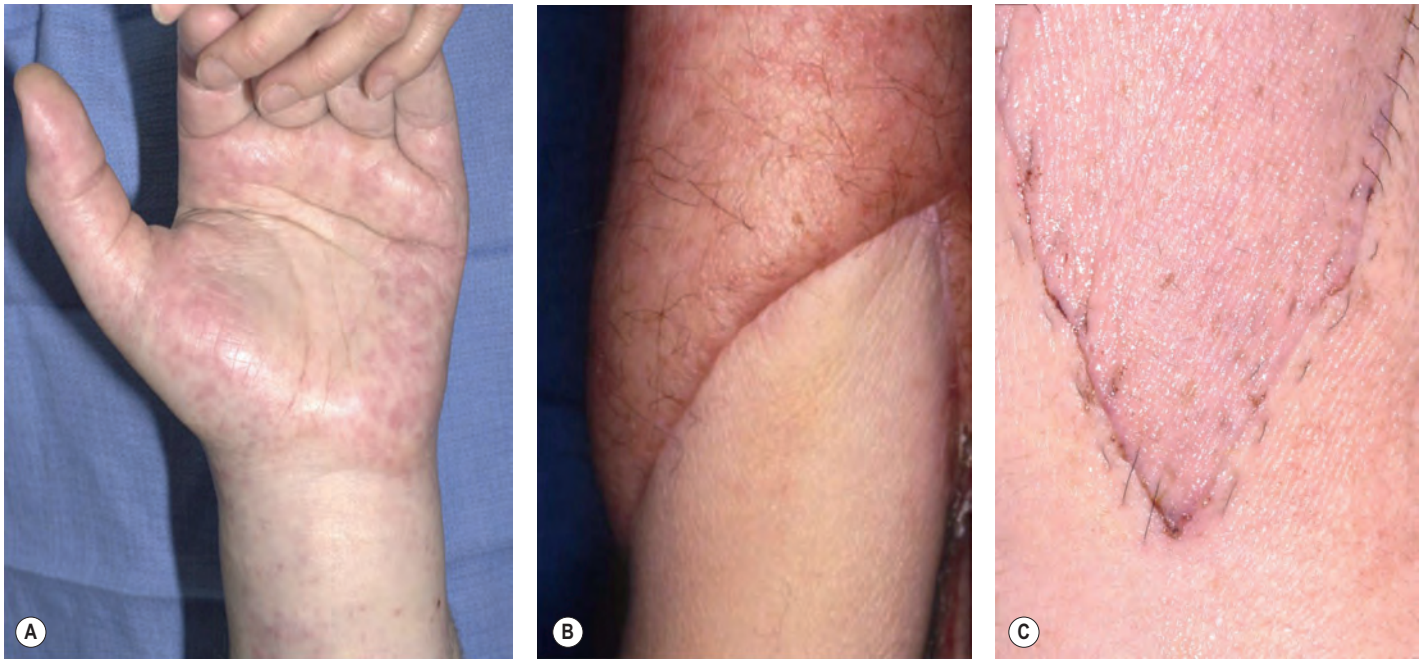

Fig. 38.8 (A–C) Clinical manifestations of acute skin rejection. These can range from discrete or diffuse maculopapular rash with or without edema and palmar involvement.

Rehabilitation and functional assessment after upper extremity allotransplantation

Rehabilitation and functional assessment are integral components of successful upper extremity allotransplantation.[138] A fully-trained hand therapist should be involved in the entire process from initial screening of prospective patients through final discharge. The goal is functional integration of the transplanted hand into the patient's daily activities. Successful rehabilitation of upper extremity transplant patients follows guidelines similar to replant protocols. There are several significant differences, however, such as the screening process for an ideal candidate and the monitoring for signs of rejection.

The preoperative evaluation process involves patient acceptance of the amputation, attempted prosthetic use, and the establishment of realistic goals for surgery and outcomes. This includes a full history and physical exam to document the range of motion (ROM) of the available joints; manual muscle testing (MMT) of available muscles; response of the residual forearm musculature to electrical muscle stimulation; documentation of pain and sensitivity complaints; scar quality; level of amputation; sensation; edema; skin and soft tissue integrity; and circumference of the forearms at varying levels, as well as length of the forearms. Different tests, questionnaires or instruments can be used to evaluate preoperative functional level and the status of residual muscles that will power the transplanted hand. As appropriate, electrical muscle stimulation, as well as isometric exercise, can help in preoperative strengthening of these muscles.

The goals of postoperative therapy, bracing, and splinting are similar to the goals in replantation surgery. Knowledge of the exact level of nerve repair, type of osteosyntheses, and details of tendon repairs are essential in planning of splinting and therapy. Uniquely, the hand therapist can help monitor for signs of rejection as the patient spends considerable time in rehabilitation after surgery. At our institution, a rigorous rehabilitation regimen has been implemented in all patients with 3–6 h of supervised therapy, 5 days a week during the first 3–6 months postoperatively, depending on the nature and upper extremity level of the transplant. Therapy must consist of passive and active ROM exercises with appropriate static and dynamic splinting to allow for gentle active flexion/extension, limit adhesions, and promote healing. Hand-based splints such as dynamic extension outrigger splints (Fig. 38.9) and anti-claw splints should be used in all patients. The outrigger allows for an intrinsic-plus position, protects flexors and extensors, and enables constant tension throughout the range of controlled motion. Compression gloves are useful in patients with lymphedema. Qualitative and quantitative tests for hand and upper extremity function such as the Carroll score,[139] the DASH[140] score, and the Hand Transplantation Score System[141] may be utilized, along with standard tests that evaluate motor and sensory recovery (Tinel's, Semmes–Weinstein monofilaments, 2PD, dynamometry, peg board tests, etc.). After discharge at 3–6 months postoperatively, communication and coordination with a certified local therapist is critical to ensure follow-up continuity of an intensive regimen and a home therapy exercise routine that is paramount to achieving functionality.

Assessment for rejection (host-versus-graft reaction)

Acute rejection (AR) is a T-cell- and/or antibody-mediated attack of the transplant by the recipient's immune system resulting in damage and ultimately loss of the graft. The skin has been demonstrated to be the prime target of rejection and monitoring of the skin by inspection is therefore considered most important for monitoring. Protocol graft-skin biopsies must be routinely performed until the first year plus whenever clinically indicated (visible signs of rejection such as a maculopapular rash). Biopsy samples may be analyzed by means

Fig. 38.9 Dynamic extension (crane) outrigger splint.

of histology and immunohistochemistry (staining for CD3, CD4, CD8, CD20, and CD68) for quantification and characterization of cellular infiltrates. Scoring for severity of acute rejection is accomplished using established standard grading criteria such as the Banff classification (Fig. 38.10 & Table 38.3).[142,143] Important clinical characteristics of AR include edema, erythema, escharification, and necrosis. Atypical rejection in the form of scaling, leuconychia or nail dystrophy can also occur (Fig. 38.11).[137] Biopsies must also be examined for evidence of chronic rejection (CR), including intimal hyperplasia and sub-intimal foamy histiocytes in the vessels of the skin, or muscle and tissue fibrosis (Fig. 38.12).

Immunomonitoring

Recipient and donor cells must be typed before transplantation for human leukocyte antigens (HLA).[144,145] Additionally, DNA samples from recipient/donor must be stored for future typing for MICA (MHC class I chain A-related) genes in those patients in whom anti-MICA antibody is detected. All sera should be screened by antihuman globulin-enhanced complement-dependent cytotoxicity assays (AHG-CDC), by enzyme-linked immunosorbent assay (to identify immunoglobulin G anti-HLA class I- and class II-specific antibodies independently) and by Luminex (allows for the identification of anti-MICA antibodies, as well as ascertainment of their donor specificity). The MICA and MICB antigens are expressed on surface of endothelial cells and epithelial cells and elicit a strong antibody response in recipients of solid organ transplants. Cell-mediated immunity may be measured by the ImmuKnow (Cylex) assay that detects adenosine triphosphate (ATP) synthesis in CD4 cells. Immune responses are reported in ng/mL of ATP and categorized as strong (>525) moderate (226–524) or low (<225). The desirable target zone for all transplant recipients is 280 ng/mL ATP, with a 96% negative predictive value for rejection or infection.

World experience and surgical outcomes

The International Registry of Hand and Composite Tissue Transplantation (IRHCTT) (www.handregistry.com) tracks upper extremity allotransplants around the world. The 2008 and 2010 reports[146] indicated that the average age of recipients is 32 years (range 19–54 years), usually male, with time from injury to transplant ranging between 2 months and 34 years. Follow-up ranged from 1 month to 11 years. Patient survival following hand transplantation stands at 100% in the United States. Long-term graft survival among patients in Europe and the United States is approximately >80%, with only a few graft losses. The first French patient who received an upper extremity transplant underwent amputation following irreversible graft rejection secondary to medication non-compliance. Two American patients lost the upper extremity allograft due to medication non-compliance as well, while another lost bilateral upper extremity allografts immediately postoperative due to sepsis.[147] Lastly, another American patient loss the upper extremity allograft due to ischemia secondary to vascular intimal hyperplasia.[148]

Highly compliant (with respective to immunosuppressive medication and rehabilitation) hand transplant recipients show highly encouraging early and intermediate functional outcomes (Video 38.1 ▶). However, these excellent results are dependent on intensive and continuous rehabilitation. Protective sensation has been achieved in all patients within 12 months. Furthermore, the transplanted upper extremity limbs show restored abilities not otherwise afforded by prostheses.[149] These include grasping small objects, pouring water from pitchers, tying shoe laces, playing chess, throwing a ball, and using hands in activities of daily living. Recipients have also demonstrated rapid progression of their Tinel's sign and

Table 38.3 **Banff grading scale**

Grade	Histopathology of skin
Grade 0	None. Rare inflammatory infiltrates
Grade I	Mild. Mild perivascular lymphocytic and eosinophilic infiltration. No involvement of the overlying epidermis
Grade II	Moderate. Moderate-to-severe perivascular inflammation with or without mild epidermal and/or adnexal involvement (limited to spongiosis and exocytosis)
Grade III	Dense inflammation and epidermal involvement with epithelial apoptosis, dyskeratosis, and/or keratinolysis
Grade IV	Necrotizing acute rejection. Necrosis of single keratinocytes and focal dermal–epidermal separation

early return (at 1 year) of temperature and pressure sensation, touch localization, and pain sensation in the hand and fingers. Return of motor power and grip strength has also been observed. Electrophysiologic testing has confirmed clinical evidence of motor function return in the transplanted intrinsic muscles of the hand, and, in a few cases, true recovery of partial intrinsic function. Early objective testing using the Carroll test has also demonstrated return of function in upper extremity transplant recipients similarly to what is achieved after replantation and superior to what is achieved with prostheses.[149,150]

Immunosuppression protocols currently used in solid organ transplantation have proved to be sufficient to prevent allograft loss. However, the use of these immunosuppression regimens have been associated with adverse effects including opportunistic infections (i.e., cytomegalovirus, *Clostridium*, herpes, cutaneous mycosis) and *Staphylococcus aureus*-mediated ulnar osteitis; and metabolic complications such as hyperglycemia, hyperlipidemia, impaired renal function, arterial hypertension, and aseptic hip necrosis requiring bilateral hip replacement. Of note, no life-threatening complications or malignancies have been observed thus far.[146]

Unique aspects of vascularized composite allotransplantation

Unlike solid organ transplantation, upper extremity transplantation allows the continuous visual monitoring of the allograft for rejection. This facilitates early diagnosis by directed biopsy, unbiased pathologic confirmation of the earliest stages of acute rejection, and timely intervention with precise and individualized tailoring of immunosuppressive medications. When treated adequately and effectively, acute rejection does not seem to impair graft function or long-term survival. Studies from our own group have shown that whole limb allografts elicit a less intense alloimmune response than its individual components.[69] In addition, vascularized composite allografts contain immunocompetent elements such as bone marrow and lymph nodes, which some argue may hasten the rejection processes or, conversely, result in graft-versus-host disease (GvHD). Unlocking the special immune reactivity of these allogeneic tissues, unlike solid organ transplantation, provides a unique opportunity for potential immunomodulation and tolerance induction.[151,152]

Unlike solid organ transplants that are immediately functional after revascularization, a vascularized composite allograft is dependent on peripheral nerve regeneration for functional recovery. Following transplantation, the recipient's nerves/axons have to regrow and reinnervate allograft muscles and other sensory end organs. This process allows the recipient to establish motor control and receive sensory input from the allograft. As a result, neuroregeneration represents a unique challenge in VCA. Interestingly, the use of immunosuppressive drugs like tacrolimus has been shown to not only prolong the survival of limb allografts but also to augment nerve regeneration in animal models.[153–155] However, at this time there are no available agents applicable in upper extremity allotransplantation that may augment the peripheral nerve regeneration process. Although our current clinical experience has been promising, future studies that seek to improve nerve generation in VCA could ultimately translate into improved function in transplant recipients, making the risk and costs associated with upper extremity allotransplantation more acceptable.

Emerging insights in vascularized composite allotransplantation

Cortical plasticity and neuro-integration

A unique phenomenon observed after upper extremity transplantation is the reassignment of portions of the recipient's brain to control the limb. This is known as brain "reorganization" or "plasticity". Previous studies have demonstrated that changes in cortical organization occur after amputation. However, the impact of limb transplantation on spatial reorganization of the motor cortex is just now being revealed.[156]

After an upper extremity amputation, the area of the brain that was once receiving signals from the hand is gradually lost and is "molded" for use in other functions. However, after an upper extremity transplant, the area of the brain that once controlled upper extremity function can re-establish its original function.[157] Such neural integration of the transplant into the pre-motor cortex has been demonstrated using fMRI studies and high-definition fiber tracking with diffusion tractography.

Chronic rejection

In solid organ transplantation, CR is defined as low-grade injury to the vascular endothelium of the allograft leading to irreversible allograft damage (see Fig. 38.12).[148] The hallmark of CR shared by all solid organs is concentric generalized sclerosis and low-grade perivasculitis of graft arteries leading to obliterative arteriopathy. These histologic changes are the result of both immunologic and non-immunologic factors.

According to the latest report of the IRHCTT (www.handregistry.com), over a dozen patients have undergone upper extremity transplantation and have been followed for 5–10 years post-transplantation without any objective measurable vascular changes suggestive of myointimal hyperproliferation (or other indirect signs of CR). However, experimental animal studies have demonstrated that, although

less likely to occur than solid organ transplantation, chronic rejection can be induced in VCA animal models. Unadkat *et al*. using a rat hindlimb transplant model, reported histological changes consistent with chronic rejection after repeated episodes of acute rejection.[158] Similarly, using a non-human primate facial allotransplantation model, Mundinger *et al*. demonstrated that multiple acute rejection episodes can result in chronic rejection.[159] Furthermore, more recent reports by Kaufman and colleagues provide clinical evidence for chronic rejection in six hand transplant recipients who show signs of arterial vasculopathy.[160] Aggressive and severe intima hyperproliferation was observed in the early postoperative period in two of the six recipients in their patient series. Morelon *et al*. reported clinicopathological findings and the first clinically documented evidence of chronic rejection in one of their face transplant recipients.[161] This case demonstrated that chronic rejection is a complex multifactorial process in VCA. Chronic rejection of the skin seems to be driven by the recipient's cellular immune effectors, which can lead to the development of scleroderma-like features, resembling chronic GvHD. In contrast, graft vasculopathy is probably more dependent on the humoral arm of the alloimmune response, as evidenced also in solid organ transplantation. Additional mechanistic studies in reliable small and large animal settings are needed to explore these complex rejection processes. With prolonged survival of upper extremity transplants, we will inevitably see over the next 1–2 decades more allografts develop signs of chronic rejection. We will then be able to better define, diagnose, and grade this condition. Meanwhile, we are limited to minimizing the known risk factors (from the solid organ experience) that may contribute to a postulated increase of chronic rejection in upper extremity allotransplantation (Table 38.4).

Tolerance approaches and immunomodulatory strategies

VCA is different to solid organ transplantation in that it is a life-enhancing, not a life-saving, procedure. Therefore, the development of tolerance is of utmost importance in order to reduce the toxicities associated with chronic immunosuppression. Although tolerance has been difficult to define, an "operational" definition is "the long-term functional survival of an allograft in a patient without the need for maintenance immunosuppression".[162] Such a tolerant state is characterized by hyporesponsiveness to donor tissue with the preservation of the recipient's immune responses to microorganisms (bacteria, viruses) and tumor antigens. The strategies for induction of allograft tolerance can be broadly divided into two approaches: (1) central deletional mechanisms or (2) peripheral regulatory strategies.[163]

When considering development of novel therapeutic strategies for minimization or avoidance of maintenance immunosuppression after upper extremity allotransplantation, cell-based protocols, including mixed chimerism induction using donor bone marrow cells, mesenchymal stem cells (from various sources such as bone marrow or fat), regulatory T and B cells, or tolerogenic dendritic cells (TolDCs) have all demonstrated potential for inducing tolerance in preclinical animal models.[164] For example, in the case of bone marrow-derived stem cell therapy, stem cells are transplanted into the recipient, and the newly developing recipient T cells begin to see these donor cells as "self". Therefore, the recipient perceives an organ from the same marrow donor as "self" and accepts it without immunosuppression. The mixed chimerism model involves induction of allograft tolerance by establishing long-term mixed chimerism, a state in which both donor and recipient hematopoietic cells coexist.[165] This strategy requires engraftment of donor stem cells. Some vascularized composite allografts, in particular limb transplants, bring with them vascularized bone marrow in its microenvironment enabling a sustainable, renewable source of donor bone marrow cells that could potentially promote immunoregulation without the need for engraftment.[166,167] In solid organ transplantation, infusion of donor-derived bone marrow cells has been shown to reduce/avoid maintenance immunosuppression required for graft survival.[168] Bone marrow is critical for the establishment of macrochimerism, microchimerism, or mixed

Table 38.4 Recommendations to reduce risk of acute and chronic rejection in hand transplantation

Immunologic factors		
1.	Prevention of AR	Use selective, specific and safer immunosuppressive drugs. Potent and targeted induction agents like Campath-1H (alemtuzumab) could maximize AR prevention, allowing monotherapy maintenance and steroid avoidance
2.	Treat steroid-resistant or CD20-positive AR	Campath-1H (anti-CD52) or rituximab (anti-CD20)
3.	Monitor and curb medication non-compliance	Suggested methods include electronic measurements of pill container opening, regular monitoring of blood drug levels, frequent clinical examinations, repeated biopsies or immune monitoring
4.	Reduce risk factors	Exclude patients with high PRA, avoid sex/racial mismatch between donor/recipient and exclude hand allografts from CMV+ donors.
Non-immunologic factors		
1.	Choose younger donors and exclude donors with systemic atherosclerosis	
2.	Avoid prolonged cold ischemia	
3.	Treat recipient risk factors aggressively (antidiabetic, antihypertensive, or lipid lowering drugs with dietary or lifestyle changes if necessary).	

AR, Acute rejection; PRA, panel reactive antibody; CMV, cytomegalovirus.

chimerism after organ transplantation, and is a known prerequisite for donor-antigen-specific tolerance induction.[169,170]

Allograft rejection is caused by activated T cells and cannot occur in their absence. Campath-1H (alemtuzumab) is an antibody that binds to the CD52 receptor, critical for T-cell function in humans.[171] Campath-1H leads to peri-transplant depletion of T cells, B cells, and monocytes, but spares bone marrow stem cells. Renal transplant trials with Campath-1H have demonstrated that allograft survival could be prolonged but with low doses of maintenance immunosuppression.[172,173] Such a state of tolerance is called "prope-tolerance" or "tolerance-lite". Campath 1H has been used an induction agent in several upper extremity transplant programs toward the goal of minimizing maintenance immunosuppression; however, its efficacy is still unknown.

Over the past five decades, more than 50 different methods of tolerance induction have succeeded in small or large animal models. Yet tolerance protocols have not widely replaced immunosuppression in clinical transplantation. The transition of experimental tolerance protocols to the clinical transplant arena is fraught with questions: Can experimental tolerance protocols meet the stringent fail-safe clinical standards of reliability and efficacy? How durable or persistent is the tolerant state? How immunocompetent will the recipient be? What is the universally accepted test or "assay" for tolerance? What are the long-term adverse effects of tolerance induction? However, the few tolerance strategies that have been translated to the clinic hold great promise for becoming more widespread and clinically routine in the near future. Until this is achieved, conventional immunosuppression, as used in solid organ transplantation, will remain the "gold standard" in VCA.

Future directions of upper extremity reconstructive transplantation

VCA has emerged as a viable option to treat patients with severe defects not amenable to traditional autogenous reconstruction. Although surgical outcomes over the last two decades show great promise, the long-term results with this innovative procedure are still emerging. The main obstacles that limit the success of upper extremity VCA are the current immunotherapy requirements as well as current limits to peripheral nerve regeneration, thus limiting functional outcomes with very proximal defects. However, with current advances in cell-based therapy and the increasing immunological understanding of vascularized composite allografts, research in reconstructive transplantation is uniquely poised to make significant breakthroughs in transplant immunology, with the potential to make the application of this innovative reconstructive treatment modality widely available.

Hand therapy

Christine B. Novak and Rebecca L. Neiduski

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- In optimal situations, hand therapists work closely with hand surgeons to maximize non-operative and postoperative outcomes for patients with upper extremity conditions.
- Assessment in the area of impairment and body structures includes edema, wound, vascularity, pain, range of motion, strength, and sensibility.
- Following nerve injury and with chronic nerve compression, rehabilitation strategies should be directed not only to the distal recovery but also to re-establishing normal movement patterns and cortical remapping.
- Active motion regimens following flexor tendon repair are becoming more prevalent in both research and practice. The inclusion of a controlled arc of motion with the wrist positioned in extension creates an optimal force/excursion ratio.
- Hand fractures are challenging and require careful attention to bony integrity and maintenance of the flexor and extensor tendon-gliding systems.

Introduction

Tenets of hand therapy

According to the Hand Therapy Certification Committee (www.htcc.org/about/index.cfm), the specialty of hand therapy is defined in the following manner:

> *Hand therapy is the art and science of rehabilitation of the upper limb, which includes the hand, wrist, elbow, and shoulder girdle. It is a merging of occupational therapy and physical therapy theory and practice that combines comprehensive knowledge of the structure of the upper limb with function and activity. Using specialized skills in assessment, planning and treatment, hand therapists provide therapeutic interventions to prevent dysfunction, restore function and/or reverse the progression of pathology of the upper limb in order to enhance an individual's ability to execute tasks and to participate fully in life situations.*

In optimal situations, hand therapists work closely with hand surgeons to maximize non-operative and postoperative outcomes for patients with upper extremity conditions. The purpose of this chapter is to provide the plastic surgeon with an overview of the evaluative and rehabilitative approaches for patients with nerve, tendon, skeletal, and soft-tissue conditions as afforded by collaboration with a hand therapist.

Evaluative guidelines

A comprehensive evaluation provides valuable diagnostic and prognostic information to the plastic surgeon and hand therapist prior to intervention, and serves to inform clinical decision-making for management (non-operative and postoperative) of patients with upper extremity conditions. In concert with the International Classification of Functioning, Disability and Health,[1] hand therapists are well versed in the clinical assessment of patients in areas of impairment, activity, and participation.

Clinical tips

Assessment

- Comprehensive evaluation can provide diagnostic and prognostic information and inform clinical decision making for non-operative and postoperative management.
- Self report questionnaires provide important information to assess impact of injury, activity and participation
- Pain experiences should be documented with subjective report of intensity, quality and impact on function.
- Physical impairments can be assessed related to muscle weakness with manual muscle testing or dynamometers and sensory dysfunction with measures of threshold and discrimination

Assessment in the area of impairment and body structures includes edema, wound, vascularity, pain, range of motion, strength, and sensibility. Edema is most commonly assessed with circumferential measurement. However, it is more accurately assessed using volumetric displacement with a reported test–retest reliability within ±3 mL.[2] Wound assessment is characterized by both descriptive and objective components, including a detailed patient history and observation of wound size, color, drainage, odor, and temperature. Vascularity can be assessed both proximally and distally in the upper extremity using provocative maneuvers. In addition to the Allen's test for circulation via the radial and ulnar arteries at the wrist, vascularity may be assessed more proximally using Adson's maneuver at the subclavian artery; the costoclavicular maneuver and hyperabduction test assessed via the radial pulse; and the elevated arm stress test, as described by Roos.[3–5] Pain is a subjective and multifaceted construct, and should be assessed before, during, and after therapeutic interventions. Numeric, verbal, and visual analog scales are commonly used to rate pain intensity and have been identified as having good construct validity.[6] Simple measures and scales that assess only pain intensity may be inadequate to capture and measure the multidimensional aspects of the pain. The McGill Pain Questionnaire and the Short-Form McGill Pain Questionnaire (SF-MPQ) are the most widely used pain questionnaires to assess the multidimensional qualities of the pain experience and overall have been shown to possess good to excellent psychometric properties.[7–10] The SF-MPQ consists of a pain intensity visual analog scale, the present pain intensity index, and 15 pain adjectives (11 sensory, four affective) to calculate the pain-rating index.

Goniometric measurement (Video 39.1 ▶) is used to assess passive and active range of motion. While electrogoniometers and costly systems are available for clinical use, standard manual goniometers are easily portable and inexpensive. In a study assessing wrist motion, high intra-rater reliability was reported using multiple techniques to assess wrist range of motion, with a dorsal volar approach demonstrating the highest inter-rater reliability.[11] Ellis and Bruton found composite finger flexion measurements to be as reliable as manual goniometry between raters, with manual goniometry demonstrating increased intra-rater reliability for measurement of the proximal interphalangeal joint.[12] Manual muscle testing is employed to isolate strength of individual muscles and often graded using the Medical Research Council (MRC) grade 0–5 classification.[13] In a review, Cuthbert and Goodheart reported good evidence to support the use of manual muscle testing for patients with neuromusculoskeletal dysfunction.[14] Sensory impairment is most often assessed using monofilaments for threshold testing (Video 39.2 ▶) and/or two-point discrimination for innervation density.[15–19] Using standardized techniques, good validity and reliability have been shown using these types of assessment tools.[15,17,20–23] The Ten Test was introduced as a quick assessment of light touch sensation and has been shown to be a valid measure as compared to monofilament testing.[24]

Clinical evaluation may also include assessment of grip and pinch strength.[25–28] A calibrated, hand-held dynamometer is used to measure grip strength in a standard position of glenohumeral adduction, elbow flexion, and neutral forearm rotation.[26] One trial has been identified as equally reliable to the best or average of three trials and elicits less patient discomfort.[25] The influences of hand size and span have also been identified as factors to consider when selecting the grip handle position.[29–31] Calibrated gauges are also used to measure both lateral and tip pinch.

A paradigm shift towards increased incorporation of qualitative and patient-reported data into outcomes assessment is strongly encouraged as a means of assessing participation.[32] Clinical evaluation tools that assess physical impairments, such as range of motion, have demonstrated limited responsiveness and weak association to patient self-report measures, which may indicate that these types of assessments evaluate different constructs.[33–36] Research has also shown a weak relationship between patient perception of health-related quality of life and ratings from healthcare providers.[37] Patient perception of ability has been suggested as more valuable than functional evaluations.[38] In addition, patient assessment of the importance of change in health status is preferable to that interpreted by the healthcare professional.[39] Despite numerous tools and support in the literature, the incorporation of self-report outcome measures is inconsistent in clinical practice.[40]

The Disabilities of the Arm, Shoulder, and Hand (DASH), one of the most recognized self-report outcome measures for the upper extremity, was published as a joint effort of the American Academy of Orthopedic Surgery and the Institute for Work and Health.[41] The DASH was created as a tool to assess upper extremity disability that would allow comparison of conditions throughout the upper extremity while considering it a single, functional unit.[41,42] Careful development of this tool, including an extensive literature review and consideration of questions and attribution, has made it a popular tool in upper extremity research and clinical practice. However, uniform application in different pathologies and timing of assessments is necessary for valid comparisons of upper extremity disability scores.[43] Other studies that investigated the DASH questionnaire as a single construct using factor analysis found a three-factor structure was the best model fit.[44]

Rehabilitation following nerve injury/surgery

Following nerve injury and with chronic nerve compression, neural changes occur in the peripheral and central nervous system. The primary focus has been on the alterations that occur to the nerve and the distal sensory receptors and muscle fibers. The proximal changes that occur in the central nervous system have been less emphasized. Cortical remapping and cell body changes have been documented with nerve injury and nerve compression. Therefore to optimize outcome, rehabilitation strategies should be directed not only to the distal recovery but also to re-establishing normal movement patterns and cortical remapping. This section will review postoperative management following surgery for carpal and cubital tunnel syndrome, nerve repair, and nerve transfers.

Compression neuropathies

Postoperative care following surgery for compression neuropathies is a balance between protecting the surgical repair site and maintaining neural mobility. To minimize adhesions

and scarring, early motion is advocated. However, the definition of "early motion" following release of an entrapment site is variable and is determined by the surgical procedure performed and surgeon preference.[45,46] Compared to the historical reports in the literature, the tendency has been to decrease the length of time of immobilization and to use less restrictive postoperative dressings.[47,48] Range-of-motion exercises are instituted and restoration of muscle balance is also a goal of postoperative care.

In the acute postoperative stage, consideration is given to edema control and pain management, and the patient is instructed in strategies to minimize edema and pain. Even in the early stages following surgery, nerve-gliding exercises are instituted with range-of-motion exercises to the distal and proximal joints that are not included in the bulky dressing. These types of exercise will provide some longitudinal movement of the nerve to minimize adhesions.

Carpal tunnel syndrome

Postoperative care

Historically, following release of the carpal tunnel, immobilization was used to protect the wound and to prevent bowstringing of the flexor tendons by restricting motion at the wrist. With recognition of the importance of early motion, the duration and type of immobilization following carpal tunnel release have substantially decreased. In our practice, a bulky dressing is used for restriction of wrist movement and for patient comfort in the immediate postoperative period. Following surgery, the patient is instructed in range-of-motion exercises for the fingers, elbow, and shoulder. Two days following surgery, the bulky dressing is removed and the patient is instructed in range-of-motion exercises for the fingers, wrist, elbow, and shoulder. For patient comfort, an orthosis in a wrist neutral position may be used at night. The sutures are removed 12–14 days following surgery. Return to work is dependent upon the type of job and specific patient factors. However, at 4 weeks after surgery, patients should have full range of motion and may lift up to 2 lb (0.9 kg) and, by 2 months following surgery, full activity without restrictions is expected.[47] Depending on the severity of nerve compression, the duration of time required to achieve full sensory and motor recovery may vary.

Cubital tunnel syndrome

With failure of non-operative treatment, there are numerous surgical procedures performed for the operative treatment of cubital tunnel syndrome, ranging from simple decompression, medial epicondylectomy, to various types of anterior transposition of the ulnar nerve.[47] With each procedure, there are numerous protocols for the postoperative management and many vary depending upon surgeon preference. In general, early motion is recommended to minimize adhesions and scarring of the ulnar nerve and surrounding soft tissue.

Postoperative care

There is wide variability in the duration of immobilization following surgery for cubital tunnel syndrome and this depends upon the operative procedure performed and surgeon preference. The period of immobilization is increased for those procedures that involve more complex release of the soft tissue surrounding the ulnar nerve (i.e., least immobilization for simple decompression). In most cases, the postoperative dressing may be removed 2–3 days after surgery and then a postoperative method of immobilization may be used if required. For patient comfort, a sling may be used at night to restrict upper extremity motion while the patient is sleeping. The postoperative care following a intramuscular or submuscular transposition will be described.[47] In our experience, patients may begin range-of-motion exercises (fingers, wrist, forearm, elbow, and shoulder) when the dressing is removed at postoperative day 2 or 3. Patients are cautioned to perform these exercises slowly and initially to avoid full forearm supination combined with full elbow extension because this motion will place the most stress on the soft-tissue repair. Initially elbow extension is performed with the forearm in pronation and then, as a separate exercise, forearm supination is performed with the elbow flexed at 90°. When the patient is able to move comfortably into full supination, forearm supination is combined with elbow extension. A sling is used at night for patient comfort to avoid rapid elbow extension and may be discontinued when the patient has achieved full elbow extension with full forearm supination. The emphasis in the early postoperative period is to regain full range of motion and it is anticipated that this is achieved within the first 2–3 weeks following surgery. If the patient appears to be progressing slowly and lacking improvements in range of motion, more structured hand therapy is recommended. Strengthening exercises are instituted 1 month following surgery and full activity is permitted at 8 weeks.

Concomitant soft-tissue muscle imbalances and other sites of nerve compression in the upper extremity may require rehabilitation therapy to achieve full recovery. Some patients may also have restricted neural excursion, cervicoscapular discomfort, and/or rotator cuff tendinitis associated with muscle imbalances in this region. Specific exercises to address these more proximal soft-tissue and neural structures will help to ameliorate these types of symptoms in patients with more diffuse upper extremity discomfort, paresthesia, and/or numbness.[49–54]

Nerve repair

Changes in the peripheral and central nervous system begin shortly after nerve injury and continue through recovery. The ultimate functional outcome depends upon reinnervation of the sensory receptors and motor end plates and the appropriate remapping of the motor and sensory cortex. Based upon these proximal changes, rehabilitation is maximized by including strategies directed towards these cortical alterations.

Early postoperative care

In the immediate postoperative period, the primary goal is to protect the nerve repair site. Initially, a bulky dressing is used and, if required by the operative procedure, more rigid support can be utilized. The patient is instructed in edema control and range-of-motion exercises for the joints that are not immobilized by the bulky operative dressing. The initial dressing is removed within a few days following surgery. Immobilization is continued with the use of a custom-made or prefabricated orthosis or, in some cases, a sling or shoulder

immobilizer may provide sufficient support to restrict forces on the repair site. Nerve repairs compared to nerve grafts or nerve transfers are typically immobilized for longer periods of time – in some cases up to 3 weeks. The timing of immobilization will depend upon the location of the nerve repaired and the amount of nerve mobility and stress on the nerve coaptation site. In some cases, such as with digital nerve injuries, some surgeons have advocated no immobilization after the initial operative dressing has been removed.[55] With a nerve graft or transfer, there is excessive nerve length at the repair site and lack of tension with these reconstructions and, as such, these types of reconstruction require less rigid immobilization and may be mobilized earlier (7–14 days) compared to nerve repairs. However, other soft tissues (tendons, muscles, or ligaments) that may have been released or repaired in the operative procedure may prolong the period of immobilization. For example, repair of the pectoralis major with exploration of the brachial plexus may require 4 weeks of immobilization in internal shoulder rotation using a shoulder immobilizer to avoid tension on the soft-tissue repair or, with acute injuries that may involve a tendon repair, a tendon rehabilitation protocol would be followed.

Early postoperative pain resulting from the operative procedure may be controlled with analgesics, edema control, early motion, and hand therapy. However, ongoing severe neuropathic pain may negatively impact outcome and therefore early pain management intervention is recommended.[56,57] Neuropathic pain following trauma may require a comprehensive multidisciplinary approach and, as such, referral to a pain management team may be warranted.

The use of electrical muscle stimulation is often advocated following nerve injury to prevent muscle degeneration and to protect the muscle fiber until regeneration occurs. However, the literature does not present strong evidence for the use of this modality following nerve injury.[58,59] Historically, the rationale for electrical stimulation of denervated muscles has been to retain integrity of the muscle fibers while waiting for muscle reinnervation. Studies using animal models with denervated muscles and electrodes implanted directly into the muscle have shown preservation of some normal muscle properties.[60,61] However, no efficacy trials have provided evidence of these benefits in humans. Evidence presented in the literature suggests that longer durations of axotomy and Schwann cell denervation are predictive of poor functional outcome.[62,63] Low-frequency stimulation of the nerve following nerve transection and repair in animal models has shown an increase in axonal regeneration into the appropriate neural pathway.[63,64] In patients after carpal tunnel release, 1 h of low-frequency nerve stimulation resulted in significantly faster motor reinnervation.[65] This evidence provides the impetus for future investigation into the benefits of direct nerve stimulation to improve recovery following a motor nerve injury. However, the use of direct current stimulation for denervated muscles has not been shown to be efficacious in humans and, as such, is not advocated by the authors.

Late rehabilitation

In the later phases of rehabilitation, sensory re-education has been recognized as an integral component of therapy following nerve injury; however, the importance of motor re-education following nerve injury has been less emphasized. The integration of function between the sensory and motor cortex is essential for restoration of sensorimotor control and to optimize outcome. The concept of cortical plasticity and its importance to recovery following nerve injury have gained increased attention in the past decade.

Sensory re-education

Following sensory nerve reconstruction, sensory re-education is commonly included in the rehabilitation program to improve hand sensibility and function. These strategies have been used to maximize sensory recovery, to decrease pain and for desensitization related to allodynia and/or hyperalgesia.[66–70] Desensitization exercises using different textures and vibration techniques may be used to decrease allodynia and/or hyperalgesia. The concept of vibration for desensitization relates to the gate control theory of pain and stimulation of large A-beta fibers with vibration.[71] The use of small-amplitude vibration for desensitization is best tolerated by patients and may be achieved by using an electric shaver with the cap on it. This will provide an easy technique for the patient to continue this exercise in a home program. With decreasing sensitivity, the area of allodynia may be challenged with different types of texture to promote sensory re-education and appropriate cortical mapping.

With evidence of reinnervation of the sensory receptors, sensory re-education is advocated.[66] This typically includes a structured program with an emphasis on textures, localization, and discriminatory tasks.[66] The exercises are progressed to challenge the sensory system as the patient's sensation improves, beginning with varying textures, localization exercises, and then discriminatory tasks. However, strategies to enhance and promote cortical remapping have been also advocated in the earlier phases following surgery. Rosen and Lundborg have described re-education programs using mirror imagery, visuotactile training, and audiotactile interaction to enhance the functional reorganization of the sensory cortex in the early phases of recovery before there is evidence of sensory receptor reinnervation.[72,73]

Mirror visual feedback has been extensively used for treatment in patients following stroke and with amputation injuries and has been more recently reported for use in patients with pain syndromes or nerve injury.[74,75] The concept of mirror visual feedback is that patients observe their reflected image in the mirror, which would appear as the contralateral limb (Fig. 39.1) and thus activate the brain. Patients may perform specific exercises or movements with the unaffected hand or extremity and in the mirror it would appear as normal movement to the affected hand or extremity. With improvement in sensory function or decreased pain, more complex activities may be introduced and also combined with motor re-education.

Motor re-education

The goals of treatment for motor function are directed towards re-establishment of normal movement patterns and muscle balance. Following nerve injury, motor re-education is not as frequently advocated compared to sensory re-education. Alterations in cortical mapping and motor patterns occur following injury to a motor nerve.[76,77] With reinnervation of the denervated muscles, muscle imbalances will remain due to weakness of the reinnervated muscles compared to the

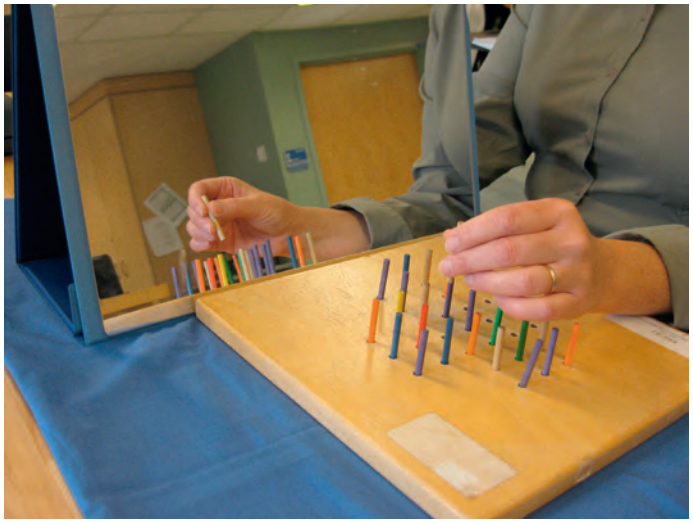

Fig. 39.1 Re-education can be optimized with the use of mirror imagery. This allows the patient to visualize the uninjured hand as the contralateral hand and perform the task. *(Courtesy of Christine B. Novak, PT, PhD.)*

uninjured muscles and also compensatory movement patterns that have been performed since the injury. Particularly in patients with brachial plexus injuries, the duration of time from injury until muscle reinnervation occurs may be prolonged (12–18 months) and abnormal movement patterns are established. Therefore motor re-education will provide the opportunity to focus on appropriate muscle recruitment and muscle balance. Even in patients with only sensory loss following median nerve injury, there will be alteration of the motor pattern due to compensation in movements as a result of numbness to the sensory distribution of the median nerve. Therefore, the emphasis should be on restoration of the integration of motor and sensory re-education following nerve injury. Sensorimotor control to perform upper extremity tasks requires the coordination of both the sensory and motor systems.[78] Alteration in either motor or sensory function as a result of nerve injury will impact sensorimotor control in the upper extremity. Improvement in hand function may occur with increased use of the hand, but progress may be enhanced with the use of activity-based sensorimotor retraining, emphasis on control, and appropriate feedback learning. As with any new task learning, repetition and feedback are essential and therefore patient education and an effective home program should be emphasized.

Nerve transfers

Historically, motor nerve transfers were used as a salvage procedure when nerve repair or graft was not possible, such as in the case of an avulsion of the proximal nerve source, and there was limited potential for excellent outcome. However, the utilization of nerve transfers has increased, particularly with proximal peripheral nerve injuries, where recovery is limited due to the lengthy distance from the injury to target muscle fibers and prolonged time for reinnervation.[79,80] Because a nerve transfer utilizes an innervation source closer to the target muscle, the distance and time for reinnervation are shorter and the results following these types of transfer have been very encouraging.[81–88] However, optimal results depend not only on the number of regenerating motor axons and reinnervation of muscle fibers but also on cortical plasticity, remapping, and functional integration. Previously established motor patterns and cortical maps are no longer relevant because a new proximal nerve source is used with a nerve transfer. Studies have evaluated cortical mapping following nerve transfers, muscle transfers, and toe-to-thumb transfers.[76,77,89–91] Collectively, these studies have illustrated shifts in the motor cortex following transfers and the importance of effective relearning to optimize outcome. Therefore, rehabilitation programs after nerve transfer should include not only range-of-motion and strengthening exercises to regain muscle balance, but also motor re-education to promote normal movement patterns and appropriate cortical mapping.[92,93]

Clinical tips

Retraining after motor nerve transfer

- Following nerve injury, rehabilitation should be directed not only to the distal motor and sensory recovery but also to cortical remapping and normal movement patterns.
- Immobilization for 7–10 days after nerve transfer.
- Initially contract muscle from the "donor" muscle to contract reinnervated recipient muscle.
- Utilize synergistic movement patterns and sensorimotor re-education.
- Be aware of antagonistic muscle co-contraction.
- Restore muscle balance.

With nerve transfers, there is alteration of the proximal nerve source, therefore muscle contraction is initially recruited with "contraction" of the muscle from the donor nerve because of the established motor pattern. The new recruitment pattern from the new proximal nerve source from the donor nerve has yet to be recognized. Even with evidence of muscle reinnervation, the newly innervated muscle may not contract with initiation of the intended action, but rather requires "contraction" of the muscle from the donor nerve. To facilitate relearning, contraction of the muscles on the uninjured contralateral side will provide cortical input of a normal movement. The relearning associated with nerve transfers is similar to relearning following tendon transfers. In general, relearning is more straightforward following a transfer (nerve, muscle, or tendon) when the donor is from a muscle with a synergistic action. While it is possible to relearn an action that is from a muscle with an antagonistic action (such as triceps-to-biceps muscle transfer), the relearning is more difficult compared to a synergistic muscle action.

In patients with brachial plexus avulsion injuries, an intercostal-to-musculocutaneous nerve transfer is often performed to restore elbow flexion.[94] Postoperative education often includes deep-breathing exercises to provide a stimulus to the intercostal nerves for contraction of the biceps and brachialis muscles, which are innervated via the musculocutaneous nerve. While deep breathing does initiate contraction of the newly innervated elbow flexors, it is difficult to provide a prolonged contraction for re-education and strengthening. The abdominal muscles and intercostal muscles are activated with core abdominal exercises. Therefore core-strengthening exercises will also provide contraction of the biceps and

brachialis muscles in patients who have had an intercostal-to-musculocutaneous nerve transfer. The muscle activity in the elbow flexors associated with trunk flexion has been shown by Chalidapong and colleagues.[95] Core exercises which use the abdominal and intercostal muscles may begin early in the rehabilitation stages (Fig. 39.2) and with early reinnervation will recruit the muscle fibers in the brachialis and biceps.

More recent descriptions of nerve transfers to restore elbow flexion have included donor pectoral nerves and fascicles from the median and ulnar nerves.[83,88] To assist with the retraining following these types of nerve transfer, re-education may begin preoperatively with education on the unaffected extremity and contraction of the muscles from the donor nerve and recipient muscle. In this way, the patient may practice co-contraction of these muscle groups to understand better the re-education that will be required with reinnervation of the denervated muscles. For a medial pectoral-to-musculocutaneous nerve transfer, the patient will simultaneously contract the pectoral and the biceps (and brachialis if included) muscles (Fig. 39.3). This is initially done bilaterally and then only to the injured side. Using place-and-hold positioning in 90° of elbow flexion, an isometric contraction is performed. Once the patient is able to hold this contraction against gravity, the degree of flexion may be altered and progressed through a full range of motion. A double fascicular transfer from the median and ulnar nerves to restore elbow flexion will require contraction of the wrist flexors to initiate contraction of the biceps and brachialis muscles (Fig. 39.4).

To restore innervation to the ulnar nerve intrinsic muscles, an anterior interosseous nerve (AIN) to deep motor branch of the ulnar nerve transfer may be performed.[84] With an AIN to deep motor branch of the ulnar nerve transfer, attempts by the patient to pinch must be initially combined with forearm pronation to recruit the newly innervated intrinsic muscles from the AIN proximal source (Fig. 39.5). With evidence of ulnar innervated actions, fine dexterity exercises and tasks can be incorporated into the rehabilitation program and the patient will be able to complete the ulnar motor nerve actions independent of the action of forearm pronation. A comprehensive motor retraining program combined with cortical remapping, and relearned motor patterns will provide the opportunity for optimal outcomes after nerve transfer.

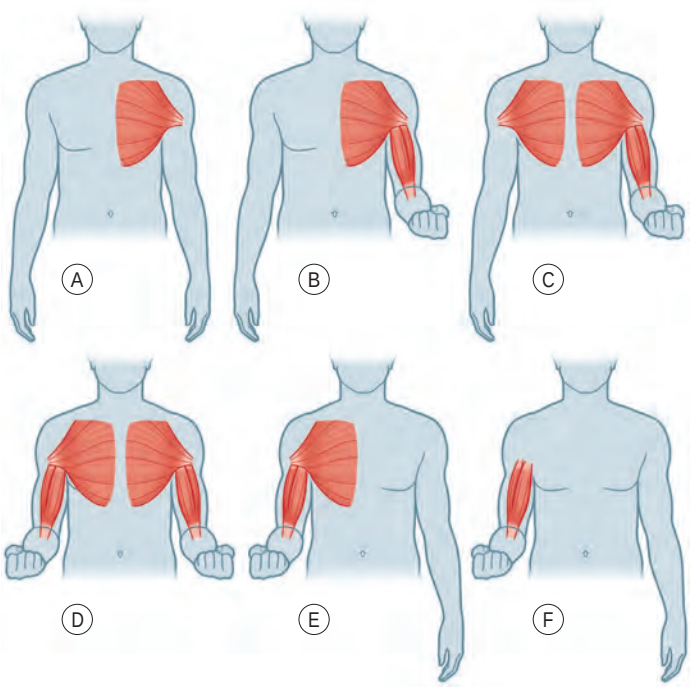

Fig. 39.3 To facilitate understanding and relearning following a motor nerve transfer, re-education begins with a muscle contraction on the unaffected side. **(A)** With a medial pectoral-to-musculocutaneous nerve transfer, the patient begins on the unaffected side with contraction of the pectoralis major muscle and **(B)** then contraction of both the pectoralis major and the biceps muscle. **(C)** This is followed by simultaneous contraction of the pectoralis major muscle on the affected side, **(D)** followed by bilateral contraction of these muscles. **(E)** The contraction is then isolated to the affected side and **(F)** finally dissociation of the donor muscle from the target muscle.

Fig. 39.2 Following an intercostal-to-musculocutaneous nerve transfer, the patient is performing an abdominal crunch to initiate contraction of the intercostal muscles and thus initiate contraction of the biceps and brachialis muscles. *(Courtesy of Susan E. Mackinnon, MD.)*

As outlined previously in this chapter, the evidence in the literature does not support the efficacy of direct current electrical stimulation with denervated muscles. With evidence of muscle reinnervation, some have advocated the use of electrical muscle stimulation using an alternating current to increase the force of the muscle contraction and thereby increase muscle strength. Theoretically, with an innervated muscle, it is possible to use an alternating current to elicit a muscle contraction. However, with a reinnervated muscle, there may be scarcity of reinnervated fibers to produce the intended muscle contraction via electrical stimulation. Passive muscle contraction will not assist in the relearning of motor patterns. Therefore, it is our recommendation that these types of modalities should not be considered as the primary treatment but may be used as an adjunct to therapy as a "sensory stimulus" for relearning if necessary.

Functional relearning may be facilitated with visual or auditory feedback, which can provide immediate response to the patient regarding the muscle contraction. Simple biofeedback units with external surface electrodes may be used to facilitate muscle contraction or to minimize aberrant co-contraction of an antagonistic muscle action. Using a two-channel or four-channel biofeedback unit, the electrodes may

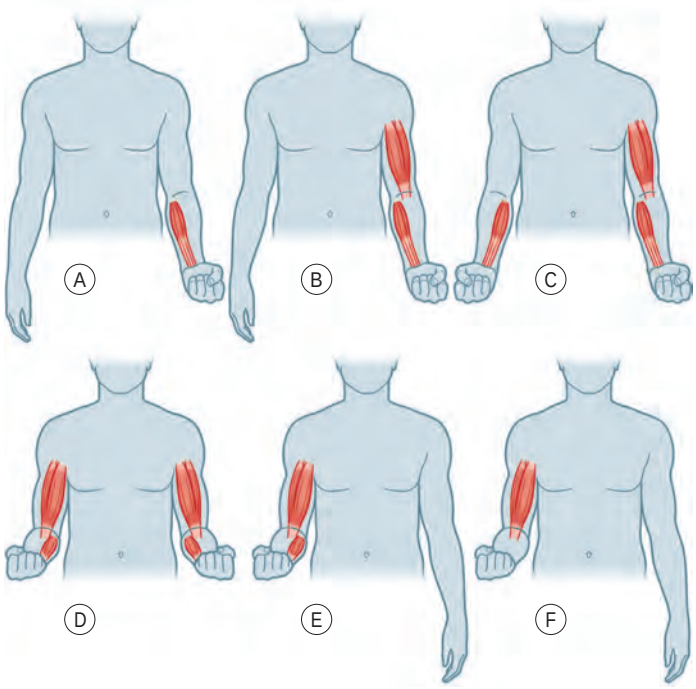

Fig. 39.4 The relearning associated with a partial ulnar and median nerve transfer from the forearm to the elbow flexors is illustrated. Initially, simple grip-strengthening exercises and/or gentle wrist flexion will initiate contraction of the biceps and brachialis muscles. **(A)** The patient begins on the unaffected side with a contraction of the forearm flexors and **(B)** then simultaneously contracts biceps/brachialis muscles and the forearm flexors. **(C,D)** The next step is bilateral contraction of these muscles and **(E)** then the exercise is isolated to the affected side. **(F)** The final exercise is to dissociate contraction of the donor muscle from the target muscle.

be placed on the appropriate muscles to increase or decrease muscle contraction. To facilitate relearning, the action should be performed on the unaffected side first to allow the patient to understand the strategies necessary to enhance or minimize the intended action. It is also useful to perform these actions simultaneously with the affected and unaffected extremity. This will provide immediate feedback on the "normal" contraction and motor pattern and provide the opportunity for the patient to reproduce the action in the newly reinnervated muscles. With adequate muscle reinnervation, the patient will receive feedback by observing and "feeling" the muscle contraction. Specific exercises to promote muscle contraction without a specific biofeedback unit will allow the patient to perform the exercises more frequently as a home program.

Fig. 39.5 With an anterior interosseus nerve to deep motor branch of the ulnar nerve transfer, forearm pronation is combined with pinching to recruit the innervated intrinsic muscles and facilitate relearning. *(Courtesy of Christine B. Novak, PT, PhD.)*

Muscle physiology and biomechanics should be considered when structuring rehabilitation programs following nerve repair or transfer. Because of the weakness and associated fatigue in newly reinnervated muscle, exercise sessions should be of short duration. A slow-onset contraction with a longer duration hold of 10–15 s is recommended to increase muscle endurance and strength. To minimize the muscle forces required initially, muscle contraction in mid-range is suggested. Place-and-hold exercises or gravity-eliminated positions may be used and then progressed to different degrees of motion as the patient is able to sustain a muscle contraction. With MRC grade 3 strength, progressive resistance exercises can be implemented. The focus of strengthening is to regain muscle balance. Because of the relative weakness between the uninjured and reinnervated muscles, it is important to regain good motor control of the reinnervated muscles before resistance exercises are instituted, otherwise learned compensatory motor patterns will be maintained.

Upper extremity movement requires composite motor patterns involving the glenohumeral and scapular muscles.[51,54] While distal nerve injuries may not include the shoulder complex, strength of uninjured upper extremity muscles may be weakened from disuse or from compensatory movement patterns. Similarly, brachial plexus nerve injuries may not include direct injury to the scapular muscles; however, these muscles (such as the middle and lower trapezius and serratus anterior muscles) may be weak from disuse and thus compromise upper extremity function. Assessment of muscle strength and length in the cervicoscapular region should be performed, and then a rehabilitation program to address these muscle imbalances implemented to optimize outcome.

Rehabilitation programs following nerve injury and nerve compression surgery must include sensorimotor re-education and the inclusion of normal movement patterns for appropriate cortical remapping. Bimanual tasks will encourage use of the injured extremity and input normal movement patterns and purposeful movements involving self-care, recreation, and work will facilitate the resumption of normal activities. In some cases, vocational rehabilitation will be necessary to assist in future planning and employment opportunities. Patient education and an effective home program are necessary to optimize learning of new motor/sensory tasks and to optimize outcome.

Rehabilitation following tendon injury/surgery

Flexor tendon injuries

Surgical and rehabilitative approaches following flexor tendon injury can be described as one of the most researched, controversial, and clinically complex aspects of hand therapy. While originally eschewed as excessively progressive or risky by many surgeons, active motion regimens are becoming more

common in both research and clinical practice. Three primary factors have emerged as crucial in informing postoperative decision-making: (1) early initiation of rehabilitation; (2) the impact of wrist position on excursion and force; and (3) the use of controlled active motion to create safe and effective tendon glide.

Clinical tips

Rehabilitation after flexor tendon injury and repair

- Specificity and timing of exercise following flexor tendon repair can be optimally arranged to facilitate high-excursion/low-force rehabilitation.
- Communication of the operative details between the therapist and plastic surgeon is essential to guide initiation and progression of exercise following flexor tendon repair.
- Early controlled motion should be initiated on the fourth or fifth postoperative day when work of flexion is likely decreased.
- Edema should be considered an objective means by which to inform therapeutic progression including range, frequency, and speed of exercise.
- Place-and-hold measurement is a safe and effective way to monitor tendon glide, progress treatment, and measure outcomes.
- Synergistic motion facilitates excursion while decreasing force.
- Tendon excursion occurs in both proximal and distal directions, and can be influenced both by type of exercise and antagonistic musculature.

The timing of rehabilitation following flexor tendon repair can readily be identified as a topic of historical and continued controversy. The study of tendon healing over time has demonstrated that early controlled motion is beneficial to tendon healing and preferable to immobilization.[96–98] The timing of early motion following flexor tendon repair continues to be researched; however, some consistency is evident. Postoperative day 4–5 is suggested as a time during which work of flexion is decreased and preferable for the initiation of rehabilitation.[99–101]

Edema is a postoperative symptom that often impedes the initiation of rehabilitation. Current research specific to edema and the flexor tendon system has identified numerous factors that can be effectively modulated by therapists in order to begin rehabilitation.[100,102,103] In a series of studies by Cao and colleagues, their results indicated that the area and severity of edema following flexor tendon repair increased both gliding resistance and work of flexion.[100,102,103] However, slow and gentle motion decreased the work of flexion. Decreasing both the arc of motion and frequency of exercise were methods to safely begin motion in the presence of edema. Conversely, recent literature has identified an intervention that should not be utilized when faced with edema after flexor tendon repair. While many therapists use self-adherent wrap as a postoperative dressing and for edema management, leaving this wrap in place during active motion significantly increases the work of flexion.[104] In summary, gentle and controlled motion at a lower frequency is suggested for patients with edema with the caveat that any compressive dressings should be removed prior to exercise.

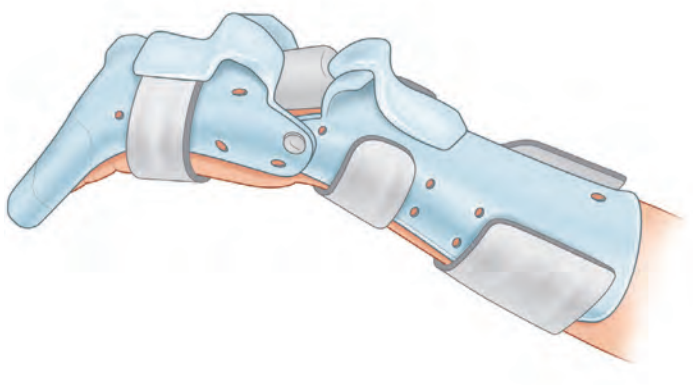

Fig. 39.6 Synergistic motion can be safely and effectively initiated with a hinged, dorsal blocking splint that allows the patient to create wrist extension prior to flexing the digits.

The position of the wrist in the postoperative orthosis can also create a potential limitation for therapeutic intervention. The impact of wrist positioning has been comprehensively studied as it pertains to force and excursion of the flexor tendon system.[105–108] The position of metacarpophalangeal (MP) flexion coupled with wrist extension has been suggested to produce the least passive tension in the extensor tendons, thereby decreasing the minimal active tension of the flexor tendons.[107] Synergistic motion has also been observed to create the greatest amount of flexor digitorum superficialis, flexor digitorum profundus, and differential excursion,[105] serve as an effective pulling force to create proximal glide,[108] and result in low force with high excursion.[109,110] Synergistic motion can be safely and effectively initiated with a hinged, dorsal blocking splint that allows the patient to create wrist extension prior to flexing the digits (Fig. 39.6). The literature indicates that asking patients to perform digit flexion when the wrist is flexed actually demands more force than the same motion performed with the wrist extended.

Prior to 2005, the most commonly used postoperative protocols maintained the wrist in a flexed position both during and between exercise for the first 6 weeks following repair.[111–113] More recent flexor tendon rehabilitation regimens have been built with consideration of the wrist and have progressed to varying levels of active motion. The Mass Protocol[114] includes immediate postoperative positioning of the wrist in 20° of extension paired with active digital flexion through the "available range". Comparatively, the Nantong Protocol[115] reverts back to a conservative wrist-flexed position for the first 2½ weeks while the patient focuses on full extension to the dorsal block. Despite the inherent risks, this protocol does suggest completion of active motion through the first two-thirds of full range. The Saint John Protocol[116] affords a similar approach, modifying the wrist to an extended position and the active motion to mid-range.

The most current and progressive approach to postoperative immobilization is the Manchester Short Splint.[117] This protocol includes a hand-based, dorsal blocking orthosis that allows wrist extension up to 45° (Fig. 39.7A,B) On the fourth or fifth postoperative day, active motion of the digits within the first third of the range is paired with active wrist extension; the patient is instructed to focus on initiation of distal

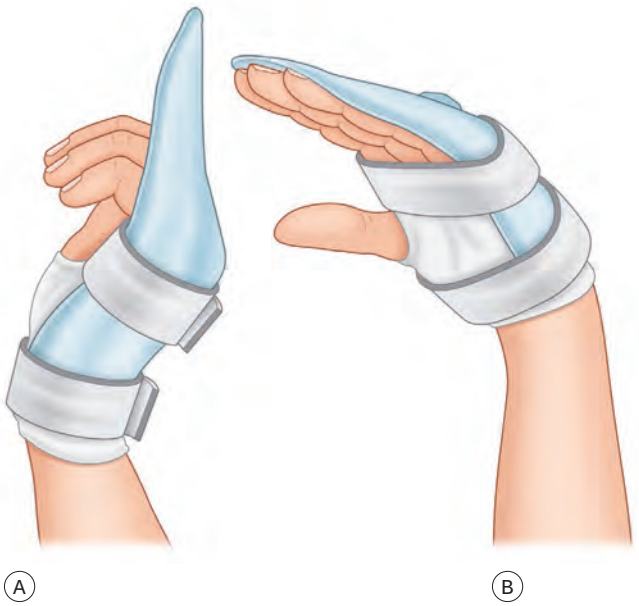

Fig. 39.7 (A,B) A hand-based, dorsal blocking orthosis allows wrist extension up to 45°.

interphalangeal (DIP) joint motion to maximize differential tendon glide. In an comparative outcome study, patients (n = 40) who completed rehabilitation with the Manchester Short Splint demonstrated significantly less flexion contractures at the proximal interphalangeal (PIP) joint at 6 and 12 weeks, had significantly greater arcs of flexion at the DIP joint, and had a greater proportion of excellent and good results compared to patients (n = 62) treated with forearm-based orthoses.[117] As all of the protocols presented here have been published within the past 10 years, it will be interesting to observe their integration into clinical practice.

Once the initial rehabilitative choices have been made, the progression of therapeutic exercise requires careful consideration as it pertains to the force exerted and consequential excursion of the tendon relative to adjacent structures. Studies have suggested that postoperative exercise should create the least possible force to achieve tendon excursion that will deter peri-tendinous adhesions.[99–101] From a rehabilitative perspective, it is important to recognize that tendon excursion occurs in both proximal and distal directions, and can be influenced by both types of exercise and antagonistic musculature.[110,118,119] A working knowledge of the force and excursion produced by specific exercises facilitates clinical progression following tendon repair (Table 39.1).[120,121]

The use of straight fist, hook fist, composite fist, and isolated joint exercises is suggested as a sequential regimen for controlled force once synergistic motion has been initiated (Fig. 39.8). Consistent communication between the therapist and plastic surgeon is essential to both initiation and progression of exercise for the patient following flexor tendon repair, beginning with a detailed operative report outlining the number of strands crossing the repair site and perceived integrity of the repair.

Extensor tendon injuries

Care of the patient following an extensor tendon injury is a far less complicated pursuit compared to flexor tendon injury. Use of standard protocols based on the anatomy and biomechanics of the extensor apparatus has led to consistent and favorable results throughout all zones of the extensor musculature.

Clinical tips

Rehabilitation after extensor tendon injury

- For a mallet finger, non-operative treatment includes continuous immobilization of the DIP joint in full extension for 6 weeks.
- For a boutonnière deformity, non-operative management includes PIP joint at 0° extension for 6–8 weeks and following surgical management, a short arc motion protocol may be initiated within 48 h.
- With zone VI–VII injuries, attention to anatomic specificity is very important and isolation of specific musculature to produce joint extension. Edema must be managed immediately to avoid tendon adhesions. A passively mobile joint with an active extensor lag is best managed via active tendon gliding in both proximal and distal directions.

Table 39.1 Analysis of tendon excursion and force

Exercise	Excursion	Force
Passive protected extension	3–8 mm Distal Duran and Houser[111]	200–300 g Urbaniak *et al*.[119]
Place-and-hold digital flexion during wrist extension	FDS 26 mm FDP 33 mm Proximal Wehbe and Hunter[120]	900 g Lieber *et al*.[110]
Active straight fist	Wrist neutral FDS 28 mm FDP 27 mm Maximum FDS Proximal Wehbe and Hunter[120]	1100 g Greenwald *et al*.[121]
Active hook fist	Wrist neutral FDS 13 mm FDP 24 mm Maximum differential Proximal Wehbe and Hunter[120]	1300 g Greenwald *et al*.[121]
Active composite fist	Wrist neutral–extension FDS 24–26 mm FDP 32–33 mm Maximum FDP Proximal Wehbe and Hunter[120]	400–4000 g Schuind *et al*.[118]
Active, isolated PIP flexion	~13 mm (calculated) FDP Proximal	900 g Schuind *et al*.[118]
Active, isolated DIP flexion	~6.5 mm (calculated) FDP Proximal	1900 g Schuind *et al*.[118]

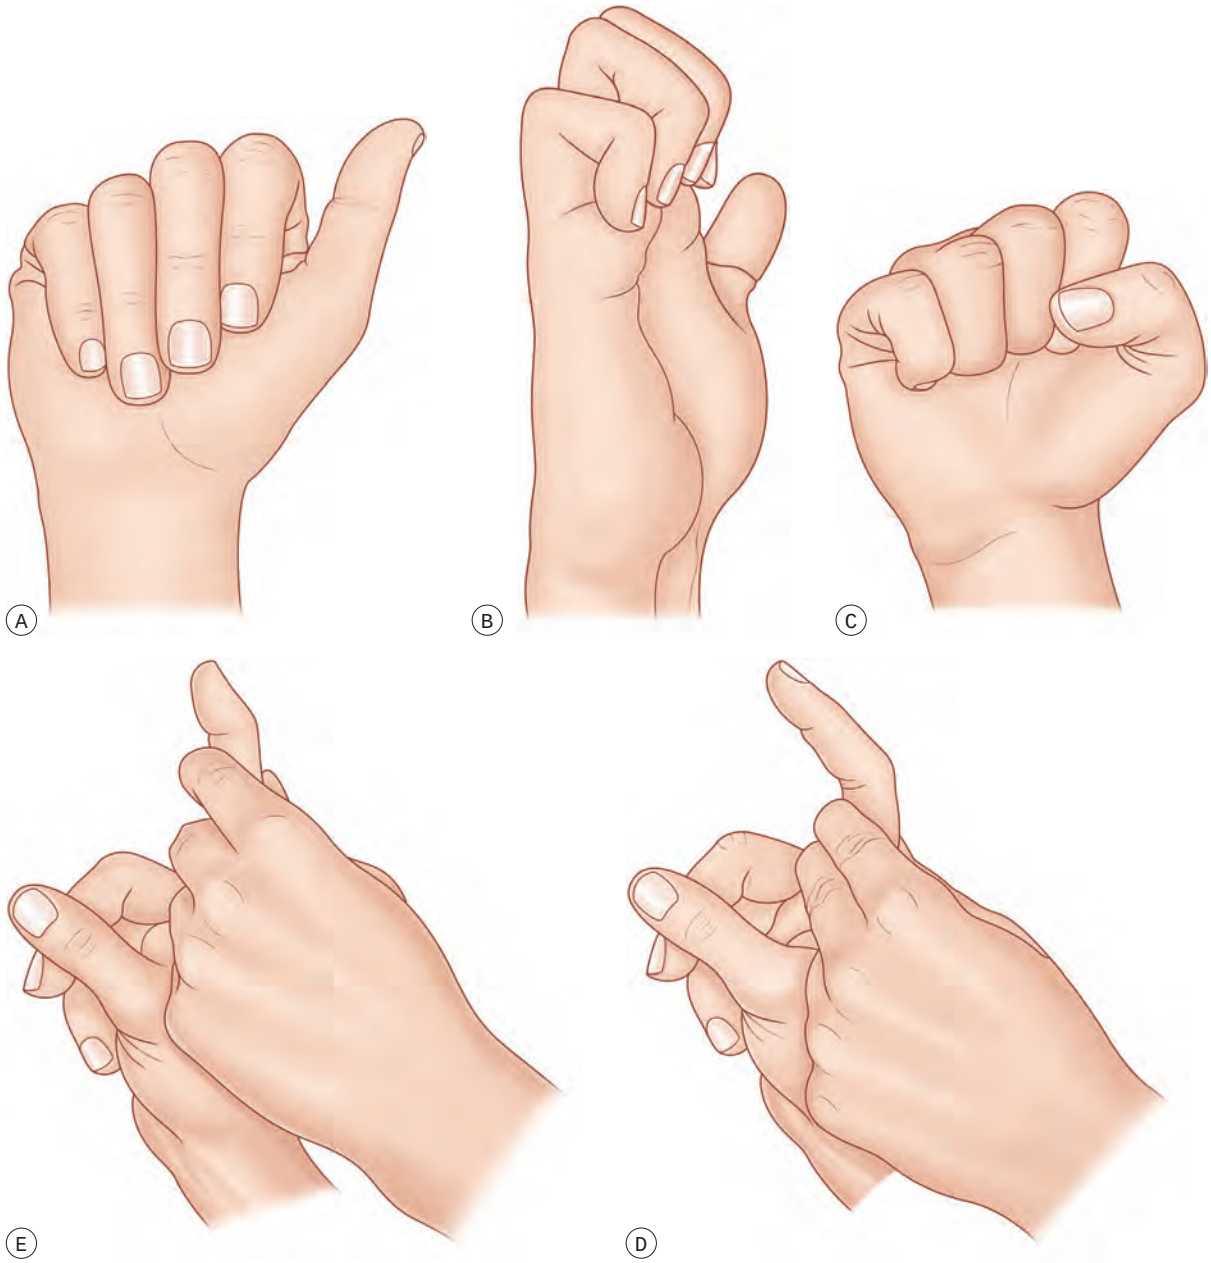

Fig. 39.8 The sequential use of **(A)** straight fist, **(B)** hook fist, **(C)** composite fist, and **(D,E)** isolated joint exercises are suggested as a means of consciously progressing forces on the healing flexor tendon.

A zone I injury is commonly referred to as "mallet finger". Upon clinical examination, patients demonstrate an inability to actively extend the DIP joint due to detachment of the terminal extensor tendon from the distal phalanx. A mallet finger is characterized by varying degrees of flexion at the DIP joint. Non-operative treatment for a mallet finger includes continuous immobilization of the DIP joint in full extension for 6 weeks (Fig. 39.9). The PIP joint is mobilized during this timeframe as a means of maintaining proper alignment of the lateral bands and balance of the flexor and extensor tendons. Fabrication or issuance of two orthoses is suggested to minimize maceration of tissues and facilitate skin integrity during daily hygiene activities. After 6 weeks, the therapist initiates a gradual orthosis-weaning process and the patient begins gentle, composite flexion exercises. The patient is also

Fig. 39.9 An injury to the extensor tendon in zone I, commonly termed mallet finger, is most often treated conservatively with distal interphalangeal extension immobilization at all times for 6 weeks. *(Courtesy of Rebecca Neiduski, PhD, OTR/L, CHT.)*

educated on the avoidance of isolated joint motion that can unnecessarily stress the terminal tendon. Lateral tracing of the digit for daily comparison serves as an effective visual aid to monitor for development of an extensor lag during the orthosis-weaning process. If an extensor lag develops at any time during this process, support in extension is resumed and flexion exercises are decreased or discontinued.

Loss of integrity of the central slip in zone III is termed a boutonnière deformity. As the lateral bands sublux volarly, flexion of the PIP joint is unopposed. Flexion contractures are common sequelae of this condition and avoidance of this difficult complication must be pursued early in the treatment process. In addition, extensor forces are transmitted to the DIP joint, resulting in hyperextension of the DIP joint. Differential diagnosis of a pseudoboutonnière from a true boutonnière is an important component of the evaluative process. In the former, the DIP joint remains passively flexible, whereas in the latter, the DIP joint cannot be passively flexed. Nonoperative management of the boutonnière deformity includes continual use of an orthosis or cast that positions the PIP joint at 0° extension for 6–8 weeks. The DIP and MP joints do not need to be included in the orthosis or cast, if the therapist is successfully able to maintain the PIP joint at 0° extension, which is often difficult. The orthosis is continued between exercises until the tenth week following injury.

A short arc motion protocol may be initiated within 48 h of surgical correction of a boutonnière deformity, as suggested by Evans.[122] A template is fabricated that allows 30° of PIP and 20° of DIP joint flexion. The patient is instructed to produce finger flexion to the template and active extension to 0°. This exercise is completed 10–20 times every 1–2 h with the wrist held in 30° flexion and the MP joints between 0° extension and slight flexion. The template is adjusted to 40° of flexion after the second week if there is no active extensor lag. It is then progressed to 50° by the third postoperative week and up to 70–80° by the end of the fourth week. The finger is immobilized in full extension between exercises and an exercise orthosis to facilitate isolated DIP flexion is also fabricated.

Injuries in zones V–VII may occur with open (such as lacerations) or closed (such as blunt trauma) mechanisms of injury. Disturbance of the sagittal bands often leads to long extensor tendon subluxation with resultant MP extensor lag. Following surgical repair, multiple protocols are considered effective for treating extensor tendon injuries in these zones.

The most conservative protocol includes immobilizing the wrist in 40–45° extension and the MP joints in 0–20° flexion. A volar interphalangeal extension orthosis is fabricated to support the joints in full extension between exercises and at night as a means of preventing both flexion contractures and an extensor lag. Treatment of edema and scar is critical in this zone as adhesions are likely and will limit both proximal and distal glide of the extensor tendons. Exercises begin at 3–4 weeks postoperatively and include a wrist tenodesis exercise with active MP flexion and extension as well as continued interphalangeal active motion.

In zone VI–VII injuries, Evans and Burkhalter suggested a dorsal dynamic extension assist orthosis to allow 30° active MP flexion and returns the digits to 0° extension via dynamic traction.[123] The early distal glide allowed by this orthosis makes it an excellent choice for patients who can manage a more intricate orthosis design. Individual PIP extension gutters are added for those patients who demonstrate extensor lags. Howell *et al.* suggest immediate controlled active motion (ICAM) for patients with repairs in these zones.[124] This protocol includes three phases, the first of which can be initiated between 0 and 21 days after surgery. The wrist is immobilized in 20–25° extension, while the MP joint of the affected digit is positioned with a "yoke" orthosis in 15–20° of hyperextension relative to the other digits (Fig. 39.10). Both orthoses are to be worn at all times and the patient must achieve full active motion within the ICAM orthosis before progressing to the next phase. Phase 2 begins 22–35 days after repair, during which the yoke orthosis is worn at all times and both the yoke and wrist orthoses are only worn for medium to heavy activities. The patient is instructed to relax the digits during wrist exercise. Phase 3 is initiated 36–49 days after repair and includes discontinuation of the wrist orthosis with the yoke orthosis or buddy taping continued during activities. The yoke orthosis is removed for active motion during the final phase.

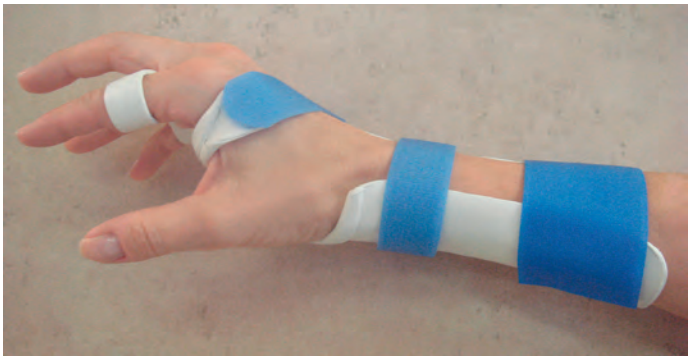

Fig. 39.10 The immediate controlled active motion protocol, as described by Howell *et al.*,[124] includes a wrist cock-up orthosis and a yoke orthosis, which effectively creates hyperextension of the affected digit relative to the other digits. *(Courtesy of Rebecca Neiduski, PhD, OTR/L, CHT.)*

Despite the seeming simplicity of extensor tendon as compared to flexor tendon rehabilitation, attention to anatomic specificity is very important as it pertains to final outcomes. Edema collects easily in the dorsal hand and must be managed immediately to avoid tendon adhesions. Attention to both active and passive motion at all joints provides valuable information for the choice and progression of interventions. A passively mobile joint with an active extensor lag is best managed via active tendon gliding in both proximal and distal directions. Resistive exercises are an excellent method of restoring tendon glide after the eighth week. Perhaps the most important approach is the isolation of specific musculature to produce joint extension including the extensor digitorum communis for MP extension and the intrinsic musculature for interphalangeal extension.

Tenolysis

Following flexor and extensor tendon repairs, the likelihood of scar adhesions that limit active excursion is unfortunately high. While early motion coupled with continual evaluation and progression can modulate scar formation, confounding factors including overall health, medical comorbidities, pain, and compliance may negatively impact postoperative results. If progress has plateaued at the 3-month interval, patients are often evaluated as candidates for tenolysis.

Proper assessment of tendon gliding includes comprehensive measurement and comparison of active and passive range of motion at all joints of the affected digit(s). The optimal candidate for tenolysis is the patient who demonstrates full passive motion of the digit and is deemed compliant by the therapist and surgeon. As the postoperative treatment of tenolysis is both painful and time-intensive, thorough education of patient and family is vital to success. A therapy schedule for daily treatment during the first 7 days post-tenolysis, including weekend days, should be established preoperatively.

Direct communication between the surgeon and the hand therapist regarding the integrity of the tendon and active motion as accomplished during surgery should be a priority and postoperative treatment should begin on the same day as surgery. It is advisable to allow the patient multiple hours of recovery time, including a full meal and initiation of pain medication if possible to decrease the likelihood of adverse reactions (i.e., fainting) if treatment is promptly initiated. Use of a sterile field and gloves is important to minimize the likelihood of infection as the therapist initiates hourly active exercises to facilitate tendon glide. Edema management and wound care are also carefully addressed as the therapist attempts to find a balance between adequate dressings for drainage absorption that provide minimal physical blockage to active motion. Consistent measurement of active and passive motion is pursued during the first 7 consecutive days of treatment.

Therapy intensity can decrease after the first week for patients who demonstrate compliance with hourly exercise and the ability to complete wound care independently. The outcomes of tenolysis are quickly recognized and difficult to remediate after the first 3–4 weeks of treatment. For this reason, communication between the surgeon and hand therapist and careful selection of patients for this procedure are perhaps the most influential factors influencing final outcome.

Tendon transfers

Rehabilitation following tendon transfers requires careful communication between the plastic surgeon and hand therapist and attention to detail. This detail not only includes surgical specificity but the unique needs and expectations of the patient coupled with a neuromuscular intervention plan. For the purposes of brevity, the example of a pronator teres (PT) to extensor carpi radialis brevis (ECRB) tendon transfer, as performed in cases of radial nerve injury, will be used throughout this section as a case example.

Patient education should include the purpose of the surgical procedure, expected timeline for rehabilitation, possible complications, and expected outcomes.[125] The patient needs to be informed that functional use will be altered following surgery and that a tendon transfer procedure will not correct for losses in sensation.[126] Prior to surgery, efforts are instituted to strengthen the donor muscle selected for the procedure.[125] If the patient has difficulty isolating the donor muscle, biofeedback and exercise orthosis may be useful.[125]

Immediately following surgery, the transfer and all involved joints are immobilized in a position to minimize tension on the newly transferred tendon. An immobilization period of 3–4 weeks is commonly implemented to allow adequate healing and reduce the risk of tendon rupture upon mobilization of the transfer.[126] During this period, the postoperative dressing is removed and the patient is immobilized in a thermoplastic orthosis. In the case of a PT-to-ECRB transfer, the patient is immobilized in a wrist cock-up orthosis at 45° extension (Fig. 39.11). For those cases in which coaptation of the muscles are considered tenuous, an orthosis that limits forearm rotation while positioning the wrist in extension can be fabricated. During this period, the therapist's focus is centered on the evaluation and treatment of edema, pain, and infection.

Fig. 39.11 The patient with a pronator teres to extensor carpi radialis brevis tendon transfer is immobilized in 45° of wrist extension for 3–4 weeks following surgery. *(Courtesy of Rebecca Neiduski, PhD, OTR/L, CHT.)*

In the absence of complications during the immobilization phase, initiation of active motion typically occurs 3–4 weeks postoperatively.[125,126] The therapist initiates neuromuscular re-education exercises, including isolation and activation of the transfer to produce a desired motion. Central to this process is the concept of cortical plasticity, or the capacity of a cortical circuit to reorganize its structure or response subsequent to an experience.[127] As suggested by Sanes and Donoghue, the primary motor cortex exhibits such plasticity as a result of repetition of simple movements.[127] Combination exercises are frequently incorporated to facilitate re-education of a donor muscle, and include training the patient to produce the primary movement of a denervated muscle utilizing a new musculotendinous unit. A PT-to-ECRB tendon transfer is performed to restore wrist extension, the patient is instructed to pronate the forearm while simultaneously extending the wrist. Proprioceptive feedback is preferable to visual as it facilitates cortical reorganization and auditory feedback can also be helpful.

The length of time it takes to isolate a transfer effectively is highly variable, depending on the type of transfer and specific patient factors. Isometric activation can be carefully initiated with those patients who find combination exercises difficult. In the case of a PT-to-ECRB transfer, gentle resistance is provided to the wrist while the patient is producing pronation with wrist extension. As the patient progresses, the goal is isolated activation of the donor muscle in production of the newly desired motion, in this case, wrist extension against gravity without simultaneous pronation.

At 6–7 weeks post-surgery, the tendon has healed and is able to tolerate functional activities and light resistance. Passive range-of-motion exercises may also be initiated to mitigate any residual tightness incurred during surgery or the immobilization period.[125] At 8 weeks post-surgery, progressive resistance exercises may be incorporated into the exercise regimen.[125]

Rehabilitation following skeletal injury/surgery

Proximal phalanx fractures are challenging and require careful attention to bony integrity and maintenance of the flexor and extensor tendon-gliding systems. Therapeutic interventions as outlined in this section are based on the assumption that a patient presents with one of the following: a potentially unstable, yet non-displaced, extra-articular fracture; an inherently stable fracture; or hardware fixation facilitating stability such as an open-reduction internal fixation or closed-reduction external fixation.

According to Feehan, structural strength following a proximal phalanx fracture is influenced by location, pattern and displacement, type of reduction, hardware, concomitant soft-tissue injuries, stage of healing, and the functional demands of the patient.[128] Initiation of early controlled mobilization is based on the surgeon's perception of structural strength and can be altered by choosing the number of joints to be mobilized, active and/or passive motion, a safe arc of motion, and the duration or repetitions of motion.[128] Isolating short arc motion at one or more joints when possible provides tendon glide and lengthening of connective tissue structures that will positively facilitate final outcomes for patients following proximal phalanx fracture. As the flexor digitorum profundus lies in close proximity to the proximal phalanx, isolated DIP motion should be initiated as soon as possible. Moving the joint actively through flexion and extension will also afford some proximal and distal excursion of the extensor mechanism.

Following a proximal phalanx fracture, MP joint positioning and PIP joint mobilization have been studied as a means of avoiding complications. MP joint flexion is the close-packed position of the joint, or the position at which the joint space is minimized, and the joint surfaces of the head of the metacarpal and the base of the proximal phalanx are maximally congruent. In addition, MP joint flexion moves the extensor hood distally, translates the force of the extensor digitorum to the PIP joint, and creates circumferential compression on the fracture.[129] From a volar perspective, flexion also decreases the proximity of the flexor tendons to the fracture site. PIP joint range of motion has been suggested to maintain the length of the joint capsule and increase soft-tissue gliding as well as creating a dynamic tension band effect in conjunction with the extensor digitorum to facilitate fracture reduction.[130,131] According to Feehan, the functional and physiologic stresses associated with early controlled mobilization increase the quality and rate of bone healing.[128]

Complications following proximal phalanx fractures are often sequelae of scar tissue that limits all structures in the zone of injury. Typical issues include extensor mechanism adherence and fracture deformity with resultant PIP joint extensor lags.[129,132] In a study by Kurzen *et al.*, 52% of patients demonstrated less than 180° of total active motion following plate fixation of a proximal phalanx fracture.[133] To avoid such outcomes, LaStayo *et al.* recommend a progressive program be initiated in the following order: protection or external support, edema management, protected and controlled mobilization of proximal and distal joints, tendon gliding, passive range of motion, and strengthening.[131] The external support, typically a custom-fabricated orthosis, can either be hand- or forearm-based and dorsally blocks the MP joints in flexion[129,134] (Fig. 39.12).

Metacarpal fractures

Metacarpal fractures are commonly seen primarily in the fourth and fifth metacarpal and often in adolescent males. From an anatomic perspective, consideration of both the metacarpals and their adjacent tendinous and connective tissue structures directs clinical decision-making. The second through fifth metacarpals are aligned as parallel long bones and serve both mobility and stability functions for the digits. The proximal bases of the second and third metacarpal are firmly affixed to the distal carpal row, more specifically, the trapezoid and capitate. More mobile carpometacarpal (CMC) joints at the thumb and small finger surround this stable center, while the fourth metacarpal demonstrates limited mobility on the hamate. Distally, the deep transverse metacarpal ligament connects the heads of the second through fifth metacarpals. The alignment of the distal carpal row, reinforced by this ligament, creates the transverse arches of the hand that contribute to grasp and function.

According to McNemar *et al.*, metacarpal head fractures are immobilized in the position of safety, with the wrist extended, MP joints fully flexed, and PIP and DIP joints extended, in either a cast or a custom-fabricated orthosis[135] (Fig. 39.13). This close-packed positioning maintains the length of the collateral ligaments, counteracts the tendency towards a claw deformity, and draws the extensor mechanism distally to support the fracture.[135] For those cases requiring open reduction and internal fixation through an incision of the extensor mechanism, early motion becomes a necessity to avoid tendon adherence.

The more typical metacarpal neck fracture often occurs in the fourth or fifth metacarpal and is typically seen in young males who have been involved in an altercation. A more conservative approach to this injury includes immobilization of the wrist in extension and the MP joints in flexion, with early mobilization of the PIP and DIP.[135] For those fractures that are minimally displaced with reasonable stability, a less

Fig. 39.12 Following a proximal phalanx fracture, immobilization of the metacarpophalangeal joint in flexion facilitates close-packed positioning, creates circumferential pressure via the extensor mechanism, and decreases the proximity of the flexor tendons to the fracture site. Allowance of proximal interphalangeal joint motion increases the opportunity for differential tendon gliding along the fracture site. *(Courtesy of Rebecca Neiduski, PhD, OTR/L, CHT.)*

Fig. 39.13 Fractures to the metacarpal head are immobilized with an orthosis or cast in wrist extension, metacarpophalangeal joint flexion, and interphalangeal joint extension. *(Courtesy of Rebecca Neiduski, PhD, OTR/L, CHT.)*

restrictive regimen of immobilization and exercise can be initiated. A cuff orthosis that creates circumferential pressure around the hand and approximates the metacarpals towards anatomical alignment is fabricated to allow unrestricted motion of the wrist and MP joints (Fig. 39.14). For additional distal alignment, the proximal phalanx of the affected metacarpal can be taped or strapped to the adjacent digit with which it is optimally aligned lengthwise. Using this approach, the patient is encouraged to perform active exercise while avoiding sustained or forceful grasp during the healing phase.

Complications after metacarpal fractures include rotational deformities, loss of length, and dense adhesions restricting tendon glide of the extrinsic extensor tendons. Rotational deformities lead to scissoring of the digits during active flexion, while metacarpal shortening can lead to active insufficiency of the extrinsic digit extensors and the possibility of decreased grip strength.[135] Extensor adherence can be avoided with early motion protocols emphasizing isolated glide of the long extensors. Composite extension of the digit will not achieve this goal; rather, the patient is instructed in transition from a full fist to a hook fist, which creates maximal, isolated glide of the extensor digitorum communis. These exercises are of increased importance following open reduction and internal fixation of metacarpal head, neck, and shaft fractures.

Fig. 39.14 Metacarpal neck and shaft fractures that are minimally displaced can be immobilized using a simple cuff which approximates the metacarpals and creates circumferential pressure. *(Courtesy of Rebecca Neiduski, PhD, OTR/L, CHT.)*

Thumb carpometacarpal osteoarthritis

Osteoarthritis of the first CMC joint is an extremely common diagnosis addressed by the plastic surgeon and hand therapist, most often observed in women of middle age. This diagnosis is the subject of much debate, ranging from anatomy to interventions.

The typical presentation of a patient with CMC osteoarthritis includes marked adduction of the first CMC joint with hyperextension of the MP joint. This positioning is influenced by numerous musculoskeletal imbalances that are presumed to have both causative and resultant roles. Prolonged adduction of the joint leads to shortening of the adductor pollicis, active insufficiency of the abductor pollicis brevis and extensor pollicis brevis, and decreased stabilization by the first dorsal interossei. The extensor pollicis longus, having the greatest moment arm for MP extension, subsequently creates compensatory MP hyperextension to increase the first webspace for grasp and function. Offsetting this compensatory pattern via positioning of the MP joint in flexion has been noted to unload the palmar surfaces of the CMC joint, suggesting that the more distal MP joint may play a role in the progression of arthritis at the proximal CMC joint.[136]

A recent systematic review of conservative interventions for osteoarthritis of the hand provides evidence for numerous interventions based on specific patient goals.[137] Moderate evidence was found to support heat, exercise, education on joint protection, and issuance of adaptive equipment as adjunctive methods for pain reduction and increased function. The use of orthoses to decrease pain and increase function was supported with high to moderate evidence. Numerous orthoses are available for conservative management of CMC osteoarthritis, both custom and prefabricated. Evidence to support the superiority of one orthosis design from a diagnostic perspective is lacking; however, studies have shown patient preferences towards prefabricated, hand-based orthoses[137] (Fig. 39.15). The work by Moulton *et al.* supports the inclusion of the MP joint in the orthosis, positioned in flexion as a means of unloading the volar surface of the CMC joint and decreasing forces on the anterior oblique ligament.[136]

For patients with advanced stages of CMC osteoarthritis, or those who have failed non-operative management, surgical intervention is often recommended. Despite the numerous surgical methods for treatment of thumb CMC arthritis ranging from simple partial or complete trapeziectomy with or without ligament reconstruction tendon interposition, postoperative care is relatively straightforward. Emphasis during the rehabilitative phase is placed on the maintenance of stability of the newly reconstructed joint as a means of facilitating pain-free thumb function. The surgical procedure performed, patient factors, and surgeon preference will guide

Fig. 39.15 Patients with carpometacarpal osteoarthritis are often immobilized in a hand-based thumb spica orthosis to relieve pain and provide support and positioning to facilitate functional use. *(Courtesy of Rebecca Neiduski, PhD, OTR/L, CHT.)*

the postsurgical management and immobilization. Following trapeziectomy with ligament reconstruction tendon interposition, the patient is typically immobilized in a forearm-based thumb spica cast or orthosis for 4 weeks following surgery. The interphalangeal joint is left free to facilitate tendon gliding of the extensor pollicis longus and flexor pollicis longus across the surgical site. This early motion can also contribute to decreasing edema and hypersensitivity, two common sequelae of this procedure.

After 4 weeks, a program of active circumduction range of motion, scar management, and desensitization is initiated. Active range of motion of the CMC joint is pursued gently, mindful of the influence of proximal stability on distal mobility and overall function of the thumb. Close attention to the balance of musculature about the thumb is also important, especially as it pertains to the length of the adductor pollicis and activation of the extensor pollicis brevis and abductor pollicis longus. MP hyperextension should be carefully monitored; blocking the interphalangeal joint of the thumb in slight flexion during active exercise is often effective in controlling the mechanical advantage of the extensor pollicis longus. Scar adhesions and hypersensitivity are common complaints following this procedure and should be addressed with early and progressive massage and desensitization.

While gentle passive motion can be initiated at 6 weeks, continued use of the orthosis between exercise sessions and at night is often continued until the eighth postoperative week. Strengthening should be avoided until pain is no longer a primary complaint, and pursued only within the realm of the function required on an individual basis.

Future directions

Advancements in the understanding of response to injury, wound healing, and other innovations in hand surgery have guided the advancements in hand therapy. Recognition of cortical changes and neural plasticity has advanced our treatment following nerve injury, repair, and nerve transfers. Emphasis on sensorimotor control and methods to exploit the neural plasticity potential have led to improved outcomes following nerve reconstruction and nerve and tendon transfers. The concept of soft-tissue mobility and methods to improve mobility and minimize adherent scarring has changed our practice after soft-tissue and bony injuries to the hand. Many of the active motion protocols presented in this chapter have been published within the past 10 years. As these protocols become integrated into clinical practice and future studies report the long-term outcomes, we will be better able to build on these successes.

Conclusion

Key points

1. Optimal outcomes necessitate a collaborative relationship and open communication between the patient, surgeon, and hand therapist.
2. A comprehensive evaluation is necessary to provide diagnostic and prognostic information and to inform clinical decision-making for non-operative and postoperative management.
3. Following nerve injury, rehabilitation should be directed not only to the distal motor and sensory recovery but also to cortical remapping and normal movement patterns.
4. Specificity and timing of exercise following flexor tendon repair can be optimally arranged to facilitate high excursion/low force rehabilitation.
5. Early controlled mobilization can increase healing, tendon glide, and joint mobility in patients with extra-articular hand fractures.

Comprehensive evaluation and multidisciplinary treatment approaches are advocated for patients following hand surgery and optimal outcomes necessitate a collaborative relationship and open communication between the patient, surgeon, and hand therapist.

Immediate controlled active motion following zone 4–7 extensor tendon repair. *J Hand Ther*. 2005;18:182–190. *The protocol described for extensor tendon injuries includes a wrist orthosis paired with a yoke orthosis which positions the metacarpophalangeal joint of the affected digit in hyperextension relative to the other digits. Full active motion within the immediate controlled active motion orthosis is expected prior to progression to the next phase of the protocol.*

128. Feehan LM. Early controlled mobilization of potentially unstable extra-articular hand fractures. *J Hand Ther*. 2003;16:161–169. *This article suggests that functional and physiologic stresses associated with active range of motion increase the quality and rate of healing in potentially unstable extra-articular hand fractures. Control of clinical factors is recommended as a means of incorporating early motion into fracture management.*

136. Moulton MJ, Parentis MA, Kelly MJ, et al. Influence of metacarpal joint position on the basal joint loading in the thumb. *J Bone Joint Surg Am*. 2001;83:709–716. *In this cadaveric study, immobilization of the metacarpophalangeal joint was studied as it pertained to forces on the trapezial surface during lateral pinch. Metacarpophalangeal flexion was noted to unload the most palmar aspect of the carpometacarpal joint effectively, decreasing strain on the palmar oblique ligament.*

Treatment of the upper extremity amputee

Gregory A. Dumanian, Jason M. Souza, and Todd Kuiken

SYNOPSIS

- Upper extremity amputees are different from lower extremity amputees: patients are younger and their amputations are primarily due to trauma and tumors rather than dysvascular conditions. The patients live longer with their residual limbs.
- Prosthetic concerns for the two groups of patients dramatically differ.
- Upper extremity prostheses require more control, more movement, and more precision than that for a leg. Fortunately, upper extremity prostheses have less load bearing requirements, since they do not need to support the weight of the body.

Introduction

Upper extremity amputees are different from lower extremity amputees in many aspects. The patients are younger and their amputations are primarily due to trauma and tumors rather than dysvascular conditions. The patients live longer with their residual limbs. Prosthetic concerns for the two groups of patients dramatically differ. Upper extremity prostheses require more control, more movement, and more precision than that for a leg. Fortunately, upper extremity prostheses have less load bearing requirements, since they do not need to support the weight of the body. The purpose of this chapter is to familiarize the reader with necessary concepts to care for the upper extremity amputee. Handling of soft tissues, bones, and nerves are reviewed for each of the levels of amputation. Prosthetics and prosthetic control will be a necessary accompaniment of this chapter. Recent advancements in the field including targeted reinnervation will be introduced.

Aesthetic prostheses

Aesthetic prostheses refer to devices that are used to camouflage a limb deformity, while functional prostheses refer to devices that are operational.[5] Aesthetic prostheses assist patients in issues of body image and self-esteem, with possible functional gains due to a newfound social openness and ability to expose the limb. Patients can appear fairly normal in public with aesthetic prostheses (Figs. 40.1 & 40.2). Most of these prostheses are custom made and require a high level of expertise on the part of the prosthetist. Because intact skin is used to secure the prosthetics in place, some amount of sensory feedback of the residual limb will be lost, and this is one drawback to these devices. Osseointegration of aesthetic prostheses into bone has been studied at length, because of the potential for improved tolerance of the soft tissues to the prosthesis, the limit on the amount of soft tissues covered, and ability to use stiffer materials in the devices for possible secondary functional gains. The bone–soft tissue–implant interface for osseointegration of upper limb prosthetics remains problematic.[6]

Control of upper extremity prosthetic devices

A prosthesis is only as good as the control signals that it receives from the user. The goal of any prosthesis is to be moved and positioned in space smoothly, quickly, intuitively, and with minimal exertion and mental fatigue to accomplish this task.[7] Multifunctional prostheses offer the potential for greater functionality, but come at the cost of increased complexity with regard to control strategies. Prostheses with both a terminal "hand" device and a prosthetic elbow require differentiation between signals intended for hand control and those intended for elbow function. This differentiation becomes even more critical when these functions are attempted simultaneously.

Historical perspective

Putti documented the history of upper extremity prostheses in the 1930s, and this work has been subsequently translated into English.[1] The field of prosthetics began soon after advancements in battlefield surgery allowed patients to survive limb amputations. Prior to cautery, surgeons were forced to allow tissue to mummify, and then to slowly separate living tissue from dead. Residual limbs developed in this manner had poor soft-tissue coverage of bone, and therefore were poorly able to tolerate the weight of a prosthesis. Advances in metalworking permitted the creation of metallic prostheses beginning in the early 1500s. A famous knight, Gottfried von Berlichingen (c.1480–1562) was known as Gotz of the Iron Hand for his below elbow amputation. The prosthesis he wore was strapped to the forearm with leather bands, and had moveable fingers and thumb that could be revolved and tightened around the hilt of a sword. Ambroise Pare documented the ingenious Petit Lorrain artificial hand that had fingers that moved into extension with springs, and could be held in flexion by sprockets that caught metal levers.[2] The Alt-Ruppin prosthesis, fished out of a canal in the town of the same name, was constructed in the 1500s and similarly had moveable fingers and thumb. These prostheses inspired the imagination of onlookers, and demonstrated the ingenuity of armor makers of the day.

The Ballif arm of 1812 was an improvement over the metallic arms for its softer materials and for the active control of the prosthetic hand. Rather than locking prosthetic fingers into place for a static grip, the Ballif arm utilized cables attached to the shoulder and arm to allow opening and closing of the prosthetic hand. The Civil War created a huge number of amputees in the United States, leading to companies such as the A. A. Marks Company (1853) of New York and the J. E. Hanger Company (1861, still in existence today). These firms and others provided body-powered prostheses to the masses by mail order. World War II led to further refinements in body-powered prostheses due to the large numbers of upper extremity amputees coupled with significant advances in technology developed for the aviation industry.[3] With minor adjustments for materials and socket designs, body-powered upper extremity prostheses have remained relatively unchanged since the 1950s. Body-powered prostheses are operated by using shoulder motion to pull on a housed cable (like a bicycle brake cable) and thus transfer power to the prosthetic joints. Generally only one joint can be operated at a time. Thus when using a prosthesis with multiple joints, the user unlocks only the joint he wishes to operate using a variety of different types of switches.

The development of externally powered prostheses powered by electricity or pressurized gas began in Germany soon after World War I. The myoelectric hand, controlled using Electromyogram (EMG) signals from the residual limb, was first created by Mr. Reinhold Reiter for the Bavarian Red Cross in 1943 during World War II and published in 1948. Parallel efforts to create a myoelectric prosthesis began in England, the Soviet Union, and the United States. The United States effort was led by the Committee on Prosthetics Research and Development of the National Research Council, with the initial meeting held at Northwestern University. Technical advancements were greatly aided by the miniaturization of electric components. The first device to use transistors was the so-called "Russian Hand" of 1959. Along with the Vaduz and Bottomley Hands, these single-function (open and close) devices received much publicity, but were rather slow and clumsy to operate. Multifunction myoelectric devices with wrist flexion/extension and pronation/supination were introduced in the mid-1960s as a means to further improve on these devices.[4] Despite research efforts that spanned the globe, these multifunction prostheses were limited by the difficulty for the amputee to control the movements of the prosthesis.

Proponents of body-powered prostheses have been arguing with the proponents of externally powered system for the last half-century. However, both types of devices are useful and often complementary. Body-powered prostheses are generally lighter and more robust than external systems with batteries and motors. Externally powered systems require more daily maintenance for battery changes and are more fragile than the simpler and sturdier harnesses and hooks. Functionally, body-powered prostheses tend to give the wearer a bit more feedback during use. A significant advantage for transradial and more distal myoelectric prostheses is that they can be anatomically suspended using the humeral condyles or using suction sleeves; this eliminates the need for cumbersome shoulder harnessing. Furthermore, as unilateral upper limb amputees tend to use the prosthetic limb only as a helper hand, the improved cosmetics of myoelectric devices can make up for their many drawbacks and are often preferred.[3] Hybrid systems also exist that try to combine the best features of both body-powered and external-powered prostheses. One example is to have a body-powered prosthetic elbow coupled with a myoelectric hand.

Fig. 40.1 Patient with multiple finger amputations due to sepsis and hypotension.

The cable systems used by body-powered devices provide a reliable method for control, but lack fluidity and do not offer simultaneous control of multiple functions. Body-powered prostheses, as previously described, utilize shoulder motions to operate the prosthesis. This is problematic, because muscles that are designed for strong movements – such as the latissimus dorsi and the serratus anterior – are required to move accurately and sensitively to control cables and switches. Body-powered devices use non-intuitive shoulder muscles to control a prosthetic elbow or hand.

Myoelectric control, derived from surface EMG recording of residual limb muscles, provides prosthetic control without the need for accessory shoulder movement. From the standpoint of aesthetics and comfort, the lack of cables and pulleys is advantageous, but is often offset by the bulk of the socket and the increased weight of the motorized device. Myoelectric control represented a promising technological advance, but the prosthetic function provided by the earlier devices remained relatively slow and disjointed, thus limiting applicability. The residual limb musculature being recorded was not usually cortically linked to the prosthetic function being controlled (i.e., biceps brachii used to control finger flexion). Also, as with body-powered devices, only one joint could be operated at a time. Multifunctional devices required an additional switch or signal to enable the device to change between functions.

Fig. 40.2 Multiple-digit prostheses for improvement of cosmetic appearance.

The potential offered by myoelectric control was realized in 1995, when Kuiken, Childress and Rymer demonstrated a new myoelectric control strategy now called "targeted muscle reinnervation" (TMR). TMR utilizes nerve transfers between the transected brachial nerves and the residual limb muscles to reclaim the neural control information that is lost as a result of upper extremity amputation.[8] As a result, prosthetic function can be directly coupled with EMG signals corresponding to the nerves responsible for the identical function in the previously intact limb. Clinically, this technique yields intuitive and relatively seamless device control. In addition, the increased number of EMG control sites provided by TMR enables simultaneous control of multiple functions. Kuiken and Dumanian first reported this procedure in shoulder disarticulation patients in 2004,[9] and in transhumeral amputees in 2008.[10]

While the functional capabilities of prosthetic devices once outpaced the amount of information available to control them, the pendulum has now swung the other way. When it was introduced, the number of nerve transfers performed as part of the TMR procedure largely dictated the number of prosthetic functions capable of being controlled. This control strategy, labeled "direct control", meant that a single reinnervated muscle segment could be used to control only one function via a single EMG electrode (i.e., reinnervation of short head of biceps by median nerve for hand closure). Recently, "direct control" has been supplanted by "pattern recognition", whereby advanced algorithms are used to correlate the pattern of muscular contractions recorded from many more electrodes. This approach provides greater flexibility for rehabilitation and has served to markedly improve the functional capacity of the amputee.

Other strategies for prosthetic control are still in the investigative phase, but show promise. Implantable myoelectric sensor systems that transmit EMG signals out to a detecting device could improve the EMG signal quality and consistency, as well as provide control signals from small muscle bodies such as the individual finger extensors of the forearm.[11] Direct signal acquisition from the amputated nerves using a variety of implanted electrodes or small muscle grafts to amplify the nerve signals have been investigated.[12,13] Prosthetic control using fine wire electrodes was recently demonstrated in an acute experiment in humans.[14] Direct recording and stimulation of the cerebral cortex has been performed in monkeys in order to effect peripheral movement. This brain–machine interface, if successful, could have wide applicability, not only for amputees, but also for patients with spinal cord injuries.[15]

Prosthetic implications of upper limb amputation surgery

The surgical treatment of patients with unreconstructable upper extremity disorders must take into account issues unique to the amputee. The amputation must have durable soft tissues to allow for prosthetic fitting. In all instances, an evaluation is performed as to how to preserve intact nerves and how to manage unavoidable end-neuromas. The means

by which the prosthesis will be controlled must be considered. With these concepts in mind, a level-by-level analysis of common upper extremity amputations is presented.

Finger amputation

Patients undergoing reconstructive upper extremity surgery do best when the surgeon "Think(s) Nerve" first.[16] Patients can easily tolerate a painless stiff digit, while they are greatly troubled by a mobile painful digit with a symptomatic neuroma. Patients with wounds of the fingers should be evaluated as to which nerves are irreparably cut, and which digital nerves are intact. If a major portion of one of the two digital nerves is intact, then a flap should be performed for wound closure, rather than a shortening amputation with division of both digital nerves. The digital nerves to the finger pulp trifurcate approximately 2 mm distal to the volar distal interphalangeal joint skin crease. One branch travels to the nail fold, a second branch travels to the volar tip, and the third branch innervates the volar pad. Amputations at or proximal to the trifurcation have two cut digital nerves, and therefore a revision amputation will not cut a new nerve to achieve wound closure. In the figure shown, the ulnar digital nerve to the ring finger is intact, while the radial digital nerve is cut (Figs. 40.3 & 40.4). The cross finger flap is performed to achieve wound closure, but more importantly to avoid the necessity of dividing an intact digital nerve as part of a revision amputation.

Much has been written about more proximal finger amputations. For these patients, a traction neurectomy is performed to keep the nerve from trying to reinnervate the skin laceration area. The surgeon should attempt to achieve a smooth and tapered end to the digit, rather than having a bulbous tip. This requires removal of the condyles for joint disarticulations, and longer skin incisions down the midaxial lines of the digits for removal of 1 "dog ears".

Partial hand

Again "Thinking Nerve", loss of the ulnar, radial, or dorsal aspect of the hand with preservation of the volar nerves warrants flap reconstruction to obviate the need to divide nerves that remain in continuity. Typically, this will be either a free flap, or a pedicled groin flap as a second choice. If the majority of the digital nerves are divided, then the next decision is whether there is a functional and stable wrist joint. Maintenance of the wrist will allow the residual limb to be an excellent helper hand, even without a prosthesis (Figs. 40.5–40.7). In some avulsive injuries, the dorsal wrist extensors have been removed by the injury, and it is worthwhile to reinsert extensor tendons to the residual carpal bones with bone anchors and a flap for coverage. Thicker muscle flaps are preferable to skin flaps, as the associated atrophy will facilitate the placement of passive finger prostheses that can assist in grasp.[17]

Body-powered and externally powered prostheses exist for partial hand amputations, but have significant size constraints to provide moveable components that will not

cause the device to be longer than the opposite hand. Suspension of these devices is also difficult due to the need to not impede wrist motion. Rather than prosthetics, improvements in hand function for patients with thumb, multiple digit, or partial hand amputations can be achieved with toe-to-hand transfers.

Wrist disarticulation and transradial amputation

Injuries that divide the digital nerves and strip the soft tissues off of the carpal bones are better served by a wrist disarticulation or a transradial amputation than by efforts to salvage a scarred and immobile hand for the sake of "preserving length" (Fig. 40.8). These patients have already suffered a complete

Fig. 40.7 Mobile wrist joint acts as a helper hand. The patient's extensor tendons were reinserted into the carpal bones with bone anchors.

Fig. 40.8 A young worker had skin grafts applied to a proximal hand stripped of almost all soft tissues in an attempt to "save length". He underwent a transradial amputation for treatment of his painful immobile scarred hand.

division of the median, radial, and ulnar nerves from their injury, and so a more formal amputation with manipulation and re-division of the nerves where the soft tissues are more supple is appropriate.

In the operating room, plans are made for soft-tissue coverage of the residual limb with development of palmar and dorsal skin flaps. A dorsal approach to the wrist identifies the proximal carpal row, and these bones are excised much like a proximal row carpectomy. The ulnar and radial arteries are doubly ligated. The radial and ulnar styloids are trimmed to allow for easier prosthetic fitting without pressure points, but the triangular fibrocartilage complex is maintained to preserve pronation and supination. When possible, more durable volar skin is used for coverage as opposed to thinner dorsal skin.

Handling of the nerves to prevent a symptomatic mixed major nerve neuroma from developing is important, as a painful neuroma will complicate prosthetic wear. Standard treatment is traction neurectomy, where the nerves are placed on stretch, divided, and allowed to retract away from the incision line. A general concept is that the better "padded" is a neuroma, the less symptomatic. Other treatments supported both by experimental animal surgery and clinical experience include placing the cut nerve ending within immobile muscle as opposed to simply allowing them to retract.[18,19]

Clinical work with TMR has revealed that major mixed nerves do not form symptomatic neuromas when nerve transfers are performed. Nerve transfers are now often performed at the time of a wrist disarticulation. This is not for obtaining new control signals (although this may occur), but rather for prevention of symptomatic end-neuromas. Through a proximal incision between the flexor carpi ulnaris (FCU) and flexor digitorum superficialis (FDS), the median nerve is transferred to a motor nerve of the FDS, the ulnar nerve is transferred to a motor nerve innervating the FCU, and the radial nerve is transferred to the motor nerve innervating the pronator quadratus. This strategy has been successful for neuroma control, and there is no morbidity associated with sacrifice of the recipient motor nerves due to the distal amputation. Also, as demonstrated clinically with every muscle flap harvest, cut motor nerves in humans do not form symptomatic neuroma.

If the patient is unlikely to wear a prosthesis, a wrist disarticulation with good soft coverage will give the patient a longer and more functional residual limb. Wrist disarticulation prostheses do well in capturing the distal bony structures for wrist rotation; however, room is limited for prosthetic components and the devices tend to look bulky. A long transradial amputation generally facilitates better prosthetic

Fig. 40.9 Patient with previous transradial amputation plagued by poor soft-tissue coverage of residual limb.

fitting by allowing room for prosthetic components and providing better cosmetic appearance.

A lack of soft tissue may require a transradial amputation as opposed to a wrist disarticulation. In these instances, the shorter lever arm will place more stresses on the residual soft tissues for movement of the prostheses. Pronation and supination will not be as easily translated into prosthetic movement and positioning. Patients undergoing transradial amputations will have similar treatments of the arteries and nerves of the forearm. The radial nerve will be divided and allowed to retract underneath the brachioradialis. A myoplasty of the extensor and flexor muscles over the cut ends of the radius and ulna will stabilize the muscle masses, and facilitate later prosthetic fitting. Drill holes through the bones for passage of suture are useful to prevent muscle movement over the end of the residual limb. At least 5 cm of ulna is necessary to retain elbow movement, but in these instances of very short residual limbs, the insertion of the biceps tendon may need to be transferred to the ulna. Preservation of length of bone may require a soft tissue flap taken from the flank.[20] This pedicled flap is divided after 3 weeks, but provides thick soft tissue and a smoother soft-tissue envelope for prosthetic fitting (Figs. 40.9 & 40.10). The function of a transradial amputation is much greater than a transhumeral amputation, thus aggressive treatment to save the elbow and reasonable forearm length is warranted.

Elbow disarticulation and long transhumeral amputation

Non-reconstructable and non-replantable injuries at the elbow level require removal of the ulna and radius. The level of amputation depends on the plan for prosthetic rehabilitation. If no prosthetic is planned, then the elbow disarticulation is a more functional level than a higher amputation, because the limb is long enough to reach a table in sitting and thus is easier to use for moving and stabilizing objects. While the condyles in an elbow disarticulation can be useful in suspension of the prosthesis and for humeral rotation, the appearance of the arm with its prosthetic appears too long. Very long transhumeral amputees can be treated with an angulation osteotomy (with or without shortening) of the distal humerus. It can provide a lever arm for suspension and for rotational control of the prosthesis.[21] Finally, if a powered elbow is planned, a transhumeral amputation 5–6 cm above the olecranon allows room for the motor and the elbow "joint" seems to be in the correct place. A transhumeral amputation at this level still allows for TMR of the median, ulnar, and radial nerves.

In the operating room, anterior and posterior skin flaps are elevated. The level of the bone division is decided, and either the elbow capsule and ligaments are divided sharply, or else the humerus is cut just proximal to the epicondyles. A myodesis of the triceps and biceps to the distal bone is performed utilizing drill holes for several reasons. Good quality soft-tissue coverage of the distal bone is a necessity. The end of the residual limb should not have too much redundancy and mobility to facilitate application of a socket and donning the prosthesis. Finally, prevention of proximal migration of the muscle mass during contraction is important for later signal detection for a myoelectric prosthesis. For performance of an angulation osteotomy, the amputation is done in the prone position for proper plate placement.

Handling of the neurovascular structures is another important decision branch point. Treatment of the median, ulnar, and radial nerves is quite important at this stage. The standard traction neurectomy is *no longer* the optimal treatment for these large mixed nerves. The question is whether targeted reinnervation should be performed at the time of the amputation or at a later date. Immediate targeted reinnervation has the advantage of avoiding a second surgery, and the nerve transfers would be performed when the nerves are at their longest length, without neuromas to resect and with a full axon complement. Benefits of immediate targeted reinnervation include a shorter time between amputation and the possibility to have additional control signals for improved prosthetic function. As has been mentioned, nerve transfers are a method to prevent the development of symptomatic

Fig. 40.10 Pedicled periumbilical perforator flap is transferred to the end of the limb after excision of skin-grafted area, and divided 3½ weeks later.

painful neuroma. The effect of targeted reinnervation on phantom limb sensation is under investigation. Amputation followed by a later TMR has the advantage of improved patient education and consent, the avoidance of new proximal incisions in a swollen traumatized limb, and the ability to advantageously thin the subcutaneous fat to improve EMG acquisition. If the prospect of delayed TMR exists, then the major mixed nerves should be left long and without additional dissection.

Transhumeral amputations through the middle third of the humerus still allow for a mobile shoulder joint and successful prosthetic fitting. Often TMR can be still be performed. Pedicled latissimus flaps can be extremely useful to achieve wound closure and maintain length when needed, but make delayed TMR a bit more challenging. Short transhumeral amputations can undergo Ilizarov lengthening or even free fibula transfer to achieve a longer lever arm for the prosthesis.

With severe brachial plexopathies resulting in flail limbs, amputation is often considered. Amputation will not relieve neuropathic plexopathy pain, but can relieve traction pain at the shoulder and it clearly removes the inconveniences of having a paralyzed arm. We recommend a transhumeral amputation at 25–30% of humeral length in these instances. This removes the weight of the limb, relieving traction pain, and preserves a nice shoulder and upper arm contour for clothing. Fusion of the shoulder to enhance prosthetic fitting is not recommended. Prosthetic fittings with flail residual limbs have extremely poor outcomes and a humerus fused in abduction and flexion interferes with some activities, especially positioning in bed.

Proximal transhumeral and shoulder disarticulation

Loss of the biceps and triceps due to electrical injury or avulsive injuries are best treated with a proximal transhumeral amputation or a shoulder disarticulation. Maintenance of the humeral head in its glenohumeral fossa has cosmetic implications in shirt fitting, and depends on the local soft tissues. Again, traction neurectomies should be avoided to preserve nerve length. Preservation of a small humeral remnant under deltoid motor control can be extremely useful to activate switches via miniature touch pads. The deltoid muscle is typically spared in electrical injuries due to the increased cross-sectional area of the body. In avulsive injuries, the deltoid is spared due to its broad origin on the scapula. The deltoid is pulled inferiorly with sutures, and the chest skin can be mobilized superiorly for closure of the glenohumeral fossa.

Surgery of the residual limb

Soft-tissue improvement

Patients with traumatic amputations often have soft tissues that are suboptimal for prolonged prosthetic wear. Contour irregularities due to scars, skin grafts, and skin redundancy compromise the fit of prosthetic sockets and liners. Skin breakdown is common, resulting in discomfort and recurrent infections that serve to further limit prosthetic wear. Because physiatrists or prosthetists manage most elements of prosthetic use, even straightforward surgical solutions are often delayed in favor of socket or behavioral modifications. Thus, the importance of close collaboration between reconstructive surgeons and rehabilitation providers cannot be overstated. Surgical techniques remain the most effective ways to achieve a wound-free residual limb without painful neuromas or poorly covered bone. The specific techniques employed will vary based on the mechanism of amputation and degree of injury, but largely include advancement flaps, excision of skin grafts, Z-plasties for scar contractures, and lipectomy either through direct excision or circumferential liposuction (Figs. 40.11 & 40.12). The patient must be aware that even after primary skin healing, swelling will take many weeks to resolve, and therefore may require multiple re-fittings and an extended period during which the patient will be without use of the prosthetic.

Skin breakdown can occur from poor prosthetic fit, but it also can occur when skin grafts have been used to preserve length in the absence of adequate soft tissue. Revision amputations can be considered when the prosthetist and physiatrist agree that a shorter residual limb with improved soft tissues

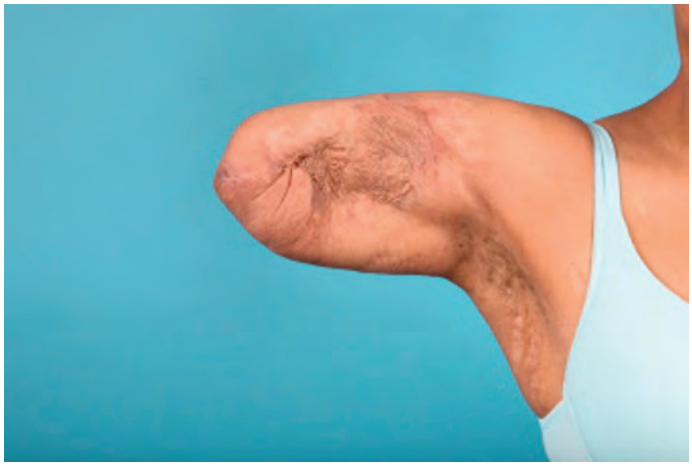

Fig. 40.11 Transhumeral amputee with scarred soft tissues of her residual limb.

Fig. 40.12 Same patient as Fig. 40.11 after excision of previously placed skin graft and closure with advanced skin flap, analogous to a brachioplasty.

will be preferable to a longer amputation covered with skin grafts. When limb shortening is not a viable option, both pedicle and free flaps are useful for improving padding and durability. The goal is a smooth contour that better distributes pressure.

In addition to addressing contour abnormalities and skin breakdown, the function of myoelectric prosthetic control can also be improved with soft-tissue revision. The removal of subcutaneous fat decreases the resistance between the underlying muscle and skin. This can markedly increase the amplitude of the EMG signals and decrease interference (cross-talk) from neighboring muscles.[22]

Neuroma management

Neuromas are significant problems after upper extremity amputations. Large series from areas of conflict document neuromas and stump pain in over one-quarter of upper extremity amputees.[23–25] Clinically, large mixed neuromas can be very symptomatic, as can superficial sensory nerve neuromas. "Pure" motor nerves are less than 50% motor fibers by staining, yet clinically they do not create symptomatic end-neuromas when cut. Neuroma pain is described as a localized area of tenderness when pressure is applied, typically with a radiation of discomfort in the area that the nerve had previously innervated. This is in contradistinction to phantom sensations, which are defined as the feeling that a deafferented body part is still present following amputation.

Numerous strategies have been reported to be successful in the management of painful stump neuromas. The simplest method of neuroma excision and traction neurectomy has a documented 70% improvement rate.[26] Neuroma excision with burying the nerve end in muscle,[27] neuroma translocation away from areas of pressure,[28] and the centro-centralization technique of Gorkisch[29] have all been documented to have high levels of patient satisfaction and low recurrence rates. These studies are all limited by being observational studies. Experimental neuroma work is hampered by the fact that all peripheral nerves form neuromas in the absence of a distal target, but not all neuromas are symptomatic, making it difficult to differentiate a quiet neuroma from a symptomatic one in a preclinical setting.

There is now growing evidence to suggest that reconstitution of the nervous system through nerve repair, grafting, or transfer serves to limit neuroma pain by inhibiting the disorganized regeneration that underlies neuroma formation. In a recent clinical report by Moran *et al*., nerve repair was shown to be superior to neuroma excision and muscle/bone implantation for treatment of symptomatic neuromas in the intact upper extremity.[30] The nerve transfers utilized in TMR provide the transected brachial nerves a vascularized scaffold for coordinated axon regeneration, necessary neurotrophic factors, and a target volume of denervated muscle to reinnervate. TMR offers the potential to restore continuity to the peripheral nervous system despite the absence of the native distal nerve segments. A multicenter retrospective review demonstrated no neuroma pain involving a transferred nerve following 82 TMR nerve transfers in 26 patients over a 10-year period.[31] More recently, TMR has been used for management of existing neuroma pain at all amputation levels proximal to the wrist with good clinical results.

Targeted muscle reinnervation

As noted above, TMR is a technique involving transfer of the median, radial, ulnar and/or musculocutaneous nerves in an amputated arm to redundant residual limb muscles. These reinnervated target muscles then serve as biological amplifiers for the nerve signals, providing surface EMG control signals for improved operation of motorized prostheses. The TMR surgical procedure was recently reviewed,[8] and demonstrates improved outcomes in comparison to standard prostheses documented.[8] The following is a brief review of the surgical techniques.

Transhumeral level

The indications to perform TMR at the transhumeral level include poor prosthetic function using standard body-powered, myoelectric, or hybrid systems despite adequate training. Good candidates are young patients with cortical control of biceps and triceps contraction without plexopathy, supple soft tissues, and without other cardiopulmonary risk factors. Bilateral amputations and long residual limbs also favor the procedure. Patients who have suffered avulsions of the limb at the time of injury or patients with brachialplexopathies are poor candidates for surgery.

On examination, Tinel's signs signifying the ends of the median, ulnar, and radial nerve are marked. Tinel's signs located at the mid-humeral level or distal have long enough nerves to perform nerve transfers. The raphe between heads of the biceps and triceps are palpated and marked preoperatively, as the absence of normal distal landmarks makes it easy to lose orientation of the arm once the patient is positioned on the operating room table. The anterior incision provides access to the median, ulnar, and musculocutaneous nerves. The median nerve is transferred to the motor nerve of the short head of the biceps, while preserving the musculocutaneous nerve innervation to the lateral head of the biceps (Fig. 40.13). This transfer provides a "hand closing" signal for the prosthesis, while preserving the native "elbow flexion" signal. In the operating room, after raising thin skin flaps, an adipofascial flap is elevated and based proximally. The neuromatous end of the median nerve is identified, cut back to healthy fascicles, and is mobilized into the space adjacent to the motor

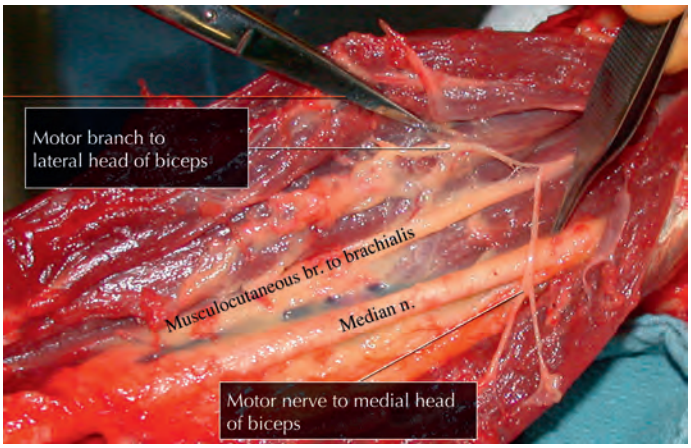

Fig. 40.13 Cadaveric dissection splitting the medial and lateral heads of the biceps to expose the motor points of the musculocutaneous nerve.

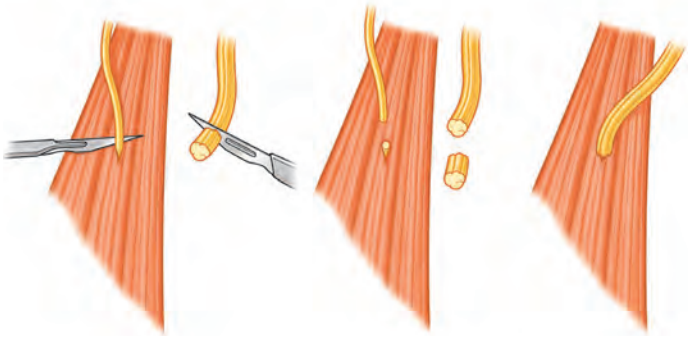

Fig. 40.14 Schematic of targeted muscle reinnervation nerve transfer.

entry point of the musculocutaneous nerve on the short head of the biceps. The nerve transfer is completed by transecting the motor nerve to this muscle segment and coapting the median nerve directly to this 1–1.5 mm motor nerve (Fig. 40.14). The coaptation site should be as near to the muscle belly as possible to decrease innervation times and to facilitate placement of a supportive epimysial suture. In the case of long transhumeral amputations, where the brachialis has been preserved, the ulnar nerve can be transferred to the motor entry point of the musculocutaneous nerve into the brachialis. This follows an identical thought process and procedure as that performed for the median nerve. At closure, the adipofascial flap is placed back between the biceps heads to spatially separate the two biceps signals. Posteriorly, the distal radial nerve is transferred to the motor nerve innervating the lateral head of the triceps, while the native innervation of the long head of the triceps is maintained. This creates a "hand opening" signal, while preserving an intact "elbow extension" signal from the proximal radial nerve. After the elevation of a proximally based adipofascial flap, the triceps is split between the long and lateral heads to reveal the motor nerve to the lateral head of the triceps and the distal radial nerve. The distal radial nerve is coapted to the newly divided motor nerve of the lateral head of the triceps. Drains and a mildly compressing dressing are applied. Therapy can begin several weeks after the nerve transfer procedure.[32]

Shoulder disarticulation level

TMR at the shoulder level should be performed only by surgical teams possessing a significant knowledge of upper chest and axillary anatomy.[33,34] Patient evaluation begins with a thorough history and physical examination. Patients with brachial plexus injuries are not candidates for the procedure, as the median, radial, and ulnar nerves must elicit action potentials under direct cortical control. Though it may seem obvious, patients cannot undergo TMR unless they have had an amputation, as there is no region of the body to accept the prosthetic arm. The indication for performing surgery is to improve prosthetic function. Painful neuromas and uncomfortable areas of heterotopic ossification have been other relative indications for the procedure. A Tinel's sign over the major three nerves is elicited, as is confirmation that the pectoralis, serratus, and latissimus muscles are under active cortical control. These will be potential recipient targets for the nerve transfers.

An infraclavicular approach to the plexus and proximal nerve branches is performed incising the skin two fingerbreadths below the clavicle and carefully opening the interspace between the sternal and clavicular heads of the pectoralis major (Figs. 40.15–40.19). During the approach, thin skin flaps are raised and the thick chest adiposity is thinned for improved signal detection in a region 10 cm in superior-to-inferior dimension, and from the medial chest to the anterior axillary line. The motor nerves to the clavicular head of the pectoralis off of the lateral cord are located at the midpoint of the clavicle and are tagged. Motor nerves to the sternal head pectoralis are identified next and come in three clusters: a motor nerve that is near the motor nerve to the clavicular head, a motor nerve that travels through the pectoralis minor or is just medial to the pectoralis minor, and a motor nerve that is on the lateral aspect of the pectoralis. The origin of these motor nerves does not matter – as only the size and location of these motor point nerves as they reach the muscle (where the transfers will be performed) is important. What major mixed nerve can reach which motor nerve? Next, either medial or lateral to the pectoralis minor tendon, the brachial plexus and the musculocutaneous, median, ulnar, and radial nerves emanating from it are identified. The radial nerve is stimulated to make sure there is no triceps remnant to leave in continuity. The identity of the nerves is made by their branching pattern off of the brachial plexus. The axillary nerve is not seen typically at this level. Deep to the plexus, the proximal thoracodorsal nerve is identified as a potential target.

Typically, there are four nerves to transfer and there must be four recipients (Table 40.1). The most common transfers are the musculocutaneous nerve to the clavicular head of the pectoralis, the median nerve to the largest motor nerve innervating the sternal head of the pectoralis, and the radial nerve to the thoracodorsal nerve. The recipient for the ulnar nerve is generally the motor nerve innervating the lateral aspect of the pectoralis major. Alternatives for the ulnar nerve include the long thoracic nerve, or the nerve innervating the pectoralis minor. If the pectoralis minor is used, it will need to be mobilized laterally, and the insertion of the pectoralis divided (if present) so that it is moved laterally for better signal detection. When the pectoralis receives more than one innervation, it can be divided along its fibers based on its vascular anatomy and motor nerve anatomy. Segments should be at least 4–5 cm in diameter for adequate signal detection. The target muscle should be completely denervated during these transfers so that the previous pectoral EMG signal is eliminated. Nerve coaptations are performed as close to the entry point of the motor nerve into the muscle as possible to decrease the time

Table 40.1 **Targeted muscle reinnervation for shoulder disarticulations**

Nerve	Possible recipient
Musculocutaneous	Clavicular head of pectoralis major
Median	Largest motor nerve innervating sternal head of pectoralis major
Radial	Thoracodorsal or long thoracic
Ulnar	Lateral motor nerve innervating sternal head of pectoralis major or minor

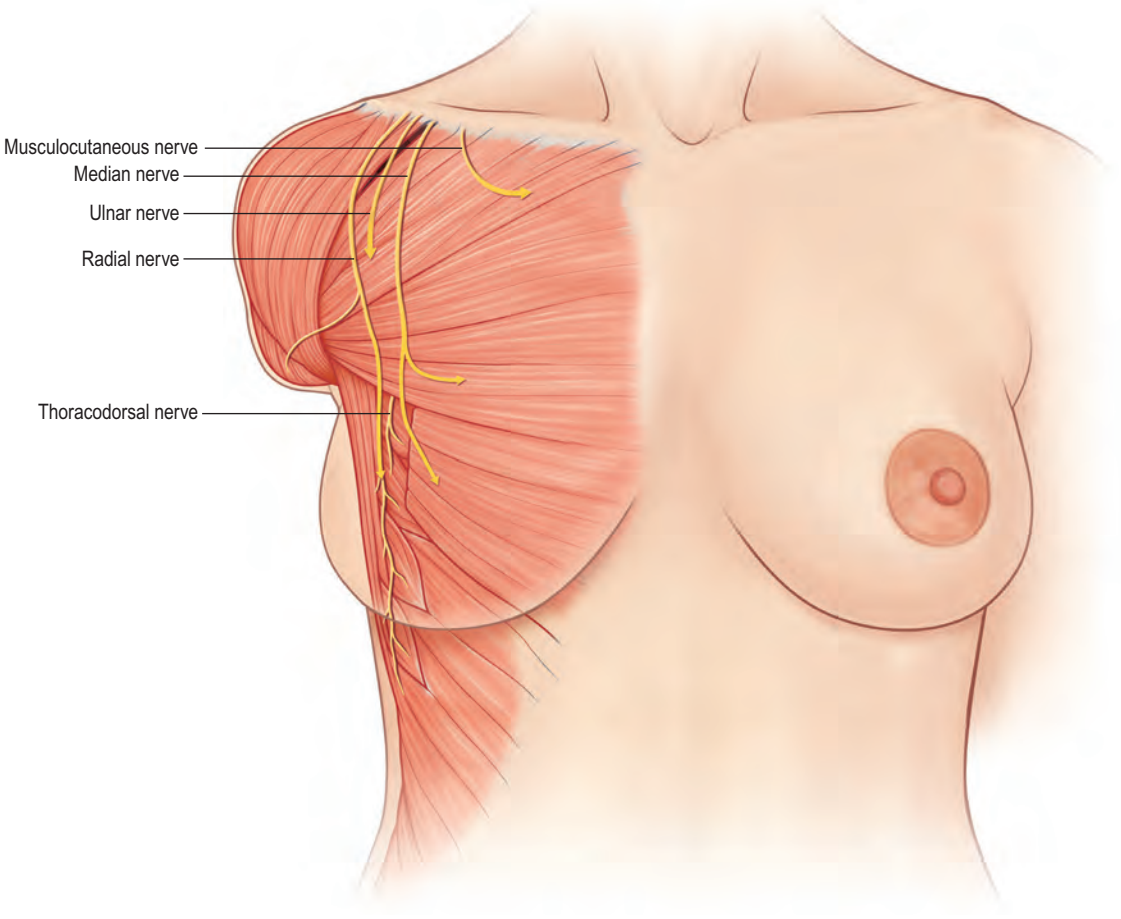

Fig. 40.15 Schematic nerve coaptations for shoulder targeted muscle reinnervation.

Fig. 40.16 Patient with small humeral remnant undergoing shoulder-level targeted muscle reinnervation. The clavicle is dotted, and the incision is drawn.

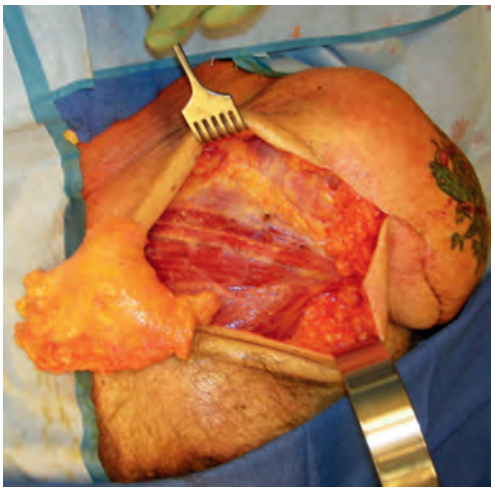

Fig. 40.17 Adipofascial flap is raised, exposing the interspace between the clavicular and sternal heads of the pectoralis major.

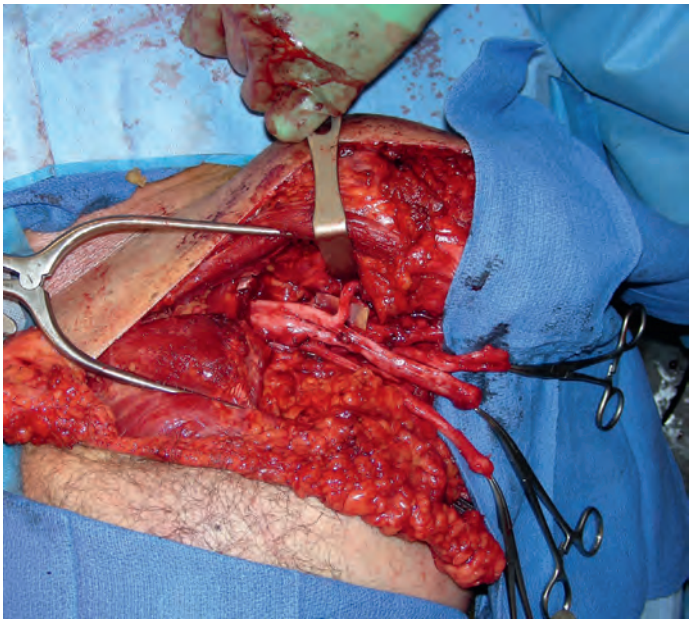

Fig. 40.18 The radial, median, and ulnar nerves are dissected free with hemostats holding them laterally. The musculocutaneous nerve is visible just inferior to the army–navy retractor.

of reinnervation. The adipofascial flap is placed between the pectoral heads to reduce aberrant reinnervation and to separate the muscle bellies from each other thereby improving EMG signal detection. The skin is closed over drains after placement of quilting sutures to decrease seromas. The patient may resume wearing his/her original prosthesis when there is adequate wound healing. Prosthetic fitting for new control sites will occur in 3–6 months. The latissimus muscle, being farthest away from the coaptation site, will take the longest to come under cortical control.

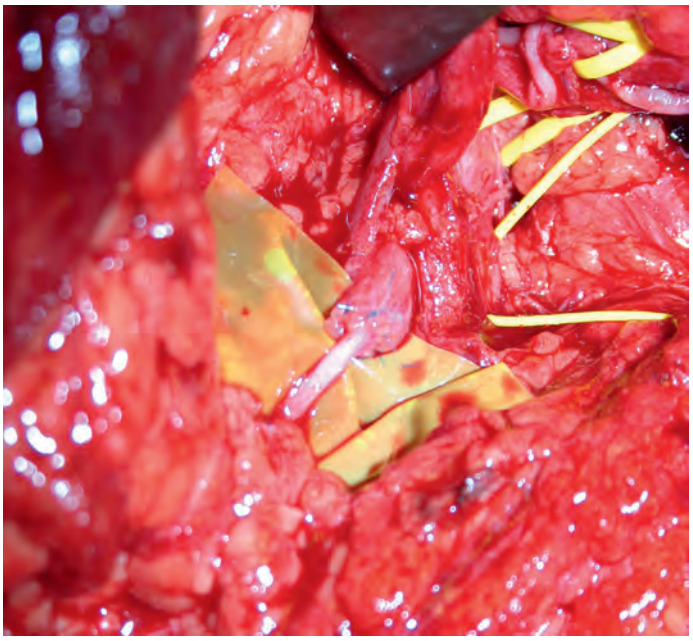

Fig. 40.19 Radial to thoracodorsal nerve coaptation.

Targeted sensory reinnervation is also possible; the afferent fibers of the transferred nerves will reinnervate any denervated skin overlying the target muscle. When this reinnervated skin is touched, the patient feels that their missing hand is being touched, providing cortical feedback to the "hand" aspect of the brain. All modalities of cutaneous sensation are restored including pressure, vibration and thermal. Special devices termed "tactors" may provide feedback from the prosthesis to the brain in the correct part of the brain for position or pressure applied by the terminal device. In doing so, targeted motor and sensory reinnervation will "close the loop" for prosthetic function. Sensory nerves, including the supraclavicular nerve and the lateral intercostal nerve, have been coapted end-to-side to medial and ulnar nerves to provide targeted sensory reinnervation. A recent review article provides a useful summary of the state of the art with regard to prosthetic sensory feedback and associated technologies for neural signaling.[35]

Transradial level

TMR has been performed for patients with transradial amputations, but for neuroma control rather than improved prosthetic function. These transfers are described above in the "Wrist disarticulation and transradial amputation" section. Several of these transradial TMR patients are currently enrolled in a study comparing TMR-based control to myoelectric control in subjects with conventional transradial amputations. It is hoped that in combination with computer-decoding algorithms, the intrinsic hand muscle EMG information derived from transradial TMR will help to better control multifunction prosthetic hands.[36]

Comparison of prosthetics with composite tissue allotransplantation

Clinically, there have not been any direct comparisons between the functional outcomes obtained with TMR-controlled prosthetics and those resulting from composite tissue allotransplantation (CTA). While a comparison of the two techniques is useful for highlighting and defining the capabilities and limitations of the individual technique, there is a role for each in the comprehensive approach to patients with upper extremity amputations.

The best patient for TMR is an above elbow amputee, because conventional myoelectric prosthetic function is poor, and CTA has provided unpredictable results. In the absence of TMR, the amputee lacks the capability for simultaneous and intuitive hand and elbow function. This amputation level also provides ample space for advanced prosthetic components. This contrasts with the transradial level, whereby space for prosthetic components is inherently limited, resulting in advanced myoelectric devices that are excessively bulky. CTA, on the other hand, is ideal in the distal forearm, where there is little muscle mass in the transplanted piece, and nerve topographic anatomy is defined. The total transplant load is relatively low, and salvage of the patient from a failed transplant would be facilitated by its distal location. Direct comparisons between transradial patients rehabilitated with either TMR/advanced prosthetics or CTA will require significant cooperation between academic centers.

Future directions

Future advancements for the prosthetic rehabilitation of the amputee are achievable in the near term. Osseointegration of the prosthetic into the humerus radius, femur, or tibia will dramatically improve the control and strength of the terminal device, as well as make the prosthetic more comfortable to wear. The absence of a prosthetic liner will render more facile the recording of EMG signals on the residual limb. Improvements in TMR will be obtained by further subdividing the nerve into smaller fascicles and the use of regenerative peripheral nerve interfaces for direct recording of nerve depolarizations. Alternatively, implantable myoelectric sensors (IMES) will be able to beam the muscle signal out to a detector without a surface electrode. Finally, improved prosthetic processing of the complex EMG signal termed "pattern recognition" has been shown to permit independent finger movements, even in the most proximal amputations.

Clinical tips

1. Targeted muscle reinnervation (TMR) requires an amputated limb with the nerve normally connected to the brain and spinal cord. Patients with brachial plexus injuries are not candidates for TMR.
2. Physical examination suffices for location of end-neuromas and muscles under cortical control. There is no need for magnetic resonance imaging, ultrasound, and electromyography so long as there is no history of a brachial plexus injury in addition to the amputation.
3. Soft-tissue revision of the amputated limb can and should be performed when indicated at the time of TMR.
4. TMR procedures can be performed in a straightforward manner with loop magnification and a simple nerve stimulator to identify motor nerves of adjacent muscles.
5. Free muscle flaps can be used advantageously as a recipient for the nerve transfer when there are no available local motor nerves.
